Abstract—In this paper, we present an empirical rate-distortion study of a communication scheme that uses compressive sensing (CS) as joint source-channel coding. We investigate the rate-distortion behavior of both point-to-point and distributed cases.

First, we propose an efficient algorithm to find the $\ell_1$-regularization parameter that is required by the Least Absolute Shrinkage and Selection Operator which we use as a CS decoder.

We then show that, for a point-to-point channel, the rate-distortion follows two distinct regimes: the first one corresponds to an almost constant distortion, and the second one to a rapid distortion degradation, as a function of rate. This constant distortion increases with both increasing channel noise level and sparsity level, but at a different gradient depending on the distortion measure. In the distributed case, we investigate the rate-distortion behavior when sources have temporal and spatial dependencies. We show that, taking advantage of both spatial and temporal correlations over merely considering the temporal correlation between the signals allows us to achieve an average of a factor of approximately 2.5× improvement in the rate-distortion behavior of the joint source-channel coding scheme.

I. INTRODUCTION

Compressive sensing (CS) is a novel technique which allows to reconstruct signals using much fewer measurements than traditional sampling methods by taking advantage of the sparsity of the signals to be compressed. Previous works related to the rate-distortion analysis of CS have been focused on its performance related to image compressing [1] and introduce the notation and parameters for our simulations.

II. BACKGROUND AND PROBLEM SETUP

In this section, we review the fundamentals of compressive sensing (CS), introduce the cross-validation algorithm we use, and introduce the notation and parameters for our simulations.

A. Compressive Sensing

Let $X \in \mathbb{R}^N$ be a $k$-sparse vector and let $\Phi \in \mathbb{R}^{m \times N}$ be measurement matrix such that $Y = \Phi X$ is the noiseless observation vector, where $Y \in \mathbb{R}^m$. $X$ can be recovered by using $m \ll n$ measurements if $\Phi$ obeys the Restricted Eigenvector (RE) Condition [7].

We consider noisy measurements, such that the measurement vector is $Y = \Phi X + Z$, where $Z$ is a zero-mean random Gaussian channel noise vector.

It was shown in [8] that CS reconstruction can be formulated as a Least Absolute Shrinkage and Selection Operator (LASSO) problem, which is expressed as

$$\hat{X} = \arg \min_X \frac{1}{2m} \|Y - \Phi X\|_2^2 + \lambda \|X\|_{\ell_1}$$

where $\lambda \geq 0$ is the $\ell_1$-regularization parameter.

Equation (1) thus outputs a solution $\hat{X}$ that is desired to have a number of non-zero coefficients close to $k$, while maintaining a high-fidelity

...
reconstruction of the original signal. Thus, as $\lambda$ is increased, so is the number of coefficients forced to zero.

In the next section, we propose an algorithm to choose $\lambda$ using cross-validation, based on work by [9] and [10].

B. Cross-validation with modified bisection

As explained in [11], cross-validation is a statistical technique which allows to choose a model which best fits a set of data. It operates by dividing the available data into a training set to learn the model and a testing set to validate the model. The goal is then to select the model that best fits both the training and testing set.

We use a modified version of this algorithm to choose the value of $\lambda$ which minimizes the energy of the relative error between some original signal and its reconstruction. As such, the $m \times N$ measurement matrix $\Phi$ in (1) is separated into a training and a cross-validation matrix, as shown in (2),

$$
\Phi \in \mathbb{R}^{m \times N} \rightarrow \begin{bmatrix} \Phi_{tr} \in \mathbb{R}^{m_{tr} \times N} \\ \Phi_{cv} \in \mathbb{R}^{m_{cv} \times N} \end{bmatrix}
$$

where $m_{tr} + m_{cv} = m$. In order for the cross-validation to work, $\Phi_{tr}$ and $\Phi_{cv}$ must be properly normalized and have the same distribution as $\Phi$. For the purpose of the schemes we consider, we fix the number of cross-validation measurements at 10% of the total number of measurements, so $m_{cv} = \text{round}(0.1m)$, which provide a reasonable trade-off between complexity and performance of the algorithm [9].

Algorithm 1 summarizes the cross-validation technique used to find the best value of $\lambda$ for the rate-distortion simulations.

**Algorithm 1** Cross-validation with modified bisection method

1. $Y_{cv} = \Phi_{cv}X + Z_{cv}$
2. $Y_{tr} = \Phi_{tr}X + Z_{tr}$
3. $\lambda = \lambda_{\text{init}}$
4. Let $\epsilon$ be an empty vector with coefficients $\epsilon_i$
5. while $i \leq \text{MaxIterations}$ do
6. Solve $\hat{X}_{tr}[\lambda] = \arg \min_{X} \frac{1}{2m} \|Y_{tr} - \Phi_{tr}X\|_2^2 + \lambda \|X\|_1$
7. $\epsilon_i \leftarrow \|Y_{cv} - \Phi_{cv}\hat{X}_{tr}[\lambda]\|_2$
8. $\lambda \leftarrow \lambda/1.5$
9. end while
10. $\lambda^* = \arg \min_{\lambda} \epsilon = \arg \min_{\lambda} \|Y_{cv} - \Phi_{cv}\hat{X}_{tr}[\lambda]\|_2$

Given an original signal $X$, the cross-validation and the training measurement vectors $Y_{cv}$ and $Y_{tr}$ are generated by taking the CS measurements and corrupting them with zero-mean Gaussian channel noise, represented by $Z_{cv}$ and $Z_{tr}$ (Lines and 2). The initial value of $\lambda$ that is investigated is one that we know leads to the all-zero reconstructed signal $\hat{X}_{tr}[\lambda] = 0$ (Line 3). For a chosen number of repetitions, an estimation $\hat{X}_{tr}[\lambda]$ of the reconstructed signal is obtained by decoding $Y_{tr}$ (Line 6) and the cross-validation error is computed (Line 7). The next value for $\lambda$ to be investigated is obtained by dividing the current value by 1.5. The optimal value $\lambda^*$ is then the one that minimizes the cross-validation error (Line 10).

In the field of CS, cross-validation mainly used with homotopy continuation algorithms such as LARS [12], which iterate over an equally-spaced range of decreasing values for $\lambda$. While this iterative process allows for better accuracy for smaller range steps, it comes at the cost of a latency which increases with the number of values of $\lambda$ tested, due to the time-consuming decoding (Line 6). In our scheme, we circumvent this latency issue by considering a decreasing geometrical sequence of values of $\lambda$, which still guarantees that we find a solution for $\lambda^*$ of the same order as the one predicted by an homotopy continuation algorithm, but in a fraction of the time. Indeed, we are able to obtain a solution after a maximum of 15 iterations of Lines 6 to 8, by using a method comparable to the bisection method [13] to obtain the values of $\lambda$ to be tested. However, in order to improve the accuracy, we choose a common ratio of $1.5^{-1}$ instead of $2^{-1}$. By abuse of notation, we refer to this technique as a “cross-validation with modified bisection method.”

C. Simulations setup

In this section, we define the signal and measurement matrix models that were used for the simulations, the distortion measures used to obtain the rate-distortion results, as well as the software we use.

1) Signal model and measurement matrix: We consider a $k$-sparse signal $X$ of length $N = 1024$, and define its sparsity ratio as $k/N = \alpha$. $X$ is formed of spikes of magnitudes $\pm 1$ and $\pm 0.5$, where each magnitude has a probability of $\alpha/4$.

We choose the measurement matrix $\Phi$ with a Rademacher distribution defined as follows

$$
\Phi_{ij} = \frac{1}{\sqrt{m}} \begin{cases} -1 & \text{with probability 0.5} \\ +1 & \text{with probability 0.5} \end{cases}
$$

where $m$ is the number of measurements taken. It is shown in [14] that the RE condition holds for this type of matrix.

2) Distortion measures: We consider two distortion measures: the mean-squared error ($MSE$) and a scaled version of the percent root-mean-square difference ($PRD$) [15] often used to quantify errors in biomedical signals [15] and defined as follows:

$$
PRD = \sqrt{\sum_{n=1}^{N} |X - \hat{X}|^2} / \sqrt{\sum_{n=1}^{N} |X|^2}
$$

where $X$ is the original signal of length $N$ and $\hat{X}$ its reconstruction.

The simulations were implemented in MATLAB using the software `cvx` [16], a modeling system for convex optimization which uses disciplined convex programming to solve (1) [17].

III. JOINT CS-BASED SOURCE-CHANNEL CODING FOR A POINT-TO-POINT CHANNEL

In this section, we evaluate the performance of a joint source-channel coding scheme using compressive sensing (CS) proposed in [7]. The signal and measurement models are defined in Section II-C. The sensing-communication scheme is performed in the following steps:
a) Step 1 (Encoding): The CS encoding is done by taking \( m \) measurements of the signal \( X \) of length \( N = 1024 \) using a measurement matrix \( \Phi \in \mathbb{R}^{m \times N} \) distributed as in (3) to obtain a measurement vector \( Y = \Phi X \).

b) Step 2 (Transmission through channel): The measurement vector \( Y \) is transmitted through a channel, which is either noiseless or noisy. If it is noisy, the standard deviation of the noise level is defined as a percentage of power of the signal \( Y \). For our simulations, we consider 5% and 10% channel noise. The signal reaching the receiver is \( Z = Y + W = \Phi X + W \), where \( W \in \mathbb{R}^n \) is additive zero-mean random Gaussian noise.

c) Step 3 (Decoding): At the receiver, the LASSO decoder outputs a reconstructed signal \( \hat{X} \) of \( X \) by solving the following complex optimization

\[
\hat{X} = \arg\min_X \frac{1}{2m} ||Z - \Phi X||_2^2 + \lambda^* ||X||_1
\]

where we use Algorithm 1 to find \( \lambda^* \).

Rate is calculated as \( m/N \) and we compare how both the channel noise level and the sparsity of the original signal affect the rate-distortion behavior of the scheme, for the PRD and MSE distortion measures. In these simulations, each point has been achieved by averaging the distortion values obtained by running each setting (channel noise, \( m \), and sparsity ratio) 15 times.

A. Rate distortion as a function of noise level

We observe the rate-distortion behavior at 3 channel noise levels: noiseless, 5% and 10% channel noise. Figure 1 shows the rate-distortion in terms of PRD and MSE for a sparsity ratio \( k/N = 0.075 \).

![Rate-Distortion for sparsity ratio k/N = 0.075](image)

As seen in Figure 1, we can distinguish two regimes in the rate-distortion curves: the first one corresponds to an almost constant distortion \( D^* \) after the number of measurements exceeds some critical value \( m^* \). As expected, both \( m^* \) and \( D^* \) increase slightly with increasing channel noise. However, we observe that this increase is much more important when PRD is used a distortion measure.

The second observed regime demonstrates a rapid degradation of the distortion, as the number of measurements is insufficient to properly reconstruct the original signal. This rapid degradation corresponds to the settings of the simulations where the number of measurements is inferior to \( m^* \).

B. Rate distortion as a function of sparsity level

We observe the rate-distortion behavior at 4 sparsity ratios \( k/N = [0.01, 0.025, 0.05, 0.075] \) and present the corresponding rate-distortion curves in Figures 2 and 3. Both of these sets of curves correspond to a level of channel noise of 5%.

![Rate-Distortion for channel noise level of 5% with MSE as distortion measure](image)

![Rate-Distortion for channel noise level of 5% with PRD as distortion measure](image)

For a given noise level, we observe an upper-right shift of the curves for increasing sparsity ratio. In particular, we can see that the value of \( m^* \) increases almost linearly with the sparsity ratio. We also notice that the value of \( m^* \) increases much sharply when MSE is used as a distortion measure. As before, we can observe that the changes in rate-distortion curves are much distinguishable when the distortion measure is PRD.

IV. JOINT CS-BASED SOURCE-CHANNEL CODING FOR A DISTRIBUTED CASE

In this section, we evaluate the performance of the compressive sensing-based joint source-channel coding scheme for a distributed case. We consider a single-hop network depicted in Figure 4 with two sources \( s_1 \) and \( s_2 \), whose samples exhibit both spatial and temporal redundancies [7]. The temporal redundancy refers to the fact that each signal is sparse; the
spatial redundancy refers to the fact that the difference between
the two signals at the two sources is sparse.

\[ X_1 \rightarrow S_1 \rightarrow (\tilde{X}_1, \tilde{X}_2) \]

\[ X_2 \rightarrow S_2 \rightarrow (\tilde{X}_1, \tilde{X}_2) \]

Fig. 4. Single-hop network for distributed cases

In our simulations, \( X_1 \) is \( k_1 \)-sparse and \( X_2 = X_1 + E \), where \( E \) is a \( k_2 \)-sparse error signal; we assume that \( k_1 \gg k_2 \). The goal is to reconstruct both \( X_1 \) and \( X_2 \) at the receiver \( r \).

We present two ways of performing these reconstructions, and in both cases, the total rate and the distortion were respectively calculated as following

\[ R_{\text{total}} = \frac{m_1 + m_2}{N} \]

(6)

\[ D_{\text{total}} = D_1 + D_2 \]

(7)

where \( m_i \) is the number of compressive sensing measurements taken at source \( s_i \) and \( D_i \) is the distortion measured between the original and reconstructed signal \( X_i \) and \( \tilde{X}_i \). For both of the cases, we present the results of the simulations for when the measurements are subjected to both no noise and 5% noise.

A. Case 1: Only temporal dependency is considered

In this case, we treat \( s_1 \) and \( s_2 \) as if there were two independent sources, that is \( X_1 \) and \( X_2 \) are compressed and decompressed independently. Algorithm 2 summarizes how this process is done.

**Algorithm 2** Distributed case 1

1. \( Y_1 = \Phi_1 X_1 + Z_1 \)
2. \( Y_2 = \Phi_2 X_2 + Z_2 \)
3. Decompress \( Y_1 \) to obtain \( \tilde{X}_1 \) by solving
   \[ \tilde{X}_1 = \arg \min_{X_1} \frac{1}{2m} ||Y_1 - \Phi_1 X_1||_2^2 + \lambda^* ||X_1||_1 \]
4. Decompress \( Y_2 \) to obtain \( \tilde{X}_2 \) by solving
   \[ \tilde{X}_2 = \arg \min_{X_2} \frac{1}{2m} ||Y_2 - \Phi_2 X_2||_2^2 + \lambda^* ||X_2||_1 \]

The signals that \( r \) receives are shown in Lines 1 and 2 of Algorithm 2, where \( Z_i \) represents an additive zero-mean Gaussian noise associated with the channel. \( \Phi_1 \in \mathbb{R}^{m_1 \times N} \) and \( \Phi_2 \in \mathbb{R}^{m_2 \times N} \) are random matrices similar to (3).

Lines 3 and 4 of the algorithm correspond to the CS LASSO decoding performed at \( r \) to obtain estimates of the original signals \( X_1 \) and \( X_2 \).

B. Case 2: Both spacial and temporal dependencies are considered

In this case, we take advantage of the spatial correlation between \( X_1 \) and \( X_2 \), as shown in Algorithm 3.

**Algorithm 3** Distributed case 2

1. \( Y_1 = \Phi_1 X_1 + Z_1 \)
2. Decompress \( Y_1 \) to obtain \( \tilde{X}_1 \) by solving
   \[ \tilde{X}_1 = \arg \min_{X_1} \frac{1}{2m} ||Y_1 - \Phi_1 X_1||_2^2 + \lambda^* ||X_1||_1 \]
3. \( Y_2 = \Phi_2 \tilde{X}_2 + Z_2 \)
4. \( Y_2 = \Phi_2 (X_1 + E) + Z_2 \), and we already have an estimate for \( X_1 \)
5. Let \( Y_E = Y_2 - \Phi_1 \tilde{X}_1 \)
6. Thus \( Y_E = \Phi_2 E + Z_E \)
7. Decompress \( Y_E \) to obtain \( \tilde{E} \) by solving
   \[ \tilde{E} = \arg \min_{E} \frac{1}{2m} ||Y_E - \Phi_1 \tilde{X}_1||_2^2 + \lambda^* ||X_1||_1 \]
8. Hence \( \tilde{X}_2 = \tilde{X}_1 + \tilde{E} \)

Lines 1 and 3 of Algorithm 3 corresponds to the signal received at \( r \) from source \( s_1 \) and \( s_2 \) respectively, where as before \( \Phi_1 \in \mathbb{R}^{m_1 \times N} \) is generated using (3) and \( Z_i \) is a random Gaussian noise vector corresponding to the noisy channel between \( s_i \) and \( r \). We set \( m_1 \gg m_2 \). The receiver then uses the LASSO decoder to obtain \( \tilde{X}_1 \) (Line 2). Given the spatial dependency between \( X_1 \) and \( X_2 \), Lines 3 and 4 are equivalent for \( Y_2 \). The measurement vector \( Y_E \) can thus be defined (Line 5), and decoded to obtain an estimate for the error \( E \) (Line 7). Line 8 shows how \( \tilde{X}_2 \) is computed as the sum \( \tilde{X}_1 + \tilde{E} \).

The compared performance of the two algorithms for the distributed case are shown on Figures 5 to 8 for a noiseless and 5% channel noise settings. We observe that, for the noiseless channel, at a rate of 0.5, we obtain on average a factor of 2.5× improvement when using Algorithm 3 over Algorithm 2 with PRD as a distortion measure. When using \( MSE \), an average improvement of almost 3× is obtained for the same setting.

When the channel is noisy, the similar average improvements at a rate of 0.5 are respectively factor of 2× and 2.5× for \( PRD \) and \( MSE \). These results prove that taking advantage of the spatial and temporal correlations between the two signals allows to achieve a much improved rate-distortion behavior.
characterized the rate-distortion behavior of the joint source-channel scheme in a point-to-point channel using two distortion measures and showed that there exists an optimal sampling rate above which the distortion remains relatively constant, and below which it degrades sharply.

We then studied a single-hop network with two spatially and temporally correlated sparse sources and a receiver which uses compressive sensing decoders to reconstruct the source signals. We observed the effect of these signal correlations on the rate-distortion behavior of the scheme and showed that taking both spatial and temporal correlation in consideration allows us to achieve a factor of $2.5 \times$ improvement in rate-distortion compared to only taking temporal correlation.

**REFERENCES**

---

**V. CONCLUSIONS**

In this paper, we empirically evaluated the rate-distortion behavior of a joint source-channel coding scheme, based on compressive sensing for both a point-to-point channel and a distributed case.

We first proposed an efficient algorithm to choose the $\ell_1$-regularization parameter $\lambda$ from the LASSO, which we used as a compressive sensing decoder. This algorithm, which combines cross-validation and modified bisection, offers a reasonable trade-off between accuracy and computation time.

Using the values of $\lambda$ obtained with this algorithm, we...
