Retrograde BMP Signaling Modulates Rapid Activity-Dependent Synaptic Growth via Presynaptic LIM Kinase Regulation of Cofilin

Zachary D. Piccioli and J. Troy Littleton
The Picower Institute for Learning and Memory, Department of Biology and Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

The *Drosophila* neuromuscular junction (NMJ) is capable of rapidly budding new presynaptic varicosities over the course of minutes in response to elevated neuronal activity. Using live imaging of synaptic growth, we characterized this dynamic process and demonstrated that rapid bouton budding requires retrograde bone morphogenic protein (BMP) signaling and local alteration in the presynaptic actin cytoskeleton. BMP acts during development to provide competence for rapid synaptic growth by regulating the levels of the Rho-type guanine nucleotide exchange factor Trio, a transcriptional output of BMP–Smad signaling. In a parallel pathway, we find that the BMP type II receptor Wit signals through the effector protein LIM domain kinase 1 (Limk) to regulate bouton budding. Limk interfaces with structural plasticity by controlling the activity of the actin depolymerizing protein Cofilin. Expression of constitutively active or inactive Cofilin in motor neurons demonstrates that increased Cofilin activity promotes rapid bouton formation in response to elevated synaptic activity. Correspondingly, the overexpression of Limk, which inhibits Cofilin, inhibits bouton budding. Live imaging of the presynaptic F-actin cytoskeleton reveals that activity-dependent bouton addition is accompanied by the formation of new F-actin puncta at sites of synaptic growth. Pharmacological disruption of actin turnover inhibits bouton budding, indicating that local changes in the actin cytoskeleton at pre-existing boutons precede new budding events. We propose that developmental BMP signaling potentiates NMJs for rapid activity-dependent structural plasticity that is achieved by muscle release of retrograde signals that regulate local presynaptic actin cytoskeletal dynamics.

**Key words:** actin; BMP; *Drosophila*; neuromuscular junction; synapse formation; synaptic plasticity

Introduction

Activity-dependent changes in synaptic structure play an important role in developmental wiring of the nervous system. The *Drosophila* larval neuromuscular junction (NMJ) has emerged as a model glutamatergic synapse that is well suited to study activity-dependent structural plasticity. The NMJ can be imaged *in vivo* during developmental periods of rapid synaptic growth when the axonal terminal expands ~5- to 10-fold in size over 5 d (Zito et al., 1999). Forward genetic screens to identify mutations that alter synaptic growth have revealed essential roles for retrograde bone morphogenic protein (BMP) signaling (Aberle et al., 2002) mediated by the secreted ligand Glass bottom boat (Gbb; Marqués, 2005). Mutations that disrupt BMP signaling lead to synaptic undergrowth and neurotransmitter release defects (Aberle et al., 2002; Marqués et al., 2002; McCabe et al., 2003; Rawson et al., 2003). Multiple pathways downstream of retrograde BMP signaling through the type II receptor *wishful thinking* (*wit*) have been linked to synaptic growth, synapse stability, and homeostatic plasticity in *Drosophila*. BMP signaling via the Smad transcription factor Mothers against Dpp (Mad) regulates the expression of the Rho-type guanine nucleotide exchange factor (GEF) trio to control normal synaptic growth (Ball et al., 2010). *Wit* also interacts with LIM domain kinase 1 (*Limk*) to enhance synaptic stabilization in a pathway parallel to canonical Smad-dependent signaling (Eaton and Davis, 2005). BMP signaling through *wit* also potentiates synapses for homeostatic plasticity in a pathway that is independent of *limk* and synaptic growth regulation (Goold and Davis, 2007).

In additional to developmental synapse formation during the larval stages, the NMJ displays acute structural plasticity in the form of rapid presynaptic bouton budding in response to elevated levels of neuronal activity (Ataman et al., 2008). These rapidly generated presynaptic varicosities, referred to as ghost boutons, lack presynaptic and postsynaptic transmission machinery when initially formed. The budding of ghost boutons requires retrograde signaling mediated by the postsynaptic Ca$^{2+}$-sensitive vesicle trafficking regulator synaptotagmin (*Syt*) 4 (Korkut et al., 2013). *Syt*4 also participates in developmental synaptic
growth and controls retrograde signaling that mediates enhanced spontaneous release at the NMJ (Yoshihara et al., 2005; Barber et al., 2009). Beyond the role of Syt4 in ghost bouton budding, little is known about the signaling pathways that underlie this rapid form of structural synaptic plasticity. In particular, it is unclear whether pathways that regulate synaptic growth over the longer time scales of larval development also trigger acute structural plasticity. To address these issues, we identified synaptic pathways that are required for rapid structural plasticity at Drosophila NMJs. We find that ghost bouton budding can be locally regulated at the synapse level, occurring in axons that have been severed from the neuronal cell body. In addition, activity-induced ghost bouton formation requires Syt1-mediated neurotransmitter release and postsynaptic glutamate receptor function. Like developmental growth, retrograde BMP signaling is required for ghost bouton budding. BMP signaling functions through a permissive role mediated by developmental Smad and Trio signaling, as well as through a local Wit-dependent modulation of Limk and Coffin (Twinstar) activity that alters presynaptic actin dynamics.

Materials and Methods

Drosophila genetics and molecular biology. Flies were cultured on standard medium at 25°C. All stocks were obtained from the Bloomington Stock Center unless otherwise specified. Wild-type flies used in the analysis were Canton S. CDNA encoding the endosomal target SNARE (t-SNARE) syntaxin 13 was modified to add a monomeric RFP (mRFP) tag to the N terminus of the encoded protein. The sequence was subcloned into PUAST and transgenic flies were generated. The following RNA hairpin lines from the Harvard TRiP collection were used:

- UAS-gbbRNAi (HMS01243), UAS-glurRALiRNAi (JH02647), UAS-glurRiIBRNAi (JF03145), and UAS-Syt4RNAi (JF02272). (JF02272).
- Wildish thinking mutants were analyzed as the heterozygote allelic combination wit12/r11, Trio17203 mutants (Ball et al., 2010) were analyzed as homozygotes. LimkP1 (PEY08757); Eaton and Davis, 2005) animals were analyzed as male hemizygotes. Homozygous Syt4RNAi (Yoshihara et al., 2005) mutants were used for Syt4-null animals. Syt 1-null mutants were generated by crossing syt P1 and syt2 A5 alleles. The following Gal4 lines were used: elav-Gal4 (C155), c164-Gal4 (Torroja et al., 1999), and 24B-Gal4 (Brand and Perrimon, 1993). UAS-glurRALiRNAi, UAS-glurRiIBRNAi, UAS-gbbRNAi, UAS-dad, UAS-trio, UAS-wit, UAS-witAc, UAS-limk, UAS-tsrS3E, UAS-tsrSMA, and UAS-sh were analyzed as transheterozygotes with the indicated Gal4 driver. Live imaging was performed using the following lines: (1) elav-Gal4, UAS-mRFP-synx13; (2) c164-Gal4, UAS-CD8-GFP/+; (3) c164-Gal4, UAS-CD8-RFP/+; UAS-GMAA/+; (4) UAS-tsrS3E/+; c164-Gal4/+; UAS-GMAA/+; (5) UAS-tsrSMA +, UAS-CD8-GFP/UAS-GMAA/+; and rescue lines consisted of the following genotypes: (1) wit rescue: c164-Gal4/UAS-wit, wit12/wit11, and (2) witAc rescue: c164-Gal4/UAS-witAc, wit12/wit11.

High K+ stimulation of larval NMJs. The activity-dependent ghost bouton growth protocol was adapted from Ataman et al. (2008). Wandering third instar larvae were dissected in HL3 saline solution as follows (in mM): 70 NaCl, 5 KCl, 0.2 CaCl2, 20 MgCl2, 10 NaHCO3, 5 trehalose, 115 sucrose, and 5 HEPES-NaOH, pH 7.2. Larvae were dissected according to a guide with consistent dissecting pin locations varying in size by 5% increments (schematic representation of guide with pins placed according to line termini: — — —). Dissecting pins were then moved inward to the same guide shape at 60% of the original size for each larva. Relaxed fillets were subjected to three 2 min incubations in the following 90 mM K+ solution (in mM): 40 NaCl, 90 KCl, 1.5 CaCl2, 20 MgCl2, 10 NaHCO3, 5 trehalose, 5 sucrose, and 5 HEPES-NaOH, pH 7.2, spaced by 10 min in HL3 solution. After the third 90 mM K+ incubation, larvae were returned to HL3 solution for 2 min and then stretched to the original position by moving the dissecting pins outward according to the original guide. Ghost boutons were identified by the appearance of a bouton that was not previously observed in live imaging, or by the presence of a presynaptic bouton (HRP labeled) that lacked Discs large (DLG) staining in fixed preparations. Muscle 6/7 NMJs from abdominal segments 2 through 5 were included in the analysis. Histograms show the mean ± SEM, and the imbedded text indicates number of replicates (n). Statistical significance in two-way comparisons was determined by Student’s t-test, while ANOVA analysis was used when comparing more than two datasets. The p values associated with ANOVA tests were obtained from a Tukey’s post-test.

Live imaging of NMJ growth. Wandering third instar larvae expressing UAS-mRFP-synx13, UAS-CD8-GFP, or UAS-GMA were dissected in HL3 saline solution. For experiments involving high K+ stimulation, after initial imaging, larvae were subjected to the high K+ protocol as described above and imaged again after one, two, or three 2 min 90 mM K+ solution incubations. Laruncanin A (Sigma) and jasplakinolide (Invitrogen) were prepared as 1 mM stocks in DMSO, and diluted in HL3 and 90 mM K+ solutions. Drug treatments were performed by pretreating dissected larva in HL3 solution containing 10 µM laruncanin A or 10 µM jasplakinolide for 15 min. Stimulation using HL3 and 90 mM K+ solutions containing either 10 µM laruncanin A or 10 µM jasplakinolide was then used as described above. Images were acquired with a PerkinElmer Ultraview Vox spinning disc confocal microscope equipped with a Hamamatsu C9100–13 ImageEM EM CCD at 8–35 Hz with a 40× 0.8 numerical aperture (NA) water-immersion objective (Carl Zeiss). Immunostaining. Larvae were fixed for 40 min in HL3.1 solution containing 4% formaldehyde. Following washes in PBS and PBS containing 1% Triton X-100, larvae were incubated overnight with primary antibody at 4°C, incubated with secondary antibodies for 4 h at room temperature the following day, and mounted in 70% glycerol in PBS for imaging. Antibodies were diluted as follows: mouse anti-DLG (1:500; Developmental Studies Hybridoma Bank at the University of Iowa); mouse anti-Trio (1:250; Developmental Studies Hybridoma Bank at the University of Iowa); TRITC-conjugated anti-HRP (1:500; Jackson ImmunoResearch), and Alexa Fluor 488 goat anti-mouse (1:1000) (Invitrogen). Images were acquired with a 40× 1.3 NA oil-immersion objective (Carl Zeiss) and analyzed with Velocity Software.

Results

Rapid synaptic growth at Drosophila NMJs requires local activity-dependent signaling

Prior studies at the Drosophila NMJ identified patterns of developmental synaptic growth by imaging through the cuticle of intact larval tissue genetically expressing fluorescent synaptic markers at multiple time points separated by several days (Zito et al., 1999). To more acutely analyze patterns of synaptic growth over a shorter time interval, we performed live imaging of NMJs of dissected larva genetically expressing fluorescently tagged synaptic proteins. For our initial analysis, transgenic animals were generated that expressed UAS-mRFP-Syntaxin 13. Syntaxin 13 is a t-SNARE protein that decorates endosomal compartments and the presynaptic membrane when expressed in motor neurons with elav-Gal4 (Fig. 1A), and proved to be an effective marker for visualizing synaptic growth dynamics. mRFP-syntx13 expressing third instar larvae were dissected, and selected NMJs were imaged at 1 Hz over 30 min in live preparations with the brain intact. Using this approach, rapid presynaptic budding events were observed that triggered formation of a new bouton in <1 min during normal central pattern generated muscle contraction (Fig. 1A, Movie 1). These budding events occurred very rarely and generated extremely round boutons with thin axonal connections to the parent bouton. The newly formed presynaptic varicosities morphologically resembled ghost boutons that have been previously described (Ataman et al., 2006). Ghost boutons lack postsynaptic specializations, including the PSD-95 homolog DLG and glutamate receptor clusters (Fig. 1B). Undifferentiated boutons have been previously observed developmentally in the absence of external stimulation (Ataman et al., 2006; Fuentes-
Piccoli and Littleton • Rapid Activity-Dependent Growth at Drosophila NMJs

Medel et al., 2009; Korkut et al., 2009; Mosca and Schwarz, 2010), indicating that they may contribute to normal synaptic development. Muscle and surrounding glia have also been shown to engulf a subset of these immature boutons (Fuentes-Medel et al., 2009), indicating that some ghost boutons are normally eliminated during development. In unstimulated preparations, we observed that ghost boutons represented ∼1% of all synaptic boutons at muscle 6/7 NMJs, with their frequency positively correlated with overall NMJ size (n = 68, r² = 0.3002, p < 0.0001; Fig. 1C). In several cases, we observed ghost bouton–like presynaptic structures that were surrounded by trace amounts of DLG (Fig. 1D), suggesting a subset of these varicosities may be maturing into functional connections.

During live imaging of normal larval synaptic dynamics, we observed two general patterns by which new synaptic boutons appeared. In the first, an existing presynaptic bouton would bud off membrane in a relatively rapid fashion over 10–30 s, appearing to split following the emergence of the new bouton (Movie 1, Fig. 1A). These events were often associated with muscle contraction. Given that the presynaptic arbor extends into the muscle at the Drosophila NMJ, we hypothesize that adhesive interactions between the muscle and the presynaptic bouton at particular attachment points may participate in “pulling” out a new bouton from an existing varicosity, with force for the process generated during muscle contraction. In a second pathway, often observed in preparations with less muscle contraction, presynaptic membrane would slowly flow from an existing bouton into a small bud over several minutes to form a bigger structure that would take on the shape of a new bouton and eventually separate from the main arbor. This budding mechanism appeared to rely more on presynaptic force generation than the postsynaptic “pulling” events shown in Movie 1. Syntaxin 13–positive compartments were often observed near these budding sites, suggesting that local endosomal dynamics may contribute to membrane addition or to the recycling of cell adhesion proteins at budding sites. In both cases, newly formed varicosities were highly dynamic, often moving tens of micrometers within the muscle while pulling on small axons that connected the bouton to the main arbor. Since we were only able to image over 30 min in dissected preparations before signs of tissue damage, it is unclear how many newly formed boutons mature into functional connections or are disassembled by neighboring glia or muscle.

Due to the rarity in capturing synaptic budding events with live imaging in unstimulated larvae, we proceeded to examine the molecular mechanisms that underlie rapid synaptic growth using a modified high K⁺ stimulation protocol in dissected larvae that has been previously shown to rapidly induce presynaptic bouton budding (Ataman et al., 2008). We dissected third instar wandering larvae such that the resulting fillets were relaxed enough to allow for muscle contraction. Dissected preps were stimulated by washing in high K⁺ solution three times for 2 min, with each spaced by 10 min in HL3 dissecting solution. After the third incubation with high K⁺ solution, larvae were allowed to rest in HL3 solution for 2 min before being stretched and fixed. Ghost boutons were identified either by live imaging of NMJs in animals

**Movie 1.** Rapid presynaptic bouton budding imaged at muscle 12/13. Visualization of a presynaptic arbor expressing mRFP-syntaxin 13 at muscle 12/13 in a dissected larval NMJ presynaptically expressing mRFP-Syn13. The arrow indicates the site of a new bouton spontaneously budding and stabilizing (arrow) over the course of a minute. A second bouton can also be seen to emerge from the same budding site, but later collapses. Scale bar, 5 μm. **B**, Ghost boutons can be detected in fixed tissue by staining for the presynaptic neuronal membrane (anti-HRP, red) and the postsynaptic scaffold protein DLG (green), appearing as presynaptic varicosities that lack DLG staining. Scale bar, 11 μm. Arrowheads indicate ghost boutons. **C**, Histogram of ghost bouton frequency observed at unstimulated NMJs. N = 68 NMJs, 12 animals. **D**, Putative ghost boutons identified by morphology in a fixed preparation can display faint DLG accumulation (arrowheads), suggesting some newly formed varicosities are likely to be undergoing synaptic maturation. Scale bar, 5 μm.

**Figure 1.** Rapid synaptic growth occurs spontaneously and in response to elevated activity. **A**, Live confocal imaging of a dissected larval NMJ presynaptically expressing mRFP-Syn13. The arrow indicates the site of a new bouton spontaneously budding and stabilizing (arrow) over the course of a minute. **B**, Ghost boutons can be detected in fixed tissue by staining for the presynaptic neuronal membrane (anti-HRP, red) and the postsynaptic scaffold protein DLG (green), appearing as presynaptic varicosities that lack DLG staining. Scale bar, 11 μm. Arrowheads indicate ghost boutons. **C**, Histogram of ghost bouton frequency observed at unstimulated NMJs. Scale bar, 5 μm.
Ghost bouton budding requires synaptic transmission and retrograde BMP signaling

It has been demonstrated previously that ghost bouton budding in response to K⁺ stimulation requires muscle depolarization (Korkut et al., 2013). To further characterize the requirements for synaptic transmission in ghost bouton budding, we examined mutants in the presynaptic Ca²⁺ sensor syt1. Mutations in syt1 decrease neurotransmitter release at Drosophila NMJs by specifically disrupting the synchronous component of evoked fusion (Yoshihara and Littleton, 2002; Jorquera et al., 2012). We found

presynaptically expressing UAS-CD8-GFP, or by staining with DLG and HRP antibodies to identify ghost boutons that were not surrounded by a postsynaptic specialization in fixed animals. This short protocol improved upon prior efforts to promote synaptic growth and robustly induced budding of new presynaptic varicosities in live animals at ~12% of existing boutons within 30 min, providing an easily quantifiable assay for rapid activity-induced synaptic growth.

Using live imaging before and after stimulation, we observed that new ghost boutons can be generated within a single 2 min incubation with 90 mM K⁺ solution (Fig. 2A, 3’). NMJs continue to bud new boutons throughout the synaptic terminal with repeated exposures to high K⁺ solution (Fig. 2A, 15’). We did not observe budding by live imaging in mock-treated animals that were incubated with HL3 solution in place of high K⁺ spaced 10 min apart. New varicosity formation was visualized by presynaptic expression of membrane-tethered CD8-GFP. Scale bar, 7 μm. B, Quantification of ghost boutons in relation to existing bouton number at the NMJ following high K⁺ stimulation. N = 123 NMJs, 18 animals. C, New bouton budding (arrowheads) in response to high K⁺ stimulation is strongly dependent upon external Ca²⁺ but is not changed when axons are severed from motor neuron cell bodies. Scale bar, 14 μm. D, Quantification of ghost bouton budding detected by live imaging of animals presynaptically expressing membrane-tethered CD8-GFP at the indicated conditions. N (NMJs, animals): control = 38, 7; mock treated = 26, 4; 0 mM Ca²⁺ = 25, 4; 0.5 mM EGTA = 13, 4; axon cut = 21, 4. Error bars indicate SEM.

Figure 2. Ghost bouton budding induced by high K⁺ stimulation is a rapid local signaling event. A, Live imaging of bouton budding (arrowheads) in response to 2 min incubations in high K⁺ spaced 10 min apart. New varicosity formation was visualized by presynaptic expression of membrane-tethered CD8-GFP. Scale bar, 7 μm. B, Quantification of ghost boutons in relation to existing bouton number at the NMJ following high K⁺ stimulation. N = 123 NMJs, 18 animals. C, New bouton budding (arrowheads) in response to high K⁺ stimulation is strongly dependent upon external Ca²⁺ but is not changed when axons are severed from motor neuron cell bodies. Scale bar, 14 μm. D, Quantification of ghost bouton budding detected by live imaging of animals presynaptically expressing membrane-tethered CD8-GFP at the indicated conditions. N (NMJs, animals): control = 38, 7; mock treated = 26, 4; 0 mM Ca²⁺ = 25, 4; 0.5 mM EGTA = 13, 4; axon cut = 21, 4. Error bars indicate SEM.
that ghost bouton budding was substantially reduced in syt1ΔAD4/N13 mutants (Fig. 3A;B; wild-type = 8.361 ± 7.403, n = 57; syt1ΔAD4/N13 = 0.9778 ± 1.5, n = 45; p < 0.0001, ANOVA). We also tested the postsynaptic requirement for glutamate receptor subunits in ghost bouton budding. The expression of RNAi directed against the glutamate receptor subunits DGlurIIA or DGlurIIB in muscle using the 24B-Gal4 driver caused a reduction in ghost bouton budding frequency (Fig. 3A; B; 24B, glurIIA RNAi = 0.8065 ± 1.276, n = 31, p < 0.0001, ANOVA; 24B, glurIIB RNAi = 2.586 ± 3.978, n = 29, p < 0.0001, ANOVA). Knockdown of DGlurIIA reduced budding frequency significantly more than knockdown of DGlurIIB (p = 0.0214, Student’s t test). Given the prominent role of DGlurIIA-containing glutamate receptor complexes in mediating postsynaptic Ca$^{2+}$ entry, these findings suggest that a potential Ca$^{2+}$-dependent postsynaptic process may initiate rapid structural plasticity. A prime candidate for such a role would be the release of growth-promoting factors following activity-triggered fusion of postsynaptic vesicles containing the Ca$^{2+}$ sensor Syt4 (Yoshihara et al., 2005; Barber et al., 2009). Indeed, the mammalian Syt4 homolog has been shown to regulate BDNF release (Dean et al., 2012), a key modulator of structural plasticity at mammalian synapses. We therefore tested the role of Syt4 in regulating rapid activity-dependent structural plasticity in Drosophila NMJs using null mutations in the locus that we previously generated. The loss of Syt4 substantially reduced ghost bouton budding in response to K$^+$ stimulation (Fig. 3A–B; syt4AD4 = 4.585 ± 5.08; n = 65; p = 0.0037, ANOVA), similar to observations made by Korkut et al. (2013). Postsynaptic knockdown of Syt4 using a UAS-Syt4 RNAi driven by 24B-Gal transgenic line 24B-GAL phenocopied syt4AD4 mutants, indicating a postsynaptic source of Syt4 contributes to this effect (Fig. 3A; B; 24B, syt4RNAi = 3.548 ± 2.694; n = 31; p = 0.0016, ANOVA). These data indicate that ghost bouton budding is sensitive to the levels of both presynaptic neurotransmitter release and postsynaptic glutamate receptor and Syt4 function, rather than being triggered only by changes in presynaptic membrane depolarization induced by high K$^+$.

Retrograde BMP signaling from muscle to motor neuron has been well characterized for its role in normal developmental synaptic growth. To determine whether BMP signaling is also required for ghost bouton budding at larval NMJs, we manipulated components of the BMP signaling pathway and assayed their potential for rapid activity-induced presynaptic growth. Postsynaptic reduction of the BMP ligand Gbb in muscle by RNAi significantly reduced ghost bouton budding (Fig. 3A; B; 24B, gbbRNAi = 1.8 ± 1.795; n = 20; p < 0.0001, ANOVA), although baseline bouton number remained unchanged (in contrast to gbb mutants; Fig. 3C). These results suggest that partial knockdown of Gbb is sufficient to disrupt activity-induced ghost bouton budding, but does not alter normal developmental synaptic growth. This observation indicates that developmental versus acutely triggered synaptic growth is likely to have different sensitivity or distinct molecular components for driving new synapse formation. To examine whether ghost bouton budding is locally regulated at individual synapses by BMPs or is instead controlled mainly by a BMP-dependent developmental transcriptional signal that would affect all synapses of a given motor neuron, we drove RNAi against Gbb using H94-Gal4, which is expressed predominantly in muscle 6,
but not in muscle 7 (Davis et al., 1997). Muscles 6 and 7 are innervated by two motor neurons that branch onto both muscle fibers. If BMP signaling solely functioned in a developmental role to allow NMJs to express the potential to undergo structural plasticity, we would expect Gbb expression from either muscle fiber to be sufficient to promote normal ghost bouton budding. However, if BMP signaling plays a more acute instructive role in structural plasticity, we would expect Gbb expression from either muscle fiber to allow NMJs to express the potential to undergo structural plasticity.

**Wishful Thinking** controls ghost bouton budding through multiple signaling pathways

To further analyze the requirement for BMP signaling in rapid structural plasticity, we examined how disruptions of additional components of the signaling pathway would alter developmental versus acute synaptic growth. Null mutants for the BMP type II receptor wit (wit^{A12/B11}) displayed a reduction in K⁺-stimulated bouton budding (Fig. 3A; wit^{A12/B11} = 1.162 ± 2.089; n = 37; p < 0.0001, ANOVA). Wit mutant animals also strongly reduced developmental synaptic growth. However, bouton budding as a fraction of baseline bouton number was still significantly reduced (wild-type = 0.1369 ± 0.1327 ghost boutons/baseline boutons, n = 66; wit^{A12/B11} = 0.0053 ± 0.0662, n = 37; p < 0.0001, Student’s t test). Given that Wit signals through multiple pathways, we sought to determine how wit contributes to ghost bouton budding. Canonical BMP receptor signaling leads to Smad phosphorylation and, together with cofactors, translocation to the nucleus to act as a transcription factor (Bayat et al., 2011). To assay Smad signaling in ghost bouton formation, we overexpressed the inhibitory Smad, daughters against dpp (dad; Tsuneizumi et al., 1997; Kamiya et al., 2008). Overexpression of...
UAS-dad in motor neurons has previously been shown to reduce levels of phosphorylated Mad and cause synaptic undergrowth (Eaton and Davis, 2005; Dudu et al., 2006). Overexpression of UAS-dad in motor neurons inhibited ghost bouton formation (Fig. 4A, D; c164, dad = 2.633 ± 3.944; n = 60; p < 0.0001, ANOVA), indicating that Wit signals through Mad to developmentally regulate ghost bouton formation.

One well characterized transcriptional target of Mad that regulates synaptic growth in Drosophila motor neurons is the Rho-type GEF trio (Ball et al., 2010). We assayed for a requirement for Trio in rapid activity-dependent growth by performing K+ stimulation in trio\(^{c164}\) mutant animals. We observed a quantitatively similar reduction in ghost bouton budding in trio\(^{c164}\) animals compared with wit mutants (Fig. 4A, D; trio\(^{c164}\) = 1.486 ± 1.995; n = 37; p < 0.0001, ANOVA). Conversely, the overexpression of trio caused an increase in ghost bouton budding well above wild-type levels (Fig. 4A, D; c164, trio = 15.41 ± 11.39; n = 27; p < 0.0001, ANOVA). These data indicate that Trio may play a key role in the execution of activity-induced synaptic growth given this bidirectional modulation. We therefore sought to determine whether Trio protein preferentially targeted to sites of new synaptic growth. Antisera against Trio poorly detected the protein at NMJs in wild-type animals, but robustly detected overexpressed protein. As such, we performed immunostaining for Trio in larvae presynaptically expressing UAS-trio. Strikingly, Trio immunoreactivity was enriched in ghost boutons following high K+ stimulation (Fig. 4B). Average fluorescence intensity detected in ghost boutons was significantly greater than that in normal boutons throughout the terminal (Fig. 4B, C; normalized ghost bouton fluorescence intensity = 1.419 ± 0.363; ghost boutons, n = 77; NMJs, n = 9; p < 0.0001, paired t test). We hypothesize that Trio may be enriched at sites primed for bouton budding, generating a higher concentration of the protein that later becomes trapped in newly formed boutons following K+ stimulation. Together, these data indicate that Wit signaling through a canonical Smad transcriptional pathway is likely to mediate the developmental role for BMP signaling in ghost bouton budding. In terms of Smad-dependent transcriptional targets, rapid structural plasticity at the NMJ is bidirectionally correlated with levels of the Rho-type GEF trio.

In addition to Smad-dependent transcriptional changes, Wit can signal locally through Limk to promote synapse stabilization (Eaton and Davis, 2005). Limk phosphorylates and inactivates Cofilin [Drosophila Twinstar (Tsr)] at serine 3 and can induce changes in actin cytoskeletal structure to restrain normal developmental synaptic growth (Ohashi et al., 2000; Ang et al., 2006). Limk has been shown to interact directly with BMP type II receptors, which increases its kinase activity (Foletta et al., 2003; Lee-Hoeflich et al., 2004). To test whether the Wit–Limk interaction also regulates ghost bouton budding, we rescued wit\(^{S12,B11}\) animals with motor neuron expression of full-length UAS-wit or a truncated copy of the gene UAS-wit\(^{ACT}\), which lacks the Limk binding domain (Eaton and Davis, 2005). Expression of either full-length or truncated wit rescued developmental synaptic growth (Fig. 4D), indicating that the Limk-binding domain of Wit is not likely to significantly contribute to normal developmental synaptic growth. In contrast, we observed only a partial rescue of ghost bouton budding

Figure 5. Ghost bouton budding is regulated by Limk and Cofilin activity. A, Presynaptic overexpression of limk strongly reduces activity-dependent bouton budding. Presynaptic overexpression of constitutively inactive tsr\(^{S3A}\) reduces ghost bouton budding, while presynaptic overexpression of constitutively active tsr\(^{S3A}\) increases ghost bouton budding above wild-type levels. Scale bar, 12 μm. Arrowheads indicate ghost boutons. B, Quantification of ghost bouton budding frequency in the indicated genetic background. N (NMJs, animals): wild-type 57, 11; c164, limk = 40, 5; limkP1/Y = 36, 5; c164, tsrS3E = 28, 4; c164, tsrS3A = 36, 6. C, Quantification of baseline bouton number in the indicated genetic background. D, Live confocal imaging of GMA-GFP at NMJs driven by c164-Gal4. F-actin labeled by GMA appears as dynamic puncta with relatively even size and spacing in wild-type animals. GMA labeling in axons and extended interbouton regions is stable and uniform at wild-type NMJs (double arrow), but is interrupted by puncta and appears less uniform in tsr\(^{S3E}\) and tsr\(^{S3A}\) NMJs (double arrowheads). Boutons lacking discernible F-actin puncta occurred rarely at wild-type NMJs and more frequently at tsr\(^{S3E}\) NMJs (arrows). Large and bright GMA labeling was observed in some boutons in tsr\(^{S3E}\) and tsr\(^{S3A}\) NMJs that was not observed in wild-type (arrowheads). Scale bar, 12 μm. *p < 0.05; **p < 0.01; ***p < 0.001; ANOVA. Error bars indicate SEM.
frequency in full-length wit rescue animals (Fig. 4A, C; wit rescue = 3.733 ± 3.875; n = 45; p = 0.0004, ANOVA), although budding frequency was significantly higher than in witA12/B11 mutant animals (p = 0.0414, ANOVA). Wit\textsuperscript{dCT} rescued animals showed significantly greater bouton budding frequencies than full-length wit rescue animals (Fig. 4A, C; wit\textsuperscript{dCT} rescue = 7.821 ± 5.769; p = 0.0054, ANOVA). To further examine the Wit–Limk link, we overexpressed full-length wit or truncated wit\textsuperscript{dCT} in wild-type motor neurons. The overexpression of full-length UAS-wit reduced ghost bouton budding (Fig. 4C; c164, wit = 3.891 ± 3.629; n = 55; p = 0.0003, ANOVA), while overexpression of UAS-wit\textsuperscript{dCT} did not alter budding (c164, wit\textsuperscript{dCT} = 6.364 ± 4.507; n = 55; p > 0.999, ANOVA). These observations suggest that the Limk binding domain of Wit normally functions to inhibit activity-dependent ghost bouton budding events.

Given the link between Wit signaling and Limk, we sought to determine whether Cofilin might function in the same pathway for ghost bouton budding by assaying whether wit and tsr showed genetic interactions. Heterozygote wit\textsuperscript{B11/+} and tsr\textsuperscript{+/+} animals both show similar deficits in ghost bouton budding (Fig. 4E; tsr\textsuperscript{+/+} = 4.29 ± 3.95, n = 24; wit\textsuperscript{B11/+} = 3.82 ± 3.30, n = 45; p > 0.999, ANOVA), suggesting that this form of rapid structural plasticity is highly sensitive to incremental disruptions in BMP signaling and partial loss of Tsr function. Analysis of double-heterozygous tsr\textsuperscript{+/+}; wit\textsuperscript{B11/+} animals revealed a significantly greater reduction in activity-dependent plasticity than either single heterozygote (Fig. 4E; tsr\textsuperscript{+/+}; wit\textsuperscript{B11/+} = 1.25 ± 1.65 (n = 37); tsr\textsuperscript{+/+} vs tsr\textsuperscript{+/+}; wit\textsuperscript{B11/+}, p = 0.0242; wit\textsuperscript{B11/+} vs tsr\textsuperscript{+/+}; wit\textsuperscript{B11/+}, p = 0.0206, ANOVA). This dosage-dependent interaction is consistent with a model in which Wit and Tsr participate in a similar pathway to regulate ghost bouton budding.

**Link regulation of presynaptic Cofilin activity controls rapid activity-dependent synaptic growth**

To determine how Limk activity modulated Cofilin and ghost bouton budding, we assayed acute synaptic growth in strains with altered Limk function or disrupted Cofilin regulation by Limk. Motor neuron overexpression of UAS-limk strongly inhibited activity-dependent bouton budding (Fig. 5A, B; c164, limk = 1.675 ± 2.702; n = 40; p < 0.0001, ANOVA), indicating that Limk suppresses ghost bouton formation, potentially through phosphorylation-mediated inhibition of Cofilin (Tsr). To examine whether Cofilin activity regulates ghost bouton budding, we overexpressed either a constitutively inactive (UAS-ts\textsuperscript{S3E}) or a constitutively active (UAS-ts\textsuperscript{S3A}) twinstar transgene bearing a phosphomimetic or phosphoincompetent Limk phosphorylation site, respectively. A decrease in bouton budding frequency was observed when the inactive transgene was overexpressed (Fig. 5A, B; c164, ts\textsuperscript{S3E} = 3.107 ± 3.059; n = 28; p = 0.0006, ANOVA), while a strong increase in bouton budding frequency was found upon overexpression of the active transgene (Fig. 5A, B; c164, ts\textsuperscript{S3A} = 13.39 ± 7.958; n = 36; p = 0.0003, ANOVA). As predicted based on the ability of Cofilin to disassemble actin filaments, the expression of either transgene altered the presynaptic actin cytoskeleton when visualized by the expression of the F-actin marker GMA. GMA contains the actin-binding domain of Moesin fused to GFP (Dutta et al., 2002). In addition to labeling dynamic actin puncta within synaptic boutons, GMA normally labeled more stable actin structures in axons and interbouton regions (Fig. 5D). In contrast to controls, GMA...
subjected to a single 2 min incubation in high K+ solution. Third instar larvae were dissected and imaged, and then the membrane marker CD8-RFP expressed in motor neurons. To directly examine the role of presynaptic actin in bouton budding, we performed live imaging in animals expressing GMA and imaged before and after washout. To examine how these manipulations regulate bouton budding, we incubated dissected preps in HL3 solution containing 10 μM drug for 15 min and then proceeded with the K+ stimulation protocol with solutions containing 10 μM drug. Disruption of normal actin turnover with either drug resulted in a decrease in bouton budding compared with controls (Fig. 6C: no drug = 8.767 ± 7.035, n = 30; latrunculin A = 4.829 ± 6.046, n = 35, p = 0.0155, ANOVA; Jasplakinolide = 1.933 ± 2.586, n = 30, p < 0.0001, ANOVA). Some F-actin puncta were still observed in animals treated with 10 μM latrunculin A, indicating that this treatment may allow the formation of a limited number of new puncta. In contrast, the actin cytoskeleton appeared highly stable in jasplakinolide-treated animals, and caused a much greater reduction in ghost bouton budding. These data indicate that local actin rearrangement occurs during ghost bouton budding, and that actin turnover contributes to the rapid formation of new synaptic varicosities in an activity-dependent manner.

Figure 7. Model for ghost bouton formation through parallel signaling pathways involving Gbb and Wit. BMP signaling through Wit is predicted to both promote and inhibit changes to the actin cytoskeleton that regulate ghost bouton formation. Gbb signaling developmentally through the phosphorylation and nuclear translocation of Mad potentiates synaptic terminals for activity-induced bouton budding by promoting transcription of the Rho GEF trio. Trio activity may also be regulated locally and acutely by synaptic activity. Wit also signals locally through Limk to inhibit Cofilin (Tsr), thereby suppressing ghost bouton formation.

Local actin turnover is required for bouton budding

Manipulations to the actin cytoskeleton regulators limk and tsr resulted in changes to ghost bouton budding frequency and in the case of tsr observable changes to the presynaptic actin cytoskeleton. To directly examine the role of presynaptic actin in bouton budding, we performed live imaging in animals expressing GMA and the membrane marker CD8-RFP expressed in motor neurons. Third instar larvae were dissected and imaged, and then subjected to a single 2 min incubation in high K+ and imaged again. We then identified sites of ghost bouton budding to observe how K+ stimulation affected the local actin cytoskeleton at sites of new bouton formation by comparing before and after images. We consistently observed the emergence of new F-actin puncta localized at the sites of ghost bouton budding from previously existing boutons (Fig. 6A), suggesting that local actin rearrangements occur at regions where new boutons form. To test whether local actin rearrangements are required for ghost bouton budding, we directly interfered with actin turnover through bath application of the F-actin-depolymerizing drug latrunculin A or of the F-actin-stabilizing drug jasplakinolide (Spector et al., 1999). The application of 10 μM latrunculin A caused dispersal of F-actin puncta within minutes as well as a reduction in the number of puncta (Fig. 6B). The application of 10 μM jasplakinolide stabilized existing F-actin puncta and caused the formation of new puncta within minutes (Fig. 6B). The effects of the drugs were still observed 15 min after washout. To examine how these manipulations regulate bouton budding, we incubated dissected preps in HL3 solution containing 10 μM drug for 15 min and then proceeded with the K+ stimulation protocol with solutions containing 10 μM drug. Disruption of normal actin turnover with either drug resulted in a decrease in bouton budding compared with controls (Fig. 6C: no drug = 8.767 ± 7.035, n = 30; latrunculin A = 4.829 ± 6.046, n = 35, p = 0.0155, ANOVA; Jasplakinolide = 1.933 ± 2.586, n = 30, p < 0.0001, ANOVA). Some F-actin puncta were still observed in animals treated with 10 μM latrunculin A, indicating that this treatment may allow the formation of a limited number of new puncta. In contrast, the actin cytoskeleton appeared highly stable in jasplakinolide-treated animals, and caused a much greater reduction in ghost bouton budding. These data indicate that local actin rearrangement occurs during ghost bouton budding, and that actin turnover contributes to the rapid formation of new synaptic varicosities in an activity-dependent manner.

Discussion

Our experimental analysis of ghost bouton budding at the Drosophila NMJ indicates that rapid activity-dependent synaptic growth requires retrograde BMP signaling at this synapse. The current data support a model in which BMP signaling through the type II receptor Wit is required developmentally to potentiate synapses for budding in response to elevated synaptic activity. This pathway requires Smad-dependent expression of the Rho-type GEF trio (Fig. 7), and parallels a requirement for BMP signaling and Trio in developmental synaptic growth that occurs during the larval stages. In a parallel pathway, Wit interaction with Limk inhibits bouton budding through regulation of Cofilin activity. Both pathways regulate the synaptic actin cytoskeleton and may converge on similar actin regulatory molecules such as Limk and Cofilin via Rac1 or RhoA. Manipulating Cofilin activity levels by the overexpression of Limk or the expression of constitutively active/inactive Cofilin demonstrates that high Cofilin activity favors bouton budding, while low Cofilin activity inhibits budding. Local changes in the actin cytoskeleton that accompany activity-dependent bouton budding were also observed at sites of new synaptic growth. In addition, pharmacological disruption of normal actin turnover inhibits budding, suggesting that increased actin turnover mediated by Cofilin potentiates rapid activity-dependent synaptic plasticity.

BMP signaling in ghost bouton budding

Multiple genetic perturbations of BMP signaling were identified that altered the frequency of activity-dependent bouton budding at the NMJ. Although several of these mechanisms are shared with those previously characterized to control BMP-mediated developmental synaptic growth, several manipulations separated rapid activity-dependent BMP-mediated bouton budding from the slower forms of developmental growth. In the case of wit mutants or motor neuron overexpression of dad, a reduction in baseline bouton number was observed that showed varying degrees of severity. Wit mutants displayed strongly undergrown synapses, while dad overexpression animals had only modest synaptic undergrowth. In contrast, both these manipulations strongly suppressed ghost bouton budding. Additionally, synap-
tic undergrowth with partial knockdown of Gbb using postsynaptic RNAi was not observed, while this manipulation caused a strong reduction in ghost bouton budding. These observations indicate that rapid ghost bouton budding is more sensitive to modest perturbations in BMP signaling compared with developmental synaptic growth. One explanation for this differential sensitivity is that BMP signaling potentiates NMJs for activity-dependent bouton budding via transcriptional regulation of molecular components that are not required for normal synaptic growth. Alternatively, similar molecular pathways are required, but at different levels of output. In particular, trio mutants display a less severe synaptic undergrowth phenotype than wit mutants, but show similarly severe deficits in ghost bouton budding. Because trio expression is strongly dependent on BMP signaling (Ball et al., 2010), a modest reduction in BMP output could reduce Trio levels such that ghost bouton budding is significantly reduced, while normal synaptic growth is less affected. It will be interesting to determine in future studies whether the developmental role for BMP signaling for acute structural plasticity shares a critical period as has recently been found for BMP function during developmental synaptic growth (Berke et al., 2013).

Given the requirement of the postsynaptic Ca\(^{2+}\)-sensor Syt4 for normal levels of ghost bouton budding, an attractive model is that BMP is released acutely in response to elevated activity through the fusion of Syt4-positive postsynaptic vesicles. However, our analysis indicates that retrograde BMP signaling through trio transcriptional upregulation is unlikely to be an instructive cue for bouton budding, as the severing of axons and the inhibition of retrograde trafficking of P-Mad before stimulation does not reduce budding in response to elevated activity. It is possible that synaptic P-Mad may play an instructional role in ghost bouton budding, as a local decrease in budding frequency was observed when Gbb expression was specifically reduced in muscle 6. Neuronal overexpression of dad also reduced synaptic P-Mad, as has been previously observed (data not shown; Dudu et al., 2006). Therefore, dad overexpression could inhibit ghost bouton budding by decreasing synaptic P-Mad signaling, in addition to decreasing nuclear Smad signaling. However, we did not observe dosage-dependent genetic interactions between syt4 and wit (data not shown), suggesting that Syt4 may participate in a separate pathway to regulate ghost bouton budding. Activity-dependent fusion of Syt4 postsynaptic vesicles (Yoshihara et al., 2005) could release a separate unidentified retrograde signal that provides an instructive cue for budding that would function in parallel to a developmental requirement for retrograde BMP signaling.

### Synaptic actin cytoskeleton regulation via Trio

In addition to instructive cues from the postsynaptic compartment that trigger ghost bouton budding, the presynaptic nerve terminal must have molecular machines in place to read out these signals and execute the budding event. The regulation of Rho GTPases via Rho GEFs and GAPs downstream of extracellular cues is an attractive mechanism, as these proteins play critical roles in the regulation of neuronal morphology and axonal guidance (Luo, 2000; Dickson, 2001). Several studies have shown that retrograde synaptic signaling regulates Rho GTPase activity to alter synaptic function and growth in Drosophila (Tolias et al., 2011). Ghost bouton budding mediated by developmental BMP signaling also shares some similarities with mechanisms underlyng homeostatic plasticity at Drosophila NMJs. The Eph receptor is required for synaptic homeostasis at the NMJ, and it interfaces with developmental BMP signaling via Wit (Goold and Davis, 2007; Frank et al., 2009). While Eph receptor-mediated homeostatic plasticity predominantly requires the downstream RhoA-type GEF Ephexin, the Eph receptor may also signal through Rac1 (Frank et al., 2009). Drosophila VAP-33A may also act as a ligand for synaptic Eph receptors, as it has been shown to regulate NMJ morphology and growth, while preferentially localizing to sites of bouton budding (Penneneta et al., 2002; Tsuda et al., 2008). Our analysis indicates that the levels of Trio, which functions as a Rho-type GEF, are bidirectionally correlated with ghost bouton budding activity and that overexpressed Trio is localized to ghost boutons after budding. As such, acute Trio regulation represents another attractive pathway for rapidly modifying bouton budding activity.

### Link regulation of Cofilin controls ghost bouton budding

Rho GTPase signaling can produce distinct effects in differering systems and cell types depending on the presence or absence of downstream effectors, although most of these pathways ultimately impinge on regulation of the actin cytoskeletal (Luo, 2000). Indeed, we have found a key role for Link regulation of Cofilin activity in the control of ghost bouton budding. The current findings indicate that Link activity normally functions to inhibit the formation of ghost boutons, as neuronal overexpression of Link strongly suppressed activity-dependent bouton budding. Consistent with an inhibitory role for Link, Cofilin activity promotes budding, while the overexpression of an inactive Cofilin inhibited budding. The expression of mutant Cofilin transgenes resulted in visible changes to the presynaptic actin cytoskeleton at NMJs, indicating that these manipulations likely alter rapid budding events by changing local actin dynamics at sites of potential growth. Using live imaging of F-actin dynamics before and after bouton budding, the formation of new F-actin puncta was observed at sites of bouton budding. Elevated Cofilin activity is sufficient to increase ghost bouton budding frequency, and is predicted to increase actin turnover and the formation of F-actin structures (Michelot and Drubin, 2011). Pharmacological disruption of actin polymerization dynamics also disrupts rapid bouton addition in response to elevated activity.

These findings support a model whereby Wit has opposing signaling roles with respect to bouton budding (Fig. 7). Providing a permissive role via Smad signaling and an inhibitory role via Link activation may provide for a system in which increased potential for rapid synaptic expansion is directly coupled to enhanced synaptic stability. This coupling could set a threshold for ghost bouton budding downstream of synaptic activity. In the background of moderate or low synaptic activity, Link prevents ghost bouton budding. When synaptic activity is elevated, additional signaling events promote new synaptic growth by either reducing or outcompeting Link activity, with a concurrent activation of Cofilin. Decreased Link activity downstream of extracellular cues has been shown to regulate cell morphology in other systems as well (Sparrow et al., 2012), providing an attractive mechanism for rapid activity-dependent regulation of synaptic structure at Drosophila NMJs.

### Notes
