We report the first measurement of target single spin asymmetries (A_N) in the inclusive hadron production reaction, e^+ ^3He \rightarrow h + X, using a transversely polarized ^3He target. The experiment was conducted at Jefferson Lab in Hall A using a 5.9-GeV electron beam. Three types of hadrons (π^−, K^+, and proton) were detected in the transverse hadron momentum range 0.54 < p_T < 0.74 GeV/c. The range of x_F for pions was −0.29 < x_F < −0.23 and for kaons was −0.25 < x_F < −0.18. The observed asymmetry strongly depends on the type of hadron. A positive asymmetry is observed for π^+ and K^+. A negative asymmetry is observed for π^−. The magnitudes of the asymmetries follow |A^π^−| < |A^π^+| < |A^K+|. The K^− and proton asymmetries are consistent with zero within the experimental uncertainties. The π^+ and π^− asymmetries measured for the ^3He target and extracted for neutrons are opposite in sign with a small increase observed as a function of p_T.

The study of the transverse single spin asymmetries (TSSAs) is one of the most active areas of research in modern hadronic physics. TSSA is an important tool to advance our understanding of the nucleon spin, to reveal the role of the quark orbital angular momentum (OAM), and to access the three-dimensional structure of the nucleon in momentum space.

The origin of TSSAs is currently interpreted using two approaches [16]. The first approach is based on the Collins effect, which represents the theoretical approaches [16]. The first approach is based on the Collins effect, which correlates the transverse polarization of the quark with the transverse momentum of the outgoing hadron (p_T). In the Sivers effect, the TSSA is generated by the Sivers distribution function, which correlates the quark’s transverse momentum and the nucleon’s spin and is sensitive to the quark OAM. More specifically, the observed asymmetry due to the Sivers function arises from the final-state interaction between the struck quark and the nucleon remnant in SIDIS. On the other hand, the Sivers function in the Drell-Yan process is expected to arise from the initial-state interactions [19]. Taking gauge links into consideration, the Sivers distribution is predicted to be process dependent in the sense that it differs in sign between SIDIS and Drell-Yan processes [19,20]. Furthermore, in models such as the diquark model [21], one can connect the Sivers distribution for each quark to its contribution to the anomalous magnetic moment of the nucleon.

The second approach is based on the twist-3 collinear factorization [22–25], where the SSAs are interpreted in terms of higher-twist quark-gluon correlations, and is mainly used to explain the TSSAs in the pp^1 reaction. It was also shown that the TMD factorization and twist-3 methods are related [26–28]. However, the Sivers function extracted from pp^1 data with the twist-3 approach is shown to have a “sign mismatch” when compared to the Sivers function extracted from SIDIS data. The sign mismatch indicates a potential inconsistency in the current theoretical formalism [29] and needs to be further investigated. In order to understand the underlying mechanism producing TSSA it is crucial to study additional reaction channels [16,30].

In this Rapid Communication, we study TSSA from one of the experimentally least explored reactions, inclusive hadron production using a lepton beam on a transversely polarized nucleon (lN^+ \rightarrow hX) [16,31]. An early study of this process was done by Anselmino et al., under the assumption that the underlying mechanism that generates TSSA is either the Collins or Sivers effects [31]. More recently, this study was re-evaluated using newly available SIDIS data on Sivers and Collins moments assuming that the TMD factorization is valid in l^p \rightarrow π^±X processes at large p_T values. Due to the presence of only one hard scale in this process, estimation of the asymmetries is generally done at large p_T values (typically
These studies of TSSAs in the reaction \( e^+e^- \to \pi^+X \) have been reported by the HERMES Collaboration using electron beams on a transversely polarized hydrogen target [9]. They predicted asymmetries between 5 and 10% for initial and final states do not interchange. Note that the sign of \( A_N \) in the laboratory coordinate system of this experiment (Eq. (1)) differs by a factor \(-1\) from the definition in the phenomenological study of this process in Ref. [16], where the authors used the center-of-mass coordinate system with the lepton moving in the \(-z\) direction.

The data were collected using a singles trigger during the E06-010 experiment in Hall A at Jefferson Lab [36]. A beam energy of 5.9 GeV was provided by the CEBAF accelerator with an average current of 12 \( \mu A \). The produced hadrons were detected in a high-resolution spectrometer (HRS) [37] at a central angle of 16° on beam left side. Positively and negatively charged particles were detected separately by changing the magnet polarity of the HRS. The central momentum of the HRS was fixed at 2.35 GeV/c, with a momentum acceptance of \( \pm 4.5% \) and solid angle of 6 msr. The average transverse momentum of the detected hadrons (\( p_T \)) was 0.64 GeV/c. We note that if the pions are produced through virtual or real-photon exchange (\( \gamma^* + N \) or \( \gamma + N \)), the minimum photon energy is \( E_{\gamma} \geq 2.6 \) GeV, corresponding to an invariant mass of \( W \geq 2.4 \) GeV for the \( \gamma + N \) system, well above the region of nucleon resonances.

The data from the two helicity states from the polarized electron beam were summed over to achieve an unpolarized beam. The residual helicity-sorted beam-charge difference was less than 100 ppm in a typical run. The target spin direction was automatically reversed (\( \phi_s = \pm 90° \)) at a rate of once every 20 min, which allowed control of the combined systematic uncertainty due to luminosity fluctuations and time dependence to below 50 ppm in this experiment.

Polarized \(^3\)He targets have often been used as an effective polarized neutron targets, because in the ground state of the \(^3\)He nuclear wave function (dominated by the \( S \) state) the two proton spins are opposite to each other, and the nuclear spin is carried by the remaining neutron [38]. The polarized target used in this measurement was a 40-cm-long glass cell filled with ~8 atm of \(^3\)He gas and a small amount (~0.13 atm) of \( N_2 \) gas to reduce depolarizing effects [37]. The radiation lengths of the materials up to the center of the \(^3\)He target were Be window (0.072%), \(^4\)He gas (0.004%), glass window (0.142%), and \(^3\)He gas (0.046%). The target was polarized via hybrid spin-exchange optical pumping of a mixture of Rh-K [39]. The \(^3\)He polarization was measured every 20 min during the spin-reversal using nuclear magnetic resonance (NMR). The NMR signal was calibrated with electron paramagnetic resonance (EPR) measurements and a known NMR signal obtained from an identical water cell. The average in-beam polarization of the target was (55.4 ± 2.8)%.

The HRS detector package consisted of four separate detectors for particle identification: (i) a light-gas threshold Čerenkov for electron identification, (ii) a two-layer electromagnetic calorimeter for electron-hadron separation, (iii) a threshold aerogel Čerenkov detector for pion identification, and (iv) a ring imaging Čerenkov (RICH) detector for \( K^\pm \) and proton identification. The electron and positron backgrounds were suppressed with a rejection factor of \( 10^{3.1} \). After all the particle identification cuts the contamination due to leptons was negligible in the hadron sample. The pion...
sample had a contamination of <1% due to other hadrons. Kaons were identified using the RICH detector, in combination with a veto from the aerogel counter, to suppress the large pion background. To further improve the purity of the kaon sample, a χ² probability distribution was constructed based on the reconstructed Čerenkov ring angle and the expected Čerenkov angle in the RICH detector for a known particle momentum [40]. A cut on this distribution effectively suppresses the background events due to misidentified particles. The contamination of the kaon sample from other hadrons was estimated to be ∼3% (proton) and ∼2% (π⁺) for positive kaons, and ∼2% (π⁻) for negative kaons. Protons were identified using the same method that was used for charged kaons, producing a very clean sample with estimated background <1%.

The raw ³He target single-spin asymmetry (A_N) was obtained using the normalized yields in target spin up or down (φS = ±90°) states, as shown in Eq. (1). The yield in each spin state is normalized with the accumulated beam charge and livetime of the data acquisition system in that state. The dilution of the measured ³He asymmetries due to the presence of a small amount of N₂ gas in the target cell was corrected using the factor

\[ f_{N₂} \equiv \frac{N₂ \sigma_{N₂}}{ρ_{3He}σ_{3He} + ρ_{N₂}σ_{N₂}}, \]  

where ρ is the density of the gas in the cell and σ is the unpolarized inclusive hadron cross section. The unpolarized N₂ and ³He cross sections were obtained from the data taken during the experiment using reference cells filled with pure N₂ and ³He gas. The f_{N₂} was extracted separately for all hadrons and was about ~10% in each case.

The overall systematic uncertainty in this measurement was small due to frequent target spin flips. The false asymmetry due to luminosity fluctuations was less than 0.04% and was confirmed by measuring the target SSA in inclusive (e,e) DIS reaction for in-plane transverse target (φS = 0°, 180°). This configuration was achieved by rotating the target spin by 90° while keeping all other conditions the same. This type of asymmetry vanishes under parity conservation, assuming one-photon exchange. In addition, the inclusive pion asymmetry was measured to be zero with a precision of 0.05% in the same configuration (φS = 0°, 180°). This asymmetry is expected to vanish due to sin(φS) moment.

There were two additional sources of systematic uncertainty associated with the RICH detector for kaons and protons. The first one was from a cut on the number of hits in the RICH detector. The relative change in asymmetry under variation of the cut threshold was assigned as a systematic uncertainty. For K⁺ it was <14% and for protons it was <3%, relative to the statistical uncertainty. The second source was local fluctuations in the kaon and proton yields arising from detector inefficiencies in certain periods of the data collection. The systematic uncertainty was estimated using the change in the asymmetry obtained in the periods with and without these fluctuations and was estimated to be <2%, <6%, and <1%, relative to the statistical uncertainty, for K⁺, K⁻, and protons, respectively. Systematic uncertainties due to the target density fluctuations, vertex cuts, data-acquisition (DAQ) livetime, and HRS single-track events were negligible.

The final ³He asymmetry results are shown for different hadron species in Fig. 2. These results include a small correction due to particle contamination for each hadron species. In Fig. 2 the data were integrated in p_T and x_F (see Table I). The error bars represent the statistical uncertainty. The systematic uncertainties are shown as a solid band. The measured A_N for π⁺ (~2%) and K⁺ (~6%) are positive, and opposite in sign to that of π⁻ (~1%). In addition, the magnitudes of these asymmetries follow |A_N^π⁺| < |A_N^π⁻| < |A_N^K⁺|. The measured A_N for K⁻ and protons was found to be small and consistent with zero. We note that the majority of the detected protons originate through a knock-out reaction from the ³He nucleus, whereas mesons are produced either through fragmentation process or in a photoproduction reaction. The SSAs for charged pions as a function of p_T for a ³He target are shown in Fig. 3. The asymmetry grows as a function of p_T and plateaus around p_T ≈ 0.63 GeV/c.

We extracted A_N on neutron from the measured ³He asymmetry using the effective polarization approach, previously used for both inclusive and semi-inclusive DIS processes [38,41]. Using this method, A_N for the neutron can be obtained.
from $^3\text{He}$ results using the relation
\begin{equation}
A_{N}^{^3\text{He}} = P_n(1 - f_p)A_{N}^n + P_pf_pA_{N}^p,
\end{equation}
where $A_{N}^{^3\text{He}}$ is the measured $^3\text{He}$ asymmetry. $P_n = 0.86^{+0.036}_{-0.02}$ and $P_p = -0.028^{+0.009}_{-0.007}$ are the effective polarizations of the neutron and proton, respectively. Hence, the contribution of proton polarization ($\pm 2.8\%$) to $A_{N}^{^3\text{He}}$ is relatively small. The factor $f_p = \frac{2P_p}{\sigma_{\text{n}}}$ in $^3\text{He}$ was measured directly in this experiment using the yields obtained from unpolarized hydrogen and $^3\text{He}$ targets. The average proton dilution $(1 - f_p)$ for $\pi^+$ was $0.156 \pm 0.007$ and for $\pi^-$ it was $0.268 \pm 0.005$. The SSA from a polarized proton target ($A_{N}^p$) was assumed to be no more than $\pm 5\%$ at $p_T \simeq 0.64 \text{ GeV/c}$, which is consistent with the HERMES data on $A_{N}^p$ [9].

The final results for $A_{N}^n$ for charged pions on an effective neutron target are shown in Fig. 4 and listed in Table II. The extracted $A_{N}^n$ is below 20\% for both $\pi^+$ and $\pi^-$, with the asymmetry amplitude for $\pi^+$ being larger than those for $\pi^-$. The $A_{N}^n$ for both $\pi^+$ and $\pi^-$ increases up to $p_T \simeq 0.63 \text{ GeV/c}$, before it plateaus. Currently there are no theoretical estimates for $A_N$ at $\sqrt{s} = 3.45 \text{ GeV}$ and $\langle p_T \rangle \sim 0.64 \text{ GeV/c}$ for a neutron target. The existing predictions were done for a proton target at $p_T = 1.5 \text{ GeV/c}$ and $\sqrt{s} \simeq 4.9 \text{ GeV}$ [16]. However, the sign of $A_N$ for $\pi^\pm$ in our experiment is consistent with the existing predictions dominated by the Sivers effect, assuming $p \leftrightarrow n$ and $\pi^+ \leftrightarrow \pi^-$. We can compare the observed behavior of our data with existing TSSAs in both proton-proton ($pp^\upsilon$) and lepton-nucleon ($lN^\upsilon$) reaction channels. Our results show that in the center-of-mass frame of the polarized neutron-electron collision, viewed along the direction of the neutron’s momentum, $\pi^+$ favors the right side of the spin vector, whereas $\pi^-$ favors the left side of the spin vector. Assuming isospin symmetry, this behavior is the same as that observed in $pp^\upsilon \rightarrow hX$ for the E704 [23] and BRAHMS [4] experiments. In addition, this behavior is also the same as the Collins asymmetry for $\pi^\pm$ and the Sivers asymmetry for $\pi^\pm$ observed in SIDIS [6–8,12–14]. The $A_{N}^n$ for $\pi^+$ is about $15\%$ at $\langle p_T \rangle = 0.64 \text{ GeV/c}$, which is larger than that for HERMES proton data for $\pi^\pm$ $(\sim 5\%)$ at $\langle p_T \rangle = 0.68 \text{ GeV/c}$ [9]. Similarly, we observed large $A_{N}^n$ for $\pi^-$ $(\sim 5\%)$ compared to that for HERMES proton data (<1\%) [9]. Furthermore, we observed a large and positive amplitude.

**TABLE II.** The extracted neutron $A_{N}^n$ results for $\pi^+$ and $\pi^-$ along with their ratio $R_{\pi^+/\pi^-}$ in five different $\langle p_T \rangle$ bins.

for the $K^+$ asymmetry compared to $K^-$ asymmetry on $^3$He, a similar feature observed in the $lp^+ \rightarrow hX$ reaction on proton target [9], and also the Sivers amplitude for kaons in the SIDIS reaction at HERMES [7].

In summary, we have reported the first measurement of SSAs in the inclusive hadron production reaction using unpolarized electrons on a transversely polarized $^3$He target at $\langle p_T \rangle = 0.64$ GeV/c. Clear nonzero asymmetries were observed for charged pions and positive kaons, showing a feature of flavor dependence similar to that observed in the Sivers asymmetry in SIDIS, and in $A_N$ in $pp^+$ collisions. Currently there are no estimates or theoretical interpretations of these asymmetries at the relatively low $p_T$ used for this measurement. We hope that the results presented here will stimulate new theoretical and experimental efforts to pinpoint the exact origin of the observed SSAs. Future experiments at Jefferson Lab [42,43], after the 12-GeV upgrade, will extend this measurement to higher values of $p_T$ on both proton and $^3$He targets and will provide precision data for future theoretical studies. Moreover, if these nonzero asymmetries survive at high energy kinematics then they can be used as monitors of transverse target polarization in a fixed target experiment or local transverse polarization of the $^3$He beam at a future electron-ion collider.

We acknowledge the outstanding support of the JLab Hall A staff and the Accelerator Division in accomplishing this experiment. This work was supported in part by the U.S. National Science Foundation and Department of Energy (DOE) Contract No. DE-AC05-06OR23177, under which the Jefferson Science Associates operates the Thomas Jefferson National Accelerator Facility.
