Search for new physics in events with opposite-sign leptons, jets, and missing transverse energy in pp collisions at $\sqrt{s} = 7$ TeV

CMS Collaboration

CERN, Switzerland

A search is presented for physics beyond the standard model (BSM) in final states with a pair of opposite-sign isolated leptons accompanied by jets and missing transverse energy. The search uses LHC data recorded at a center-of-mass energy $\sqrt{s} = 7$ TeV with the CMS detector, corresponding to an integrated luminosity of approximately 5 $fb^{-1}$. Two complementary search strategies are employed. The first probes models with a specific dilepton production mechanism that leads to a characteristic kinematic edge in the dilepton mass distribution. The second strategy probes models of dilepton production with heavy, colored objects that decay to final states including invisible particles, leading to very large hadronic activity and missing transverse energy. No evidence for an event yield in excess of the standard model expectations is found. Upper limits on the BSM contributions to the signal regions are deduced from the results, which are used to exclude a region of the parameter space of the constrained minimal supersymmetric extension of the standard model. Additional information related to detector efficiencies and response is provided to allow testing specific models of BSM physics not considered in this Letter.

1. Introduction

In this Letter we describe a search for physics beyond the standard model (BSM) in events containing a pair of opposite-sign leptons, jets, and missing transverse energy ($E_T^{miss}$), in a sample of proton–proton collisions at a center-of-mass energy of 7 TeV. The data sample was collected with the Compact Muon Solenoid (CMS) detector [1] at the Large Hadron Collider (LHC) in 2011 and corresponds to an integrated luminosity of 4.98 fb$^{-1}$. This is an update and extension of a previous analysis performed with a data sample of 34 pb$^{-1}$ collected in 2010 [2].

The BSM signature in this search is motivated by three general considerations. First, new particles predicted by BSM physics scenarios are expected to be heavy in most cases, since they have so far eluded detection. Second, BSM physics signals may be produced with large cross section via the strong interaction, resulting in significant hadronic activity. Third, astrophysical evidence for dark matter suggests [3–6] that the mass of weakly-interacting massive particles is of the order of the electroweak symmetry breaking scale. Such particles, if produced in proton–proton collisions, could escape detection and give rise to an apparent imbalance in the event transverse energy. The analysis therefore focuses on the region of high $E_T^{miss}$. An example of a specific BSM scenario is provided by R-parity conserving supersymmetric (SUSY) models, in which the colored squarks and gluinos are pair-produced and subsequently undergo cascade decays, producing jets and leptons [7,8]. These cascade decays may terminate in the production of the lightest SUSY particle (LSP), often the lightest neutralino, which escapes detection and results in large $E_T^{miss}$. This LSP is a candidate for a dark matter weakly-interacting massive particle. Another BSM scenario which may lead to similar signatures is the model of universal extra dimensions (UED) [9].

The results reported in this Letter are part of a broad program of BSM searches in events with jets and $E_T^{miss}$, classified by the number and type of leptons in the final state. Here we describe a search for events containing an opposite-sign isolated lepton pair in addition to jets and $E_T^{miss}$. We reconstruct electrons and muons, which provide a clean signature with low background. In addition, we reconstruct $\tau$ leptons in their hadronic decay modes to improve the sensitivity to models with enhanced coupling to third generation particles. Complementary CMS searches with different final states have already been reported, for example in Refs. [10,11]. Results from the ATLAS Collaboration in this final state using data and the predictions from standard model (SM) Monte Carlo
(MC) simulation. Two complementary search strategies are pursued, which are optimized for different experimental signatures. The first strategy is a search for a kinematic edge [15] in the dilepton (ee, μμ) mass distribution. This is a characteristic feature of SUSY models in which the same-flavor opposite-sign leptons are produced via the decay $\tilde{\chi}_2^0 \rightarrow \ell \ell \rightarrow \tilde{\chi}_1^0 \ell^{\pm} \ell^{-}$, where $\tilde{\chi}_2^0$ is the next-to-lightest neutralino, $\tilde{\chi}_1^0$ is the lightest neutralino, and $\ell$ is a slepton. The second strategy is a search for an excess of events with dileptons accompanied by very large hadronic activity and $E^\text{miss}_T$. We perform counting experiments in four signal regions with requirements on these quantities to suppress the tt̄ background, and compare the observed yields with the predictions from a background estimation technique based on data control samples, as well as with SM and BSM MC expectations. These two search approaches are complementary, since the dilepton mass edge search is sensitive to new physics models that have lower $E^\text{miss}_T$ and hadronic energy, while the counting experiments do not assume a specific dilepton production mechanism and are also sensitive to BSM scenarios that produce lepton pairs with uncorrelated flavor. No specific BSM physics scenario, e.g. a particular SUSY model, has been used to optimize the search regions. In order to illustrate the sensitivity of the search, a simplified and practical model of SUSY breaking, the constrained minimal supersymmetric extension of the standard model (CMSSM) [16,17] is used. The CMSSM is described by five parameters: the universal scalar and gaugino mass parameters ($m_0$ and $m_{1/2}$, respectively), the universal trilinear soft SUSY breaking parameter $A_0$, the ratio of the vacuum expectation values of the two Higgs doublets ($\tan \beta$), and the sign of the Higgs mixing parameter $\mu$. Throughout the Letter, four CMSSM parameter sets, referred to as LM1, LM3, LM6, and LM13 [18], are used to illustrate possible CMSSM yields. The parameter values defining LM1 (LM3, LM6, LM13) are $m_0 = 60$ (330, 85, 270) GeV, $m_{1/2} = 250$ (240, 400, 218) GeV, $\tan \beta = 10$ (20, 10, 40), $A_0 = 0$ ($0.0, -553$) GeV; all four parameter sets have $\mu > 0$. These four scenarios are beyond the exclusion reach of previous searches performed at the Tevatron and LEP, and are chosen here because they produce events containing opposite-sign leptons and may lead to a kinematic edge in the dilepton mass distribution. These four scenarios serve as common benchmarks to facilitate comparisons of sensitivity among different analyses.

### 2. The CMS detector

The central feature of the CMS detector is a superconducting solenoid, 13 m in length and 6 m in diameter, which provides an axial magnetic field of 3.8 T. Within the field volume are several particle detection systems. Charged particle trajectories are measured by silicon pixel and silicon strip trackers covering $|\eta| < 2.5$ in pseudorapidity, where $\eta = -\ln[\tan(\theta/2)]$ with $\theta$ the polar angle of the particle trajectory with respect to the counterclockwise proton beam direction. A crystal electromagnetic calorimeter and a brass/scintillator hadron calorimeter surround the tracking volume, providing energy measurements of electrons, photons and hadronic jets. Muons are identified and measured in gas-ionization detectors embedded in the steel return yoke outside the solenoid. The detector is nearly hermetic, allowing energy balance measurements in the plane transverse to the beam direction. The first level of the CMS trigger system, composed of custom hardware processors, uses information from the calorimeters and muon detectors to select, in less than 1 μs, the most interesting events. The High Level Trigger processor farm further decreases the event rate from around 100 kHz to around 300 Hz, before data storage. Event reconstruction is performed with the particle-flow (PF) algorithm [19], which is used to form a mutually exclusive collection of reconstructed particles (muons, electrons, photons, charged and neutral hadrons) by combining tracks and calorimeter clusters. A more detailed description of the CMS detector can be found elsewhere [1].

### 3. Event selection

The following samples of simulated events are used to guide the design of the analysis. These events are generated with either PYTHIA 6.4.22 [20], MADGRAPH 4.412 [21], or POWHEG [22] MC event generators using the CTEQ 6.6 parton density functions [23]. The tt̄, W + jets, and VV (V = W, Z) samples are generated with MADGRAPH, with parton showering simulated by PYTHIA using the ZZ tune [24]. The single-top samples are generated with POWHEG. The Drell–Yan (DY) sample is generated using a mixture of MADGRAPH (for events with dilepton invariant mass above 50 GeV) and PYTHIA (for events with dilepton invariant mass in the range 10–50 GeV), and includes decays to the $\tau \tau$ final state. The signal events are simulated using PYTHIA. The detector response in these samples is then simulated with a GEANT4 model [25] of the CMS detector. The MC events are reconstructed and analyzed with the same software as is used to process collision data. Due to the varying instantaneous LHC luminosity, the mean number of interactions in a single beam crossing increased over the course of the data-taking period to a maximum of about 15. In the MC simulation, multiple proton–proton interactions are simulated by PYTHIA and superimposed on the hard collision, and the simulated samples are reweighted to describe the distribution of reconstructed primary vertices in data [26]. The simulated sample yields are normalized to an integrated luminosity of 4.98 fb$^{-1}$ using next-to-leading order (NLO) cross sections.

Events in data are selected with a set of $ee$, $\mu\mu$, $\tau\tau$, and $\mu\tau$ double-lepton triggers. Since the online reconstruction of hadronic-$\tau$ decays ($\tau_0$) is difficult, $\tau_0$ triggers are intrinsically prone to high rates. Therefore, for the analysis with two $\tau_0$ only, we use specialized triggers that rely on significant hadronic activity $H_T$, quantified by the scalar sum of online jet transverse energies with $p_T > 40$ GeV, and $E^\text{miss}_T$ as well as the presence of two $\tau_0$. The efficiencies for events containing two leptons passing the analysis selection to pass at least one of these triggers are measured to be approximately $1.00^{+0.00}_{-0.01}$, $0.95 \pm 0.02$, $0.90 \pm 0.02$, $0.80 \pm 0.05$, $0.80 \pm 0.05$ and $0.90 \pm 0.05$ for $ee$, $\mu\mu$, $\tau\tau$, $\mu\tau_0$, $\mu\tau_0$, and $\tau_0\tau_0$ triggers, respectively. In the following, the simulated sample yields for the light lepton channels are weighted by these trigger efficiencies. For the $\tau_0$ channels the trigger simulation is applied to the MC simulation and then a correction is applied based on the measured data and MC efficiencies for these triggers. Because leptons produced in the decays of low-mass particles, such as hadrons containing b and c quarks, are nearly always inside jets, they can be suppressed by requiring the leptons to be isolated in space from other particles that carry a substantial amount of transverse momentum. The details of the lepton isolation measurement are given in Ref. [14]. In brief, a cone is constructed of size $\Delta R \equiv \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} = 0.3$ around the lepton momentum direction. The lepton relative isolation is then quantified by summing the transverse energy (as measured in the calorimeters) and the transverse momentum (as measured in the silicon tracker) of all objects within this cone, excluding the lepton, and dividing by the lepton transverse momentum. The resulting quantity is required to be less than 0.15, rejecting the large background arising from QCD production of jets. The $\tau_0$ decays are reconstructed with the PF algorithm and identified with the hadrons-plus-strips (HPS) algorithm, which considers candidates with one or three charged pions and up to
two oppositely-signed leptons with highest (second highest) $p_T$. The requirements on jet multiplicity, scalar sum of jet transverse energies ($H_T$), missing transverse energy ($E_T^{\text{miss}}$), and dilepton mass are also indicated.

Table 2

Data yields and MC predictions in the light lepton channels after preselection, using the quoted NLO production cross sections $\sigma$. The $t\bar{t} \rightarrow \ell^+\ell^-$ contribution corresponds to dilepton $t\bar{t}$ with no $W \rightarrow \tau$ decays, $t\bar{t} \rightarrow \ell^+\tau^+\tau^-$ refers to dilepton $t\bar{t}$ with at least one $W \rightarrow \tau$ decay, and $t\bar{t} \rightarrow \ell^{+}+\text{jets/hadrons}$ includes all other $t\bar{t}$ decay modes. The quoted cross sections for these processes include the relevant branching fractions. The LM points are benchmark SUSY scenarios, which are defined in the text. The MC uncertainties include the statistical component, the uncertainty in the integrated luminosity, and the dominant uncertainty from the $t\bar{t}$ cross-section determination. The data yield is in good agreement with the MC prediction, but the latter is not used explicitly in the search. The difference between the $ee+\mu\mu$ versus $ee$ yields is due to the rejection of $e\mu$ events with an invariant mass consistent with that of the $Z$ boson.

The two neutral pions [27]. As part of the $t\bar{t}$ identification procedure, loose isolation is applied for the $t\bar{t}$ final states. Isolated electrons and muons can be misidentified as $t\bar{t}$ candidates. For this reason $t\bar{t}$ candidates are required to fail electron selections and not to match a muon signature in the muon system.

Events with two opposite-sign isolated leptons are selected. At least one of the leptons must have $p_T > 20$ GeV, both must have $p_T > 10$ GeV, and the electrons (muons) must have $|\eta| < 2.5$ ($|\eta| < 2.4$). Electrons in the range $1.44 < |\eta| < 1.57$ are excluded. In events containing a $t\bar{t}$ candidate, both leptons must satisfy $p_T > 20$ GeV and $|\eta| < 2.1$, where the acceptance requirement is tightened so that the $t\bar{t}$ decay products are contained in the tracking detector in a manner that is consistent with the requirements of the triggers used for these events. In events with more than one opposite-sign pair that satisfy the selection requirements, the two oppositely-signed leptons with highest $p_T$ are chosen. Events with an $ee$ or $\mu\mu$ pair with invariant mass of the dilepton system between 76 GeV and 106 GeV or below 12 GeV are removed, in order to suppress $Z/\gamma^* \rightarrow \ell\ell$ events, as well as low-mass dilepton resonances. Events containing two electrons, two muons, or an electron and a muon are referred to as the “light lepton channels”, while events with at least one $t\bar{t}$ are referred to as “hadronic-$\tau$ channels”.

The PF objects are clustered to form jets using the anti-$k_T$ clustering algorithm [28] with the distance parameter of 0.5. We apply $p_T$- and $\eta$-dependent corrections to account for residual effects of nonuniform detector response, and impose quality criteria to reject jets that are consistent with anomalous detector noise. We require the presence of at least two jets with transverse momentum of $p_T > 30$ GeV and $|\eta| < 3.0$, separated by $\Delta R > 0.4$ from leptons passing the analysis selection. For each event the scalar sum of transverse energies of selected jets $H_T$ must exceed 100 GeV. The $E_T^{\text{miss}}$ is defined as the magnitude of the vector sum of the transverse momenta of all PF objects, and we require $E_T^{\text{miss}} > 50$ GeV ($E_T^{\text{miss}} > 100$ GeV) in the light lepton (hadronic-$\tau$) channels.

The event preselection requirements are summarized in Table 1. The data yields and corresponding MC predictions after this event preselection are given in Table 2 (light leptons) and Table 3 (hadronic-$\tau$). For the light lepton channels, the normalization of the simulated yields has been scaled based on studies of $Z \rightarrow \ell\ell$ in data and in MC simulation, to account for effects of lepton selection and trigger efficiency and to match the integrated luminosity. As expected, the MC simulation predicts that the sample passing the preselection is dominated by lepton pair final states from $t\bar{t}$ decays (dilepton $t\bar{t}$). The data yield is in good agreement with the prediction, within the systematic uncertainties of the integrated luminosity (2.2%) and $t\bar{t}$ cross section determination (12%) [29–31]. The yields for the LM1, LM3, LM6, and LM13 benchmark scenarios are also quoted.

### 4. Search for a kinematic edge

We search for a kinematic edge (end-point) in the dilepton mass distribution for same-flavor (SF) light-lepton events, i.e., $ee$ or $\mu\mu$ lepton pairs. Such an edge is a characteristic feature of, for example, SUSY scenarios in which the opposite-sign leptons are produced via the decay $\chi^0 \rightarrow \ell\ell \rightarrow \ell^+\ell^- E_T^{\text{miss}}$. The model of UED can lead to a similar signature with different intermediate particles. In case of a discovery such a technique offers one of the best
possibilities for model-independent constraints of the SUSY mass parameters \[15\].

In contrast, for the dominant background \(tt\) as well as other SM processes such as WW and DY → \(\tau\tau\), the two lepton flavors are uncorrelated, and the rates for SF and opposite-flavor (OF) eμ lepton pairs are therefore the same. Hence we can search for new physics in the SF final state and model the backgrounds using events in the OF final state. Thus the \(tt\) background shape is extracted from events with OF lepton pairs, and a fit is performed to the dilepton mass distribution in events with SF lepton pairs.

In order to be sensitive to BSM physics over the full dilepton mass spectrum, events with a dilepton invariant mass \(m_{\ell\ell}\) consistent with that of the Z boson are not rejected. This increases the DY contribution, which is compensated by an increase in the \(E_{T}\) requirement (see Table 1). We then proceed to search for a kinematic edge in the signal region defined as \(H_T > 300\) GeV. The invariant mass distributions of SF and OF lepton pairs are in good agreement with each other (see Fig. 1). A fit is performed to the dilepton mass distribution with three candidate signal shapes, over a range of values on the position of the kinematic edge.

The flavor-uncorrelated background, as a function of the invariant mass \(m_{\ell\ell}\), is parameterized as:

\[ B(m_{\ell\ell}) = m_{\ell\ell} e^{-b(m_{\ell\ell})}, \tag{1} \]

where \(a \approx 1.4\) describes the rising edge and \(b \approx 0.002\) dominates the long exponential tail on the right hand side of the background shape; these parameters are extracted from the fit to data.

We parametrize the signal shape with an edge model for two subsequent two-body decays, according to:

\[ S(m_{\ell\ell}) = \frac{1}{\sqrt{2\pi} \sigma f} \int_{0}^{m_{\max}} \ dy \ y^{\alpha} e^{-\frac{(y-y_{0})^2}{2\sigma^2}}, \tag{2} \]

For \(\alpha = 1\) this function describes a triangle convoluted with a Gaussian, which accounts for detector resolution effects. The resolution parameters for electrons \(\sigma e\) and muons \(\sigma \mu\) are constrained with simulation. The DY contribution, found to be negligible as seen in Fig. 1, is modelled by a Breit–Wigner function with the mass and width parameters fixed at the Z boson mass and width, convoluted with a Gaussian function to account for the detector resolution.

We perform a simultaneous, extended, unbinned maximum likelihood fit to the distribution of dilepton mass for events containing ee, \(\mu\mu\) (signal, DY and background model), and e\(\mu\) pairs (background model only). The value of the kinematic edge position \(m_{\max}\) is varied, and the fit is performed for each value of this parameter. The shape parameters of the flavor-uncorrelated background that are free in the fit are assumed to be common in all categories, and the yields of signal (\(n_S\)), DY (\(n_{DY}\)) and background (\(n_{b}\)) in these three categories are constrained using the ratio of muon to electron selection efficiencies \(R_{ee} = 1.11 ± 0.05\). This quantity is evaluated using studies of DY events in data and in MC simulation.

The fit is performed in the signal region \(H_T > 300\) GeV and \(E_{T,\text{miss}} > 150\) GeV. The SF events overlaid with the signal plus background fit, and the flavor-uncorrelated shape overlaid with OF events, are shown in Fig. 1. The results of the fit are displayed for a value of the kinematic edge position \(m_{\max} = 280\) GeV, where the
largest excess is observed. The local significance is 2.1σ including statistical and systematic uncertainties. However, a correction for the look-elsewhere effect [32] reduces the global significance to 0.7σ. The extracted signal yield including statistical uncertainty (nS = 11.0 ± 3.2) at this point is consistent with the background-only hypothesis, and we derive a 95% confidence level upper limit of nS < 23 events for this kinematic edge position. No evidence for a kinematic edge feature is observed in the dilepton mass distribution.

5. Counting experiments

We next proceed to search for an excess of events containing lepton pairs accompanied by large E_{T}\text{miss} and H_T. To look for possible BSM contributions, we define four signal regions that reject all but ~0.1% of the dilepton tt events, by adding the following requirements:

- high-E_{T}\text{miss} signal region: E_{T}\text{miss} > 275 GeV, H_T > 300 GeV,
- high-H_T signal region: E_{T}\text{miss} > 200 GeV, H_T > 600 GeV,
- tight signal region: E_{T}\text{miss} > 275 GeV, H_T > 600 GeV,
- low-H_T signal region: E_{T}\text{miss} > 275 GeV, 125 < H_T < 300 GeV.

The signal regions are indicated in Fig. 2. These signal regions are tighter than the one used in Ref. [2] since with the larger data sample the tighter signal regions allow us to explore phase space farther from the core of the SM distributions. The observed and estimated yields in the high-E_{T}\text{miss}, high-H_T, and tight signal regions are used in the CMSSM exclusion limit in Section 7. The low-H_T region has limited sensitivity to CMSSM models that tend to produce low-p_T leptons, since the large E_{T}\text{miss} and low H_T requirements lead to the requirement of large dilepton p_T. However, the results of this region are included to extend the sensitivity to other models that produce high-p_T leptons.

5.1. Light lepton channels

The dominant background in the signal regions is dilepton tt production. This background is estimated using a technique based on data control samples, henceforth referred to as the dilepton transverse momentum (p_T(\ell\ell)) method. This method is based on the fact [33] that in dilepton tt events the p_T distributions of the charged leptons (electrons and muons) and neutrinos are related, since each lepton–neutrino pair is produced in the two-body decay of the W boson. This relation depends on the polarization of the W bosons, which is well understood in top quark decays in the SM [34–36], and can therefore be reliably accounted for. In dilepton tt events, the values of p_T(\ell\ell) and the transverse momentum of the dineutrino system (p_T(\nu\nu)) are approximately uncorrelated on an event-by-event basis. We thus use the observed p_T(\ell\ell) distribution to model the p_T(\nu\nu) distribution, which is identified with E_{T}\text{miss}. Thus, we predict the background in a signal region S defined by requirements on E_{T}\text{miss} and H_T using the yield in a region S’ defined by replacing the E_{T}\text{miss} requirement by the same requirement on p_T(\ell\ell).

To suppress the DY contamination to the region S’, we increase the E_{T}\text{miss} requirement to E_{T}\text{miss} > 75 GeV for SF events and subtract off the small residual DY contribution using the R_{out/in} technique [14] based on control samples in data. This technique derives, from the observed DY yield in the Z mass region, the expected yield in the complementary region using the ratio R_{out/in} extracted from MC simulation. Two corrections are applied to the resulting prediction, following the same procedure as in Ref. [2]. The first correction accounts for the fact that we apply minimum requirements to E_{T}\text{miss} in the preselection but there is no corresponding requirement on p_T(\ell\ell). Since the E_{T}\text{miss} and p_T(\ell\ell) are approximately uncorrelated in individual dilepton tt events, the application of the E_{T}\text{miss} requirement decreases the normalization of the p_T(\ell\ell) spectrum without significantly altering the shape. Hence, we apply correction factors K, which are extracted from data as K = 1.6 ± 0.1, 1.6 ± 0.4, 1.6 ± 0.4, and 1.9 ± 0.1 for the high-E_{T}\text{miss}, high-H_T, tight, and low-H_T signal regions, respectively. The uncertainty in K is dominated by the statistical component. The second correction factor K_C accounts for the W polarization in tt events, as well as detector effects such as hadronic energy scale; this correction is extracted from MC and is K_C = 1.6 ± 0.5, 1.4 ± 0.2, 1.7 ± 0.4, and 1.0 ± 0.4 for the four respective regions. The uncertainty in K_C is dominated by MC sample statistics and by the 7.5% uncertainty in the hadronic energy scale in this analysis.

Backgrounds from DY are estimated from data with the R_{out/in} technique, which leads to an estimated DY contribution consistent with zero. Backgrounds from processes with two vector bosons as well as electroweak single top quark production are negligible compared with those from dilepton tt decays.

Backgrounds in which one or both leptons do not originate from electroweak decays (misidentified leptons) are assessed using
the “tight-to-loose” (TL) ratio ($R_{TL}$) method of Ref. [14]. A misidentified lepton is a lepton candidate originating from within a jet, such as a lepton from semi-leptonic $b$ or $c$ decays, a muon from a pion or kaon decay-in-flight, a pion misidentified as an electron, or an unidentified photon conversion. The results of the tight-to-loose ratio method confirm the MC expectation that the misidentified lepton contribution is small compared to the dominant backgrounds. Estimates of the contributions to the signal region from QCD multijet events, with two misidentified leptons, and in $W +$ jets, with one misidentified lepton in addition to the lepton from the decay of the $W$, are derived separately. The contributions are found to be less than \( \sim 10\% \) of the total background in the signal regions, which is comparable to the contribution to the signal in the control regions used to estimate the background from the $p_T(\ell\ell)$ method. We therefore assign an additional systematic uncertainty of $10\%$ on the background prediction from the $p_T(\ell\ell)$ method due to misidentified leptons.

As a validation of the $p_T(\ell\ell)$ method in a region that is dominated by background, the $p_T(\ell\ell)$ method is also applied in a control region by restricting $H_T$ to be in the range $125–300$ GeV. Here the predicted background yield is $95 \pm 16$ (stat) $\pm 40$ (syst) events with $E_T^{miss} > 200$ GeV, including the systematic uncertainties in the correction factors $K$ and $K_C$, and the observed yield is 59 events.

The data are displayed in the plane of $E_T^{miss}$ vs. $H_T$ in Fig. 2. The predicted and observed $E_T^{miss}$ distributions are displayed in Fig. 3. A summary of these results is presented in Table 4. The SF and OF observed yields in the signal regions are quoted separately, since many SUSY models lead to enhanced production of SF lepton pairs. For all signal regions, the observed yield is consistent with the predictions from MC and from the background estimate based on data. No evidence for BSM contributions to the signal regions is observed in the light lepton channels.

5.2. Hadronic-\(\tau\) channels

In the hadronic-\(\tau\) channels the background has two components of similar importance, events with a genuine lepton pair from dilepton $t\bar{t}$ production and events from semi-leptonic $t\bar{b}$ and $W +$ jets production with a misidentified $\tau$. Backgrounds are estimated separately with techniques based on data control samples. Other very small contributions from $D$Y and diboson production with genuine lepton pairs (“MC irreducible”) are estimated from simulation.

The background with genuine lepton pairs is predicted by extending the $p_T(\ell\ell)$ method. To translate the background prediction in the $e\mu$, $e\mu$, and $\mu\mu$ channels into a prediction for the $e\tau_b$, $\mu\tau_b$, and $\tau\tau_b$ channels, a third correction factor is used. This correction, $K_T = 0.10 \pm 0.01$ for all signal regions, is estimated from simulation and accounts for the different lepton acceptance ($\sim 0.75$), branching fractions ($\sim 0.56$), and efficiencies ($\sim 0.24$) in hadronic-\(\tau\) channels. This procedure predicts the yield of the dilepton $t\bar{t}$ background with genuine hadronic $\tau$ decays.

The background with a reconstructed $\tau_b$ originating from a misidentified jet or a secondary decay is determined using a tight-to-loose ratio for $\tau_b$ candidates measured in a dijet dominated data sample, defined as $H_T > 200$ GeV and $E_T^{miss} < 20$ GeV. Tight candidates are defined as those that pass the full $H_T$ selection criteria. For the definition of loose candidates, the HPS isolation criterion is replaced by a looser requirement. The loose isolation requirement removes any $H_T$ dependence of the tight-to-loose ratio; thus the measurement can be extrapolated to the signal regions.

To determine the number of expected events including jets misidentified as $\tau_b$ candidates in the signal region, the identification requirements for one $\tau_b$ are loosened. The obtained yields are...
Table 4
Summary of results in the light lepton channels. The total SM MC expected yields (MC prediction), observed same-flavor (SF), opposite-flavor (OF), and total yields in the signal regions are indicated, as well as the predicted yields from the \( p_{T_1}(\ell\ell) \) estimate. The expected contributions from three benchmark SUSY scenarios are also quoted. The first uncertainty on the \( p_{T_1}(\ell\ell) \) method prediction is statistical and the second is systematic; the systematic uncertainty is discussed in the text. The non-SM yield upper limit (UL) is a 95% CL upper limit on the signal contribution.

multiplied by the probability \( P_{TL}(\tau_0, \eta) \) that a misidentified \( \tau_0 \) candidate passes the tight \( \tau_0 \) selection:

\[
P_{TL}(\tau_0, \eta) = \frac{R_{TL}(\tau_0, \eta)}{1 - R_{TL}(\tau_0, \eta)}
\]

A summation over \( P_{TL} \) evaluated for all \( \tau_0 \) candidates that pass the loose selection but not the tight selection gives the final background prediction in each signal region.

The method is validated in \( t\bar{t} \) simulation, where the agreement between the predicted and true yields is within 15%. We correct for a 5% bias observed in the simulation, and assign a 15% systematic uncertainty on the background prediction from the tight-to-loose ratio based on the agreement between prediction and observation in simulation and additional control samples in data.

The results in the four signal regions are summarized in Table 5. The low-\( H_T \) region includes only \( e\tau_0 \) and \( \mu\tau_0 \) channels, because the \( \tau_0\tau_0 \) trigger is inefficient in this region. In the high-\( E_{T}^{miss} \) region the \( \tau_0\tau_0 \) trigger is not fully efficient and an efficiency correction of 3% is applied to MC simulation. Good agreement between predicted and observed yields is observed. No evidence for BSM physics is observed in the hadronic-\( r \) channels.

The results of observed yields and predicted backgrounds in all signal regions for different lepton categories are summarized in Fig. 4.

6. Acceptance and efficiency systematic uncertainties

The acceptance and efficiency, as well as the systematic uncertainties in these quantities, depend on the process. For some of the

individual uncertainties, it is reasonable to quote values based on SM control samples with kinematic properties similar to the SUSY benchmark models. For others that depend strongly on the kinematic properties of the event, the systematic uncertainties must be quoted model-by-model.

The systematic uncertainty in the lepton acceptance consists of two parts: the trigger efficiency uncertainty, and the identification and isolation uncertainty. The trigger efficiency for two leptons of \(p_T > 10\) GeV, with one lepton of \(p_T > 20\) GeV is measured using samples of \(Z \rightarrow \ell\ell\), with an uncertainty of 2%. The simulated events reproduce the lepton identification and isolation efficiencies measured in data using samples of \(Z \rightarrow \ell\ell\) within 2% for \(p_T > 15\) GeV and within 7% (5%) for electrons (muons) in the range \(p_T = 10-15\) GeV. The uncertainty of the trigger efficiency (5%) of the \(\tau\) triggers is estimated with the tag-and-probe method [37]. The \(\tau\) identification efficiency uncertainty is estimated to be 6% from an independent study using a tag-and-probe technique on \(Z \rightarrow \tau\tau\) events. This is further validated by obtaining a \(Z \rightarrow \tau\tau\) enhanced region showing consistency between simulation and data. Another significant source of systematic uncertainty is associated with the jet and \(E_{\text{miss}}\) energy scale. The impact of this uncertainty is final-state dependent. Final states characterized by very large hadronic activity and \(E_{\text{miss}}\) are less sensitive than final states where the \(E_{\text{miss}}\) and \(H_T\) are typically close to the minimum requirements applied to these quantities. To be more quantitative, we have used the method of Ref. [14] to evaluate the systematic uncertainties in the acceptance for three benchmark SUSY points. The energies of jets in this analysis are known to within 7.5%; the correction accounting for the small difference between the hadronic energy scales in data and MC is not applied [38].

The uncertainty on the LM1 signal efficiency in the region \(H_T > 300\) GeV, \(E_{\text{miss}} > 150\) GeV used to search for the kinematic edge is 6%. The uncertainties for the four benchmark SUSY scenarios in the signal regions used for the counting experiments of Section 5 are displayed in Table 6. The uncertainty in the integrated luminosity is 2.2%.

7. Limits on new physics

7.1. Search for a kinematic edge

An upper limit on the signal yield is extracted from the fit to the dilepton mass distribution, assuming the triangular shape (\(\alpha = 1\)) of Eq. (2). The 95% CL upper limit is extracted using a hybrid frequentist–bayesian CLS method [39], including uncertainties in the background model, resolution model and \(Z\)-boson. We scan the position of the kinematic edge \(m_{\text{max}}\) and extract a signal yield upper limit for each value, as shown in Fig. 5. The extracted upper limits on \(n_S\) vary in the range 5–30 events; these upper limits do not depend strongly on the choice of signal shape parameter when using two different shapes specified by a concave (\(\alpha = 4\)) and convex curvature (hatched band).

Fig. 5. A CLS 95% CL upper limit on the signal yield \(n_S\) as a function of the endpoint in the invariant mass spectrum \(m_{\text{max}}\) assuming a triangular shaped signal (black dots and thick line). The hatched band shows the variation of the expected limit (thin line) assuming two alternate signal shapes, with the alternative expected limits corresponding to the boundary of the hatched band. The SUSY benchmark scenarios LM1, LM3 and LM6 are shown with their expected yields and theoretical positions of the corresponding kinematic dilepton mass edges. The LM1 (LM3) yield is scaled to 20% (40%) of its nominal yield. At LM3 and LM6 a three-body decay is present; thus the shape of the kinematic edge is only approximately triangular.

Table 7
Summary of results in the light lepton channels used for the CMSSM exclusion of Section 7. Details are the same as in Table 4 except that these results are divided into three non-overlapping regions defined by \(E_{\text{miss}} > 275\) GeV, \(H_T > 300-600\) GeV (SR1), \(E_{\text{miss}} > 275\) GeV, \(H_T > 600\) GeV (SR2, same as the “tight” signal region), and \(E_{\text{miss}} > 200-275\) GeV, \(H_T > 600\) GeV (SR3). The regions are further divided between same-flavor (SF) and opposite-flavor (OF) lepton pairs.

7.2. Search for an excess of events with large \(E_{\text{miss}}\) and \(H_T\)

In this section we use the results of the search for events with light leptons accompanied by large \(E_{\text{miss}}\) and \(H_T\) reported in Section 5 to exclude a region of the CMSSM parameter space. The exclusion is performed using multiple, exclusive signal regions based on the high-\(E_{\text{miss}}\), high-\(H_T\), and tight signal regions, divided into three non-overlapping regions in the \(E_{\text{miss}}\) vs. \(H_T\) plane. The results are further divided between the SF and OF final states in order to improve the sensitivity to models with correlated dilepton production leading to an excess of SF events, yielding a total of six signal bins, as summarized in Table 7. The use of multiple, disjoint signal regions improves the sensitivity of this analysis to a specific BSM scenario. The predicted backgrounds in the SF and OF final states are both equal to half of the total predicted background, because the \(t\) events produce equal SF and OF yields. The inputs to the upper limit calculation are the expected background yields and uncertainties from the \(p_T(\ell\ell)\) method, the expected signal yields and uncertainties from MC simulation, and the observed data yields in these six regions. The exclusion is performed with the CLS method. In the presence of a signal, the \(p_T(\ell\ell)\) background estimate increases due to signal events populating the control regions. To correct for this effect, for each point in the CMSSM parameter space this expected increase is subtracted from the signal yields in our search regions.
ple corresponding to an integrated luminosity of 4.98 fb$^{-1}$, the generator-level efficiencies are constant across the CMSSM plane, while the uncertainty from the hadronic energy scale is assessed separately at each CMSSM point taking into account the bin-to-bin migration of signal events. The variation in the observed and expected limits due to the theoretical uncertainties, including renormalization and factorization scale, parton density functions (PDFs), and the strong coupling strength $\alpha_s$ [42], are indicated in Fig. 6 as separate exclusion contours. These results significantly extend the sensitivity of our previous results [2]. The LEP-excluded regions are also indicated; these are based on searches for sleptons and charginos [43].

### 8. Additional information for model testing

Other models of new physics in the dilepton final state can be constrained in an approximate way by simple generator-level studies that compare the expected number of events in the data sample corresponding to an integrated luminosity of 4.98 fb$^{-1}$ with the upper limits from Section 7. The key ingredients of such studies are the kinematic requirements described in this Letter, the lepton efficiencies, and the detector response for $H_T$ and $E_T^{\text{miss}}$. The trigger efficiencies for events containing $e\mu$ or $\mu\mu$ lepton pairs are 100%, 95%, and 90%, respectively. For $eT_{\ell_1}$ and $\mu T_{\ell_1}$, the efficiency is $\sim$80% [37]. The trigger used for $T_{\ell_1}$ final states has an efficiency of 90%.

We evaluate the light lepton, hadronic-\tau, $E_T^{\text{miss}}$, and $H_T$ selection efficiencies using the LM6 benchmark model, but these efficiencies do not depend strongly on the choice of model. Jets at the generator-level are approximated as quarks or gluons produced prior to the parton showering step satisfying $p_T > 30$ GeV and $|\eta| < 3$. Generator-level leptons are required to satisfy $p_T > 10$ GeV and $|\eta| < 2.5$ and not to overlap with a generator-level jet within $\Delta R < 0.4$. For generator level $T_{\ell_1}$ the visible decay products are required to satisfy the tighter $p_T > 20$ GeV and $|\eta| < 2.1$ selection. The generator-level $E_T^{\text{miss}}$ is the absolute value of the vector sum of the transverse momenta of invisible particles, e.g., neutrinos and lightest supersymmetric particles. The lepton selection efficiencies as a function of generator-level $p_T$ are displayed in Fig. 7. The efficiency dependence can be parameterized as a function of $p_T$ as

$$f(p_T) = \epsilon_\infty \text{erf}(p_T - C)/\sigma + \epsilon_C [1 - \text{erf}(p_T - C)/\sigma],$$

where erf indicates the error function, $\epsilon_\infty$ gives the value of the efficiency plateau at high momenta, $C$ is equal to 10 GeV, $\epsilon_C$ gives the value of the efficiency at $p_T = C$, and $\sigma$ describes how fast the transition is. The parameterization is summarized in Table 8 for electrons, muons, and taus.

The $E_T^{\text{miss}}$ and $H_T$ selection efficiencies are displayed in Fig. 8 as a function of the generator-level quantities. These efficiencies are parameterized using the function:

$$f(x) = \frac{\epsilon_\infty}{2} \text{erf}(x)/\sigma + 1,$$

where $\epsilon_\infty$ gives the value of the efficiency plateau at high $x$, $C$ is the value of $x$ at which the efficiency is equal to 50%, and $\sigma$ describes how fast the transition is. The values of the fitted parameters are quoted in Table 9.

This efficiency model has been validated by comparing the yields from the full reconstruction with the expected yields using generator-level information only and the efficiencies quoted above. In addition to the LM1, LM3, LM6 and LM13 benchmarks considered throughout this Letter, we have tested several additional benchmarks (LM2, LM4, LM5, LM7, and LM8) [18]. In general we observe agreement between full reconstruction and the efficiency model within approximately 15%.

9. Summary

We have presented a search for physics beyond the standard model in the opposite-sign dilepton final state using a data sample of proton–proton collisions at a center-of-mass energy of 7 TeV. The data sample corresponds to an integrated luminosity of 4.98 fb$^{-1}$, and was collected with the CMS detector in 2011. Two complementary search strategies have been performed. The first focuses on models with a specific dilepton production mechanism leading to a characteristic kinematic edge in the dilepton mass distribution, and the second focuses on dilepton events accompanied by large missing transverse energy and significant hadronic activity. This work is motivated by many models of BSM physics, such as supersymmetric models or models with universal extra dimensions. In the absence of evidence for BSM physics, we set upper limits on the BSM contributions to yields in the signal regions. Additional information has been provided to allow testing whether specific models of new physics are excluded by these results. The presented result is the most stringent limit to date from the opposite-sign dilepton final state accompanied by large missing transverse energy and hadronic activity.
Acknowledgements

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC machine. We thank the technical and administrative staff at CERN and other CMS institutes, and acknowledge support from: FMSR (Austria); FNRS and FWO (Belgium); CNPq, CAPES, FAPERJ, and FAPESP (Brazil); MES (Bulgaria); CERN; CAS, MoST, and NSFC (China); COICLIENCIES (Colombia); MSES (Croatia); RPF (Cyprus); MoER, SF0690030s09 and ERDF (Estonia); Academy of Finland, MEC, and HIP (Finland); CEA and CNRS/IN2P3 (France); BMBF, DFG, and HGF (Germany); GSRT (Greece); OTKA and NKTH (Hungary); DAE and DST (India); IPN (Iran); SFI (Ireland); INFN (Italy); NRF and WCU (Korea); LAS (Lithuania); CINVESTAV, CONACYT, SEP, and UASLP-FAI (Mexico); MSI (New Zealand); PAEC (Pakistan); MSHE and NSC (Poland); FCT (Portugal); JINR (Armenia, Belarus, Georgia, Ukraine, Uzbekistan); MON, RosAtom, RAS and RFBR (Russia); MSTD (Serbia); MICINN and CSIC (Spain); Swiss Funding Agencies (Switzerland); NSC (Taipei); TUBITAK and TAEK (Turkey); STFC (United Kingdom); DOE and NSF (USA). Individuals have received support from the Marie-Curie programme and the European Research Council (European Union); the Leventis Foundation; the A.P. Sloan Foundation; the Alexander von Humboldt Foundation; the Belgian Science Policy (IWT-Belgium); the Netherlands Foundation for the Promotion of Research and Development in Science and Technology in the Industry and in the Agriculture (FRIA-Belgium); the Agentschap voor Innovatie door Wetenschap en Technologie (IWT-Belgium); the Council of Science and Industry Research, India; and the HOMING PLUS programme of Foundation for Polish Science, cofinanced from European Union, Regional Development Fund.
