PRL 112, 231805 (2014) PHYSICAL REVIEW LETTERS week ending 13 JUNE 2014
The first search for single-top-quark production from the exchange of an s-channel virtual W boson using events with an imbalance in the total transverse energy, b-tagged jets, and no identified leptons is presented. Assuming the electroweak production of top quarks of mass 172.5 GeV/c² in the s channel, a cross section of $1.12^{+0.52}_{-0.31}$ (stat + syst) pb with a significance of 1.9 standard deviations is measured. This measurement is combined with the result obtained from events with an imbalance in total transverse momentum, b-tagged jets, and exactly one identified lepton, yielding a cross section of $1.36^{+0.17}_{-0.32}$ (stat + syst) pb, with a significance of 4.2 standard deviations.

The top quark was discovered at Fermilab in 1995 [1,2] through top-antitop-quark-pair production. This process is mediated by the strong interaction and results in the largest contribution to the top-quark-production cross section in hadron colliders. The top quark can also be produced singly via the electroweak interaction involving the $Wtb$ vertex with a W boson and a $b$ quark. The study of single-top-quark production is particularly interesting because of the direct dependence of the cross section on the magnitude of the $Wtb$ coupling. Furthermore, electroweak single-top-quark production from the exchange of an s-channel virtual W boson is of special interest since possible deviations from the standard model (SM) expectation could indicate evidence for non-SM particles such as higher-mass partners of the $W$ boson ($W'$) or charged Higgs bosons [3]. Examples of SM single-top-quark-production processes dominating at the Tevatron are shown in Fig. 1.

Single-top-quark production was observed at the Tevatron in 2009 [4–6]. However, s-channel production has yet to be observed independently. While single-top-quark production through the $t$-channel exchange of a W boson, first observed by the D0 experiment [7], was established in Large Hadron Collider (LHC) proton-proton collisions [8,9], the s-channel process has an unfavorable production rate compared to the background rates at the LHC. The D0 Collaboration reported the first evidence of s-channel single-top-quark production [10] measuring a cross section of $1.10^{+0.33}_{-0.31}$ (stat + syst) pb, with a significance of 3.7 standard deviations. More recently, CDF also obtained 3.8 standard deviation evidence using events containing one isolated muon or electron, large missing transverse energy ($E_T$) [11], and two jets, at least one of which is identified as likely to have originated from a bottom quark ($b$ tagged) [12]. This sample is referred to as the $\ell b\bar{b}$ sample. To add acceptance to the data set with identified leptons, CDF uses, for the first time, events with large $E_T$, two or three jets of which one or more are $b$ tagged and no detected electron or muon candidates. This sample of events is referred to as the $E_Tbb$ sample and contains s-channel single-top-quark contributions where $t \rightarrow Wb \rightarrow \ell b \nu$ and $\ell$ is an electron or a muon that is not identified in the detector or a tau that decays hadronically. In this Letter, the search for s-channel single-top-quark production in the $E_Tbb$ sample is reported. Most of the techniques developed for the low-mass Higgs boson search [13] in the same data sample are exploited, including the

HOBIT b tagger [14]. By combining the results of the two searches, an improved sensitivity to s-channel single top production from the 9.45 fb⁻¹ of integrated luminosity from the full CDF II data set is obtained.

In the $E_Tbb$ analysis, events are accepted by the online event selection (trigger) that requires $E_T > 45$ GeV or, alternatively, $E_T > 35$ GeV and two or more jets with transverse energy $E_T > 15$ GeV. The efficiency associated with this selection is obtained from data and is applied to the Monte Carlo simulated samples to reproduce the efficiencies of the data. The parametrization of the trigger efficiency [15] significantly improves the modeling of the trigger turn-on outside the fully efficient region, as verified using data control samples. Off-line, events containing identified electrons or muons are excluded and $E_T > 35$ GeV is required after correcting measured jet energies for instrumental effects [16]. Events with two or three high-$E_T$ jets are selected, and the two jets with the largest transverse energies $E_T^1$ and $E_T^2$ are required to satisfy $25 < E_T^1 < 200$ GeV and $20 < E_T^2 < 120$ GeV, where the jet energies are determined from calorimeter deposits corrected by track momentum measurements [17]. Some of these events consist of single-top-quark candidates in which the tau lepton from the $t \rightarrow Wb \rightarrow \tau \nu b$ decay is reconstructed as a jet in the calorimeters. To increase the acceptance for events with an unidentified $\tau$ lepton, events in which the third-most energetic jet satisfies $15 < E_T^3 < 100$ GeV are accepted. Because of the large rate of inclusive quantum chromodynamics (QCD) multijet (MJ) production, events with four or more reconstructed jets, where each jet has transverse energy in excess of 15 GeV and pseudorapidity $|\eta| < 2.4$, are rejected. To ensure that the two leading-$E_T$ jets are within the silicon-detector acceptance, they are required to satisfy $|\eta| < 2$, with at least one of them satisfying $|\eta| < 0.9$.

The MJ background events most often contain $E_T$ generated through jet energy mismeasurements. Neutrinos produced in semileptonic b-hadron decays can also contribute to the $E_T$ of these events. In both cases, the $E_T$ is typically aligned with $E_T^3$, and events are rejected by requiring the azimuthal separation between $E_T$ and $E_T^3$ (or $E_T^2$, for events with a third jet) to be larger than 0.4. The remaining MJ background has a large contribution of events with jets from fragmenting light-flavored $u, d,$ and $s$ quarks or gluons, which can be further reduced by requiring $b$-tagged jets. Charm quarks, which share some features associated with $b$ quarks, are not explicitly identified. Events are assigned to three independent subsamples depending on the $b$-tag output of the two leading jets. Jets with $b$-tag values larger than 0.98 are defined as tightly tagged (T jet), whereas jets with outputs between 0.72 and 0.98 are defined as loosely tagged (L jet). The tagging efficiency and misidentification rate applied to each jet depend on the jet $E_T$ and $\eta$. Scale factors for these variables are applied on a per-jet basis to bring the $b$-tagging efficiencies in the simulation into agreement with those in the data. $TT$ events are defined as those in which both jets are tightly tagged, $TL$ events as those in which one jet is tightly tagged and the other is loosely tagged, and $IT$ events as those in which only one jet is tightly tagged while the other is untagged. Events with two and three jets are analyzed separately, leading to six event subsamples with differing signal-to-background ratios. This strategy enhances sensitivity and helps separate s-channel single-top-quark production enhanced in the double-tag categories from the $t$-channel production enhanced in the single-tag categories.

In order to extract the s-channel electroweak single-top-quark signal from the more dominant background contributions, the rates and kinematic distributions of events associated with each process need to be accurately modeled. The kinematic distributions of events associated with top-quark-pair, single-top-quark, $V+$ jets (where V stands for a W or a Z boson), $W+c$, diboson ($VV$), and associated Higgs and $W$ or $Z$ boson ($VH$) production are modeled using simulations. The ALPGEN generator [18,19] is used to model $V+$ jets at leading order (LO) with up to four partons based on generator-to-reconstructed-jet matching [20,21] and $W+c$. The POWHEG [22] generator is used to model $t$- and s-channel single-top-quark production, while PYTHIA [23] is used to model top-quark-pair, $VV$, and $VH$ production at LO. Each of the event generators uses the CTEQ5L parton distribution function [24] as input to the simulations. Parton showering is simulated in all cases using PYTHIA tuned to the Tevatron underlying-event data [25]. Event modeling also includes simulation of the detector response using GEANT [26]. The simulated events are reconstructed and analyzed in the same way as the experimental data. Normalizations of the event contributions from $t$-channel single-top-quark, $VV$, $VH$, and $tt$ pair production are taken from theoretical-cross-section predictions [27–30], while normalization for $W+c$ production is taken from the measured cross section [31]. For $V+$ jets production, the heavy-flavor contribution is normalized based on the number of $b$-tagged events observed in an independent data control sample [32]. Contributions of $V+$ jets and $VV$ events containing at least one incorrectly $b$-tagged, light-flavored jet are determined by applying per-event mistag probabilities obtained from a generic event sample containing light-flavored jets [33] to simulated events. The MJ background [13] remaining after the full selection criteria is modeled by applying a tag-rate matrix derived from a MJ-dominated data sample to events in an inclusive sample selected without $b$-tagging requirements (pretag events) that, otherwise, satisfy the signal sample selection criteria.

In order to separate the $s$-channel single-top-quark signal from the backgrounds, a staged neural network (NN) technique is employed. A first network $NN_{QCD}$ is trained to discriminate MJ events from signal events. Events that
TABLE I. Numbers of predicted and observed two-jet events in the 1T, TL, and TT subsamples. The uncertainties on the predicted numbers of events are due to the theoretical-cross-section uncertainties and the uncertainties on signal and background modeling. Both the uncertainties and the central values are obtained from the fit to the data, which incorporates the theoretical constraints.

satisfy a minimal requirement on the NN\textsubscript{QCD} output variable are further analyzed by a function NN\textsubscript{sig} derived from the outputs of two additional NNs, NN\textsubscript{Vjets} and NN\textsubscript{t\bar{t}}, designed, respectively, to separate the signal from V + jets (and the remaining MJ events) and t\bar{t} backgrounds.

The NN\textsubscript{QCD} discriminant is trained using MJ data events for the background sample. Since the kinematic properties associated with the presence of a W boson in the $s$-channel single-top-quark and W + jets production processes are very similar, in contrast with those of events originating from MJ production, W + jets events are used for the signal sample. The discriminant is trained separately for the two-jet and three-jet samples using 12 to 15 kinematic, angular, and event-shape quantities for the input variables. By requiring a threshold on NN\textsubscript{QCD}, the multijet contribution is reduced by 88% while keeping 85% of the signal. The observed and estimated event yields after the NN\textsubscript{QCD} requirement are shown in Tables I and II.

The two additional networks NN\textsubscript{Vjets} and NN\textsubscript{t\bar{t}} are trained for events that satisfy the minimum requirement on the NN\textsubscript{QCD} output variable. The first NN\textsubscript{Vjets} is trained to separate the $s$-channel single-top-quark signal from V + jets and the remaining MJ backgrounds. In the training, a simulated signal is used, while the background sample consists of pretag data events that satisfy the requirement on NN\textsubscript{QCD} reweighted by the probability for an event to be $b$ tagged (tag-rate probability) as derived from the tag-rate matrix. The NN\textsubscript{QCD} requirement changes the pretag data composition, enhancing the V + jets contribution and selecting MJ events with properties closer to those expected for V + jets events. The background model obtained by reweighting these events via the tag-rate probability accounts for both the V + jets and MJ event contributions, allowing for more straightforward training of the NN\textsubscript{Vjets}. The second NN\textsubscript{t\bar{t}} is trained to separate the $s$-channel single-top-quark from t\bar{t} production using simulation for both components. Variables which describe the energy and momentum flow in the detector and angular variables are used in the training of the NN\textsubscript{Vjets} and NN\textsubscript{t\bar{t}} discriminants. The final discriminant NN\textsubscript{sig} is defined as the quadrature sum of the NN\textsubscript{Vjets} and NN\textsubscript{t\bar{t}} output variables, both weighted by an appropriate weight optimized to improve the sensitivity in each analysis subsample, taking into account the differing background contributions. Figure 2 shows the predicted and observed shapes of the NN\textsubscript{sig} output variable for each of the six event subsamples.

The modeling of SM backgrounds is tested in several control samples. A first (EWK) control sample is defined containing events with at least one charged lepton that, otherwise, satisfy the selection criteria. This sample is independent from the signal sample and is sensitive primarily to top-quark-pair, V + jets, and, to a lesser extent, VV production. A second (QCD) control sample contains events that do not meet the minimal requirement on the NN\textsubscript{QCD} output variable but, otherwise, satisfy the selection criteria. This event sample dominated by MJ production is used to validate the data-driven MJ background model and obtain scale factors ranging from 0.7 to 0.9 for normalizing modeled contributions to the TT, TL, and 1T event subsamples. Comparisons of modeled and observed distributions for multiple kinematic variables, including those used as inputs to the NN\textsubscript{QCD}, NN\textsubscript{Vjets}, and NN\textsubscript{t\bar{t}} are used to validate the accuracy of the model.

To measure the signal contribution, the sum of contributions to the NN\textsubscript{sig} distribution is fitted to the observed data, accounting for statistical and systematic uncertainties. The dominant systematic uncertainties arise from the normalization of the V + heavy-flavor background contributions (30%), differences in $b$-tagging efficiencies between the data and simulation (8%–16%), and mistag rates (20%–30%) [14]. Other uncertainties are on the t\bar{t} (3.5%), $t$-channel single-top-quark (6.2%), VV (6%), VH (5%), and W + c (23%) cross sections [27–31], initial- and final-state radiation (2%), normalizations of the QCD multijet background (3%–7%), luminosity measurement (6%) [34], jet-energy scale (1%–6%) [16], trigger
of their likelihoods and simultaneously varying the correlated uncertainties.

The measured $s$-channel single-top-quark cross section in the $E_T\ell\ell b\bar{b}$ sample is $1.12^{+0.05}_{-0.05}$ (stat + syst) pb. The probability of observing a signal as large as the observed one or larger that results from fluctuations of the background ($p$ value) is determined using pseudoexperiments to be $3.1 \times 10^{-2}$, corresponding to a significance of 1.9 standard deviations. The median expected significance assuming that a signal is present at the SM rate is 1.8 standard deviations.

This result is combined with the result of a similar search in the $\ell v b\bar{b}$ sample [12]. In that search, candidate events were selected by requiring exactly one reconstructed muon or electron in the final state. Hence, no such events are included in the $E_T\ell\ell b\bar{b}$ analysis described above. Four independent tagging categories, according to the score of the HOBIT tagger on the two leading jets (tight tight $TT$, tight loose $TL$, single tight $IT$, and loose loose $LL$) were analyzed separately. Events were also divided into three independent samples based on different categories of reconstructed leptons. To further discriminate the signal from all other backgrounds, neural networks were employed. These NNs were optimized separately for each tagging and lepton category. Correlated systematic uncertainties were treated as described above for the $E_T\ell\ell b\bar{b}$ search. Finally, a binned-likelihood technique was applied to the final NN output to extract the $s$-channel single-top-quark cross section. The significance of the result from the $\ell v b\bar{b}$ channel was 3.8 standard deviations, and the measured cross section was $1.41^{+0.44}_{-0.42}$ (stat + syst) pb, assuming a top-quark mass of 172.5 GeV/$c^2$.

The two analyses are combined by taking the product of their likelihoods and simultaneously varying the correlated uncertainties, following the same procedure explained above. The uncertainties associated with the theoretical cross sections of the $t\bar{t}$, $t$-channel electroweak single-top-quark, $VV$, and $VH$ production processes, the luminosity, the $b$-tagging efficiency, and the mistag rate are considered fully correlated between the two searches. The combined measurement results in an $s$-channel single-top-quark-production cross section of $1.36^{+0.32}_{-0.37}$ pb, consistent with the SM cross section of $1.05 \pm 0.05$ pb [28]. The combined background-only $p$ value is $1.6 \times 10^{-3}$, which corresponds to a signal significance of 4.2 standard deviations. The median expected significance is 3.4 standard deviations.

In summary, we perform for the first time a search for $s$-channel single-top-quark production in the $E_T\ell\ell b\bar{b}$ channel. The result is combined with that of a search in the $\ell v b\bar{b}$ channel [12] to strengthen the reported evidence for $s$-channel single-top-quark production, leading to an improvement of more than 10% on the uncertainty of the measured cross section.

The factorization and renormalization scale in the ALPGEN samples are both set to be \( \sqrt{M_W^2 + \sum_{\text{partons}} m_T^2} \), where \( m_T^2 = m^2 + p_T^2/c^2 \). For light-flavored partons, \( m \) is zero, while for \( b \) quarks, \( m = 4.7 \text{ GeV}/c^2 \), and for \( c \) quarks, \( m = 1.5 \text{ GeV}/c^2 \).
