A search is presented in proton–proton collisions at √s = 7 TeV for fermionic triplet states expected in type III seesaw models. The search is performed using final states with three isolated charged leptons and an imbalance in transverse momentum. The data, collected with the CMS detector at the LHC, correspond to an integrated luminosity of 4.9 fb\(^{-1}\). No excess of events is observed above the background predicted by the standard model, and the results are interpreted in terms of limits on production cross sections and masses of the heavy partners of the neutrinos in type III seesaw models. Depending on the considered scenarios, lower limits are obtained on the mass of the heavy partner of the neutrino that range from 180 to 210 GeV. These are the first limits on the production of type III seesaw fermionic triplet states reported by an experiment at the LHC.

1. Introduction

Experiments on neutrino oscillations [1–4] indicate that neutrinos have mass and their masses are much smaller than those of the charged leptons. However, the origin of neutrino mass is still unknown. An interesting possibility is provided by the seesaw mechanism, in which a small Majorana mass can be generated for each of the known neutrinos by introducing massive states with Yukawa couplings to leptons and to the Higgs field. Seesaw models called type I [5,6], type II [7–11], and type III [12,13] introduce heavy states of mass M, that involve, respectively, weak-isospin singlets, scalar triplets, and fermion triplets. The neutrino masses are generically reduced relative to charged fermion masses by a factor v/M, where v is the vacuum expectation value of the Higgs field. For sufficiently large M (of the order of 10\(^14\) GeV), small neutrino masses are generated even for Yukawa couplings of ≈1. On the other hand, either smaller Yukawa couplings or extended seesaw mechanisms, such as those of the inverse seesaw models [14], are required to obtain small neutrino masses while keeping M close to a few hundreds of GeV. At the Large Hadron Collider (LHC), type II and III states can be produced through gauge interactions, so that the possible smallness of the Yukawa couplings does not affect the production cross section of the heavy states. In particular, the possibility of discovering a type III fermion at a proton–proton centre-of-mass energy of √s = 14 TeV is discussed in Refs. [15–17]. Recently, a leading-order (LO) computation of the signal expected at √s = 7 TeV has become available as a computer program for simulating such final states [18].

Given the electric charges of the lepton triplet, hereafter referred to as Σ\(^+\), Σ\(^0\), and Σ\(^-\), the most promising signature for finding a Σ state with a mass M\(_{Σ}\) of the order of a few hundreds of GeV is in production through quark–antiquark annihilation q\(\bar{q}\) → Σ\(^0\)Σ\(^+\), followed by the decays Σ\(^0\) → ℓ\(^+\)W\(^\pm\) and Σ\(^+\) → W\(^+\)ν. The mass differences among the three electric charge states are assumed to be negligible. The mass range relevant for this analysis is bounded by the present lower limits (∼100 GeV) from the L3 experiment [19] and by the CMS loss of sensitivity near ∼200 GeV because of the very steep decrease of the expected cross section with mass. Since there are twice as many u as d valence quarks in the proton, the production of Σ\(^+\)Σ\(^0\) via virtual W\(^\pm\) bosons in the s-channel (Fig. 1) has the highest cross section of all the Σ charge combinations. (The cross section for the charge conjugate intermediary W\(^-\) is expected to be about a factor two smaller.) Selecting W\(^\pm\) → ℓ\(^\pm\)ν decays (where ℓ is an electron or muon) as the final states for the search, offers a very clean signature of three charged, isolated leptons. The decay Σ\(^+\) → ℓ\(^+\)Z, with Z → ν\(\bar{ν}\) or Z → q\(\bar{q}\), can also contribute significantly to the three-lepton final state, especially since its relative yield grows with M\(_{Σ}\). The τ lepton also contributes to the three-lepton final states through τ → ℓνν decay. Details of the phenomenology and the different contributions to the final state of interest can be found in Ref. [18].

The total width of the Σ states and their decay branching fractions to SM leptons depend on the mixing matrix element for the
leptons $V_{\alpha}$, where $\alpha$ labels each of the $e$, $\mu$, and $\tau$ generations of leptons. Constraints on the mixing parameters and their products are available in Refs. [18,20].

The $\Sigma \Sigma$ production cross section does not depend on the matrix elements $V_{\alpha}$, which enter only in the $\Sigma$ decays. The fraction of $\Sigma$ decays to the lepton $\alpha$ is proportional to:

$$b_{\alpha} = \frac{|V_{\alpha}|^2}{|V_{e}|^2 + |V_{\mu}|^2 + |V_{\tau}|^2}. \quad (1)$$

If all three $V_{\alpha}$ values are less than $\approx 10^{-6}$, the $\Sigma$ states can have sufficiently long lifetimes to produce leptons at secondary vertices, a possibility not considered in this analysis.

This Letter reports on a search for fermionic triplet states expected in type III seesaw models, in final states with three charged leptons and an imbalance in transverse momentum ($E_{\text{T}}^{\text{miss}}$). The data sample corresponds to an integrated luminosity of 4.9 fb$^{-1}$, collected in proton–proton collisions at $\sqrt{s} = 7$ TeV with the Compact Muon Solenoid (CMS) detector at the LHC in 2011. The analysis is based on the model described in Ref. [15], using the implementation of Ref. [18]. Three possibilities are considered for the ratios $b_{\alpha}$, defined in Eq. (1): first, $b_e = b_\mu = b_\tau = 1/3$, hereafter referred to as the flavor-democratic scenario (FDS), second, $b_\mu = 1$, $b_e = 0$, and $b_\tau = 0$, and third, $b_\mu = 1$ and $b_\tau = b_e = 0$, hereafter referred to as the muon scenario ($\mu S$) and the electron scenario (e$S$), respectively.

2. The CMS detector

A detailed description of the CMS detector can be found in Ref. [21]. The central feature of the CMS apparatus is a superconducting solenoid that provides an axial magnetic field of 3.8 T. A silicon tracker, a lead-tungstate crystal electromagnetic calorimeter (ECAL), and a brass/scintillator hadron calorimeter (HCAL) reside within the magnetic field volume. Muons are identified using the central tracker and a muon system consisting of gas-ionization detectors embedded in the steel return yoke outside of the solenoid.

The directions of particles in the CMS detector are described using the azimuthal angle $\phi$ and the pseudorapidity $\eta$, defined as $\eta = -\ln(\tan(\theta/2))$, where $\theta$ is the polar angle relative to the anticlockwise proton beam. All objects are reconstructed using a particle-flow (PF) algorithm [22–24]. The PF algorithm combines information from all subdetectors to identify and reconstruct particles detected in the collision, namely charged hadrons, photons, neutral hadrons, muons, and electrons. Jets are reconstructed using the anti-$k_T$ jet clustering algorithm with a distance parameter of 0.5 [25]. Jet energies are corrected for non-uniformity in calorimeter response and for differences found between jets in simulation and in data [26]. An imbalance in transverse momentum ($E_{\text{T}}^{\text{miss}}$) is defined by the magnitude of the vectorial sum of the transverse momenta ($p_T$) of all particles reconstructed through the PF algorithm.

3. Simulation of signal and background

To estimate signal efficiency, $\Sigma^+ \Sigma^0$ events are generated using the FeynRules and MadGraph computer programs described in Ref. [18], while parton showers and hadronization are implemented using the Pythia generator (v6.420) [27]. The detector simulation is based on the GEANT4 program [28]. Given the number of $M\Sigma$ mass points to be generated, part of the detector simulation is performed using the CMS Fast Simulation framework [29,30]. Several background sources are considered in this analysis, the most relevant one being WZ production with both bosons decaying into leptons. A smaller contribution to the background comes from ZZ production, where the $Z$ bosons decay leptonically, and one of the leptons is either outside of the detector acceptance or is mis-reconstructed. These two-boson events, calculated at next-to-LO with MCFM [31], are generated with Pythia. Backgrounds from the production of three EW bosons are generated with MadGraph 5 [32]. Backgrounds from jets and photons that are misidentified as leptons are also taken into account, including events from Drell–Yan $e^+e^-\gamma$ production, with $\gamma$ and $Z$ intermediaries representing virtual $\gamma$ or $Z$ bosons.

The presence of additional simultaneous pp interactions (pileup) is incorporated by simulating and mixing additional interactions with a multiplicity matching that observed in data.

4. Event selection criteria

The online trigger and the offline selection criteria are analogous to those used in other multi-lepton analyses performed by the CMS Collaboration [34,35]. Events are selected through two-lepton triggers in which two muons, two electrons, or one electron and one muon are required to be present. Because of the steady increase in instantaneous luminosity in 2011, some of the lepton $p_T$ thresholds were increased over time to keep the trigger rates within the capabilities of the data acquisition system. For the two-muon trigger, the $p_T$ requirements evolved from 7 GeV for each muon to asymmetric requirements of 17 GeV for the highest-$p_T$ (leading) muon and 8 GeV for the second-highest $p_T$ muon. For the two-electron trigger, the requirement is asymmetric, with a threshold applied to the energy of an ECAL cluster projected onto the plane transverse to the beam line ($E_T = E \sin \theta$). The cluster of the leading electron is required to have $E_T > 17$ GeV, and that of the next-to-leading electron to have $E_T > 8$ GeV. For the electron–muon trigger, the thresholds are either $E_T > 17$ GeV for the electron and $p_T > 8$ GeV for the muon, or $E_T > 8$ GeV for the electron and $p_T > 17$ GeV for the muon. The selected events must contain at least two lepton candidates with trajectories that have a transverse impact parameter of less than 0.2 mm relative to the principal interaction vertex. The chosen vertex is defined as the one with the largest value for the sum of the $p_T^2$ of the emanating tracks.

Muon candidates are reconstructed from a fit performed to hits in both the silicon tracker and the outer muon detectors, thereby defining a “global muon”. The specific selection requirements for a muon are: (i) $p_T > 10$ GeV, (ii) $|\eta| < 2.4$, (iii) more than 10 hits in the silicon tracker, and (iv) a global-muon fit with $\chi^2$/dof < 10, where dof is the number of degrees of freedom.
Electron candidates are reconstructed using clusters of energy depositions in the ECAL that match the extrapolation of a reconstructed track. The electron track is fitted using a Gaussian-sum filter [36], with the algorithm taking into account the emission of bremsstrahlung photons in the silicon tracker. The specific requirements for a reconstructed electron are: (i) $p_T > 10 \text{ GeV}$, (ii) $|\eta| < 1.44$, within the fully instrumented part of the central barrel, or $1.57 < |\eta| < 2.5$ for the endcap regions, (iii) not being a candidate for photon conversion, and (iv) the tracks reconstructed using three independent algorithms [23] to give the same sign for the electric charge.

All accepted lepton candidates are required to be isolated from other particles. In particular, selected muons must have $(\sum p_T)/p_T^\mu < 0.15$, where the sum over scalar $p_T$ includes all other PF objects within a cone of radius $\Delta R = \sqrt{(\Delta \eta)^2+(\Delta \phi)^2} = 0.3$ of the muon track, where $\Delta \eta$ and $\Delta \phi$ are the differences in pseudorapidity and azimuthal angle between the lepton axis and the positions of other particles. Similarly, an electron candidate is accepted if $(\sum p_T)/p_T^e < 0.20$ within a cone of $\Delta R = 0.3$.

The candidate events used for the search are required to have: (i) three isolated charged leptons originating from the same primary vertex, as defined above, (ii) sum of the lepton charges equal to $+1$, (iii) $E_{\text{miss}} > 30 \text{ GeV}$, (iv) $p_T > 18, 15, 10 \text{ GeV}$ for the lepton of highest, next-to-highest, and lowest $p_T$, and (v) $H_T < 100 \text{ GeV}$, where $H_T$ is the scalar sum of the transverse momenta of jets with $p_T > 30 \text{ GeV}$ and $|\eta| < 2.4$, which reduces the background from $t\bar{t}$ events.

The selected events are classified into six categories that depend on lepton flavour and electric charge: $\mu^-e^+e^+$, $\mu^-e^-\mu^+$, $\mu^+e^-\mu^+$, $e^-\mu^+\mu^+$, e$^-e^+e^+$, and e$^-e^-e^+$. Except for the first and fourth categories, such configurations can also result from $W^+Z$ events. Fig. 2 shows the distributions of the $\mu^-\mu^+$ invariant mass for $\mu^-e^+\mu^+$ and $\mu^-e^-\mu^+$ events in data, before applying any requirement on the $\mu^-\mu^+$ mass, compared to the sum of SM background contributions. A peak in the $\mu^+\mu^-$ effective mass close to that of the $Z$ boson is evident in both simulated events and in data. To reduce the background from $W^+Z$ events, a $Z$ veto is added to the selection requirements for the corresponding categories as follows. Events with at least one $E_T$ invariant mass combination in the range $82 < m_{E_T} < 102 \text{ GeV}$ are rejected. To reject lepton pairs from decays of heavy-flavour quarks, events with $m_{E_T} < 12 \text{ GeV}$ are also discarded.

Other sources of background in final states with three leptons arise from conversions of photons into additional $e^+e^-$ pairs through the process $Z \to e^+e^-\gamma \to e^+e^-\ell^+\ell^-\ell^-$. If one of these additional conversions carries most of the momentum of the photon, the final state can appear as a three-lepton event. In such cases, the invariant mass of the $\ell^+\ell^-\ell^-$ state peaks close to the mass of the $Z$ boson [34]. Since the probability of a photon conversion to electrons is higher than to muons, an additional $Z$ veto of $82 < m_{E_T} < 102 \text{ GeV}$ is applied to the $\mu^-e^+\mu^+$ and $e^-e^+e^+$ categories to reject such events. This is discussed further in the next section.

5. Background estimation

Three types of SM processes can produce a three-lepton final state: (i) events containing three or more prompt leptons from production and leptonic decays of two or three EW bosons. This is referred to as irreducible background, since it corresponds to the same final states as the signal from $Z$ production, (ii) $V + \gamma$ and $V + \gamma^*$ events, where $V$ represents any EW boson, with the accompanying photons converting to $\ell^+\ell^-$, and (iii) events with one or two prompt leptons and additional non-prompt leptons that arise from leptonic decays of hadrons within jets, called “misidentified jets”.

The irreducible background from more than two leptons is dominated by SM WZ production, but also includes ZZ and three-boson events. The two-boson contribution, which is reduced substantially by the $Z$ mass veto, and the three-boson contribution, which is dominated by the WWW channel, are both evaluated using MC simulation. The contribution from three-boson production is small relative to the other sources, as shown in Table 1.

As mentioned in Section 4, photon conversions in the presence of $W$ or $Z$ bosons can produce isolated leptons that constitute another source of background. External conversions of photons, namely of produced photons that interact with the material in the detector to yield primarily $e^-e^+$ pairs, are evaluated from simulation [24]. Internal conversions, involving the direct materialisation of virtual photons into $e^-e^+$ or $e^-e^+$ pairs, can also provide a similar source of background. Both external and internal conversions can become problematic when one of the two final-state leptons carries off most of the photon energy, and the second lepton is not detected. The contribution of conversions to electrons is reduced by the additional three-lepton-mass rejection applied to the $\mu^-e^+\mu^+$ and $e^-e^+e^+$ categories as discussed above. The
Table 1

Summary of the mean number of SM background events expected in each event category, after final selections. V represents a Z or a W bosons and Vγ is the contribution from external photon conversions. The column labelled “Misidentified jets” includes backgrounds with non-prompt leptons, the column γ∗ → μ+μ− shows background expectation from internal photon conversions, where a virtual photon converts to a muon pair, and one muon is lost. The contribution of γ∗ → e+e− is removed by the rejection criteria on three-lepton masses. Statistical uncertainties are included for the six categories, and systematic uncertainties on normalizations are listed in the last row.

6. Systematic uncertainties

Systematic uncertainties can be divided in two categories: those related to the extraction of the signal and those relevant to the sources of background. The first group includes efficiencies of trigger selections, particle reconstruction, and lepton identification. In the kinematic region defined by the analysis, the trigger efficiency for the signal is very high because it is based on a combination of three separate two-lepton triggers, each of which is found to be 92% to 100% efficient, and the estimated overall efficiency is (99 ± 1)%.

Uncertainties on lepton selection efficiencies are determined using a “tag-and-probe” method [37], both in data and through MC simulations, and the differences between these are taken as systematic uncertainties on the efficiencies. Additional contributions include uncertainties on the energy scales and on resolutions for leptons and for EmissT as well as uncertainties in the modeling of pileup, all of which are obtained from a full GEANT4 simulation. As mentioned in Section 3, GEANT4 simulation of the signal is restricted to a limited number of Mgg masses. In fact, the largest available value for this simulation is Mgg = 140 GeV. The efficiencies are therefore extrapolated to higher mass points using fast detector simulation. The difference between the efficiencies evaluated with the full and fast simulation at 140 GeV is taken as an additional contribution to the overall uncertainty. The largest difference is for the channel with three muons. Statistical uncertainties of the extrapolation are also taken into account. The uncertainties attributed to the expected signal efficiencies are summarized in Table 2 for Mgg = 180 GeV, and are expected not to differ significantly for higher mass points [18].

As mentioned above, the uncertainties on backgrounds are estimated using MC simulations or control samples in data. For the dominant irreducible background of WZ production, we apply a 17% uncertainty on the measured cross section [38]. Uncertainties of 7.5% for ZZ [39], and 13% for Vγ [40] cross sections are also taken into account. For very small backgrounds, such as WWW, we assume a normalization uncertainty of 50%.

Uncertainties on background estimates from methods based on data were discussed in Section 5, and those statistical and systematic uncertainties are summarized in Table 1.

The overall uncertainty on integrated luminosity is 2.2% [41]. For backgrounds determined from simulation, the systematic uncertainties on efficiency and luminosity are common to all signals.
Table 2

 uncertainties on signal efficiency for each event category for $M_\Sigma = 180$ GeV. Total systematic and total systematic + statistical (fourth and sixth columns) are calculated in quadrature.

7. Results

Table 3 presents the results of our search for the fermionic $\Sigma$ triplet states in terms of the expected number of signal events, the expected number of events from SM background, and the number of observed events in each of the analyzed event categories. Each of the three possibilities for mixing (FDS, $\mu S$, $e S$) described in Section 1 is considered in the analysis.

No significant excess of events is observed relative to the SM expectations in any of the six analysis channels. Combining all channels, we set upper limits at the 95% confidence level (CL) on $\sigma \times B$, on the product of the production cross section of $\Sigma^+ \Sigma^0$ and its branching fraction ($B$) to the three-lepton final states, where the lepton can be an electron, muon or $\tau$ (contributing through $\tau \to \ell \nu \ell \nu$). The branching fraction to three-lepton final states depends on $M_\Sigma$ [18], and is predicted to be about 9% for $M_\Sigma \approx 200$ GeV, where we extrapolate signal yields to $M_\Sigma > 180$ GeV using the results of Ref. [18].

The upper limits on $\sigma B$ as a function of fermion mass $M_\Sigma$, combining for all channels by multiplying the corresponding likelihood functions, are shown in Figs. 3, 4, and 5, for FDS, $\mu S$, and $e S$ possibilities, respectively. The dashed lines correspond to the expected limits obtained from MC pseudo-experiments, and are based on the CLs criterion [42,43]. The observed limits on data are computed following both a Bayesian approach [33, Ch. 33], and a frequentist method also based on the CLs criterion. In the former, the assumed prior is a constant. In both calculations, the uncertainties on efficiencies for detecting the signal, the uncertainty on integrated luminosity and on the expected SM background, are treated as uninteresting “nuisance” parameters with Gaussian or log-normal distributions. Upper limits are computed at 95% CL using the RooStats software [44], and the package developed to combine results from searches for the Higgs boson [45]. The two results are similar, as shown in Figs. 3, 4, and 5. The results are stable relative to variations of ±20% on the systematic uncertainties. Finally, we extract lower limits on $M_\Sigma$ using the theoretical dependence of the cross section on $M_\Sigma$, as represented by the solid blue lines of Fig. 3, 4, and 5, for the three possibilities for the type III seesaw model for signal. The expected and observed 95% CL limits obtained with the Bayesian method are given in Table 4.

Fig. 3. The expected (dashed line) and observed (asterisks and black points) exclusion limits at 95% confidence level on $\sigma B$ as a function of the fermion mass $M_\Sigma$, assuming $b_0 = b_y = b_z = 1/3$ (FDS) for the signal. The solid (blue) curve represents the predictions of the LO type III seesaw models. The light (yellow) and dark (green) shaded areas represent, respectively, the 1 standard deviation (68% CL) and 2 standard deviations (95% CL) limits on the expected results obtained from MC pseudo-experiments, which reflect the combined statistical and systematic uncertainties of the SM contributions. The asterisks and the black points show, respectively, the observed limits computed following a frequentist method based on the CLs criterion and a Bayesian approach.

The reported limits are valid only for short $\Sigma$ lifetimes, which hold for values of the matrix elements $V_{\alpha \tau}$ greater than $\approx 10^{-6}$. For smaller values, the analysis requires a different approach, since the leptons can originate from displaced vertices in an environment that, as indicated previously, is not considered in this analysis.

8. Summary

A search has been presented for fermionic triplet states expected in type III seesaw models. The search was performed in events with three isolated leptons (muons or electrons), whose charges sum to $+1$, and contain jets and an imbalance in transverse
momentum. The data are from proton–proton collisions at $\sqrt{s} = 7$ TeV, recorded during 2011 by the CMS experiment at the CERN LHC, and correspond to an integrated luminosity of 4.9 $fb^{-1}$.

No evidence for pair production of $\Sigma^+\Sigma^0$ states has been found, and 95% confidence upper limits are set on the product of the production cross section of $\Sigma^+\Sigma^0$ and its branching fraction to the examined three-lepton final states. Comparing the results with predictions from type III seesaw models, lower bounds are established at 95% confidence on the mass of the $\Sigma$ states. Limits are reported for three choices of mixing possibilities between the $\Sigma$ states and the three lepton generations. Depending on the considered scenarios, lower limits are obtained on the mass of the heavy partner of the neutrino which range from 180 to 210 GeV. The results are valid only if at least one of the mixing matrix elements is larger than $\approx 10^{-6}$. These are the first limits on the production of type III seesaw fermionic triplet states reported by an experiment at the LHC.

Acknowledgements

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC machine. We thank the technical and administrative staffs at CERN and other CMS institutes, and acknowledge support from BMWF and FWF (Austria); FNRS and FWO (Belgium); CNEP, APEPI, and INAF (Italy); INFN (Italy); CEA and CNRS/IN2P3 (France); BMBF, DFG, and HGF (Germany); GSRT (Greece); OTKA and NKTH (Hungary); DAE and DST (India); IPM (Iran); SFI (Ireland); INFN (Italy); NRF and WCU (Korea); LAS (Lithuania); CINVESTAV, CONACYT, SEP, and UASLP-FAI (Mexico); MSI (New Zealand); PAEC (Pakistan); MSHE and NSC (Poland); FCT (Portugal); JINR (Armenia, Belarus, Georgia, Ukraine, Uzbekistan); MON, RosAtom, RAS and RFBR (Russia); MSTD (Serbia); SEIDI and CPAN (Spain); Swiss Funding Agencies (Switzerland); NSC (Taipei); ThEPCP, IPST, and NECTEC (Thailand); TUBITAK and TAEK (Turkey); NASU (Ukraine); STFC (United Kingdom); DOE and NSF (USA). Individuals have received support from the Marie-Curie programme and the European Research Council (European Union); the Leventis Foundation; the A.P. Sloan Foundation; the Alexander von Humboldt Foundation; the Belgian Federal Science Policy Office; the Fonds voor Wetenschappelijk Onderzoek (Belgium); CNPq, CAPES, FAPERJ, and FAPESP (Brazil); MES (Bulgaria); CERN; CAS, MoST, and NSFC (China); COLCIENCIAS (Colombia); MSES (Croatia); RPF (Cyprus); MoER, SF0690030s09 and ERDF (Estonia); Academy of Finland, MEC, and HIP (Finland); CEA and CNRS/IN2P3 (France); BMBF, DFG, and HGF (Germany); GSRT (Greece); OTKA and NKTH (Hungary); DAE and DST (India); IPM (Iran); SFI (Ireland); INFN (Italy); NRF and WCU (Korea); LAS (Lithuania); CINVESTAV, CONACYT, SEP, and UASLP-FAI (Mexico); MSI (New Zealand); PAEC (Pakistan); MSHE and NSC (Poland); FCT (Portugal); JINR (Armenia, Belarus, Georgia, Ukraine, Uzbekistan); MON, RosAtom, RAS and RFBR (Russia); MSTD (Serbia); SEIDI and CPAN (Spain); Swiss Funding Agencies (Switzerland); NSC (Taipei); ThEPCP, IPST, and NECTEC (Thailand); TUBITAK and TAEK (Turkey); NASU (Ukraine); STFC (United Kingdom); DOE and NSF (USA). Individuals have received support from the Marie-Curie programme and the European Research Council (European Union); the Leventis Foundation; the A.P. Sloan Foundation; the Alexander von Humboldt Foundation; the Belgian Federal Science Policy Office; the Fonds voor Wetenschappelijk Onderzoek (Belgium); CNPq, CAPES, FAPERJ, and FAPESP (Brazil); MES (Bulgaria); CERN; CAS, MoST, and NSFC (China); COLCIENCIAS (Colombia); MSES (Croatia); RPF (Cyprus); MoER, SF0690030s09 and ERDF (Estonia); Academy of Finland, MEC, and HIP (Finland); CEA and CNRS/IN2P3 (France); BMBF, DFG, and HGF (Germany); GSRT (Greece); OTKA and NKTH (Hungary); DAE and DST (India); IPM (Iran); SFI (Ireland); INFN (Italy); NRF and WCU (Korea); LAS (Lithuania); CINVESTAV, CONACYT, SEP, and UASLP-FAI (Mexico); MSI (New Zealand); PAEC (Pakistan); MSHE and NSC (Poland); FCT (Portugal); JINR (Armenia, Belarus, Georgia, Ukraine, Uzbekistan); MON, RosAtom, RAS and RFBR (Russia); MSTD (Serbia); SEIDI and CPAN (Spain); Swiss Funding Agencies (Switzerland); NSC (Taipei); ThEPCP, IPST, and NECTEC (Thailand); TUBITAK and TAEK (Turkey); NASU (Ukraine); STFC (United Kingdom); DOE and NSF (USA). Individuals have received support from the Marie-Curie programme and the European Research Council (European Union); the Leventis Foundation; the A.P. Sloan Foundation; the Alexander von Humboldt Foundation; the Belgian Federal Science Policy Office; the Fonds pour la Formation à la Recherche dans l’Industrie et dans l’Agriculture (FRIA-Belgium); the Agentschap voor Innovatie door Wetenschap en Technologie (IWT-Belgium); the Ministry of Education, Youth and Sports (MEYS) of Czech Republic; the Council of Science and Industrial Research, India; the Compagnia di San Paolo (Torino); and the HOMING PLUS programme of Foundation for Polish Science, cofinanced from European Union, Regional Development Fund.
