ABSTRACT Mechanical characteristics of single biological cells are used to identify and possibly leverage interesting differences among cells or cell populations. Fluidity—hysteresivity normalized to the extremes of an elastic solid or a viscous liquid—can be extracted from, and compared among, multiple rheological measurements of cells: creep compliance versus time, complex modulus versus frequency, and phase lag versus frequency. With multiple strategies available for acquisition of this nondimensional property, fluidity may serve as a useful and robust parameter for distinguishing cell populations, and for understanding the physical origins of deformability in soft matter. Here, for three disparate eukaryotic cell types deformed in the suspended state via optical stretching, we examine the dependence of fluidity on chemical and environmental influences at a timescale of ~1 s. We find that fluidity estimates are consistent in the time and frequency domains under a structural damping (power-law or fractional-derivative) model, but not under an equivalent-complexity, lumped-component (spring-dashpot) model; the latter predicts spurious time constants. Although fluidity is suppressed by chemical cross-linking, we find that ATP depletion in the cell does not measurably alter the parameter, and we thus conclude that active ATP-driven events are not a crucial enabler of fluidity during linear viscoelastic deformation of a suspended cell. Finally, by using the capacity of optical stretching to produce near-instantaneous increases in cell temperature, we establish that fluidity increases with temperature—now measured in a fully suspended, sortable cell without the complicating factor of cell-substratum adhesion.

INTRODUCTION

Biological tissue cells are arguably the preeminent mechanical material to be understood—not other material is so complex and yet so intimate to our existence. The capacity to parameterize the mechanical response of such cells to applied loads informs our understanding and modeling of structurally dynamic, contractile polymer networks. Further, a distinct mechanical signature can potentially enable the sorting of useful or diseased cells from mixed populations. To this end, researchers have quantified the rheology (deformation and flow characteristics) of single animete cells (1–4) and of inanimate soft condensed matter comprising cytoskeletal and motor proteins (5). Such studies have included analysis of both internal (6–8) and cortical (9–13) deformability of attached and contractile cells. Others have also explored chemical modulation of metabolism and cytoskeletal rearrangements (14,15) to elucidate molecular origins of single-cell stiffness and contraction. Although fewer studies have considered the rheology of cells in the nominally detached or fluid-suspended state (16–18), this state is more relevant to practical applications of cell biophysics to technology and medicine. For example, identification and isolation of valuable cells from mixed populations (e.g., circulating tumor cells or stem cells) may rely wholly or in part on mechanical signatures of cells dispersed in solution (19–23). Given the potential for comparatively higher throughput analysis of such cells in the suspended state, it is reasonable to expect that biophysical characterization of whole suspended cells will continue to inform diagnostic assays (19), injections of cells for targeted delivery (24), and basic understanding of tissue cells that lack cytoskeletal stress fibers when located within highly compliant, three-dimensional tissues or synthetic constructs (25–27).

To evaluate biophysical models or to compare cells (or cell populations) quantitatively, mechanical behavior is often parameterized by the complex modulus, which reports both the stiffness and viscoelastic damping or hysteresivity. Here, we focus on a single parameter—fluidity, \( f \), or normalized hysteresivity—that is related to the position of the cell in a solid-liquid continuum of soft matter. (It is possible to calculate this parameter from, for example, the phase lag of sinusoidal deformation caused by sinusoidal loading in the linear regime. One can consider this phase lag to be bounded by zero (corresponding to an elastic solid) and \( \pi/2 \) radians or one quarter period (corresponding to a viscous liquid); normalizing to these extremes produces a fluidity value (28–30) that measures the tendency of the cell to flow (versus stretch and rebound) in response to a mechanical load.) As in this study we seek to identify potential differences among single-cell mechanical parameters (as a function of cell type and chemical and physical environment), the lengthscale of interest in extracting and discussing fluidity is the whole cell, whereas the relevant timescale is ~1 s. At such a timescale, the cell is considered a viscoelastic material that is also a spatially heterogeneous composite comprising an actin cortex, cytoplasm, nucleus, and numerous organelles (3,31). We note that at
this timescale and related frequency, high-throughput sorting of individual cells is plausible. However, it is known that other timescales exhibit distinct features; specifically, at much higher frequencies, the contribution of water viscosity predominates (1,32), whereas at much longer times, cytoskeletal rearrangements and remodeling in response to loads become measurable (33).

It is important to note that the parameter referred to here as fluidity is independent of models used to interpret and predict cell deformation. However, fluidity measurements can be used to evaluate models of soft matter that are applied to whole-cell deformation around our timescale of interest. For example, deformation behavior has often been modeled with an assembly of several springs and dashpots (34–40). Here, models predict time constants (35,36) near 1 s, corresponding presumably to cytoskeletal biophysical mechanisms, at which relatively large changes in fluidity are mathematically predicted. Alternatively, others have used a structural damping or fractional derivative model in which creep compliance versus time, complex modulus versus frequency, and stress relaxation versus time all appear as power laws (1,12,16,41–44). Here, fluidity—equivalent to the power-law exponent—is viewed as frequency-independent (2,10) at timescales near 1 s. Even within the neighborhood of our timescale of interest, therefore, the question remains as to which model is best suited to parameterize whole cells accurately; especially considering the smaller number of studies of cells in the suspended state, there is also uncertainty regarding whether contractile stress fibers are needed for the cell to manifest power-law rheology (45).

We investigate and quantify the fluidity of the suspended cell via optical stretching, a technique requiring no cell-probe or cell-substratum contact. In optical stretching, dual counterpropagating laser beams attract and center a single suspended cell, which deforms by outward photon-induced stress caused primarily by the change in refractive index at the cell edge (Fig. 1) (46,47). The cell response is typically characterized by its deformation along the laser axis as a function of time. This approach enables us to elucidate how suspended cells deform by removing the influence of stress fibers and adhesion sites, by probing cells in both the time and frequency domains, and by testing cells exposed to chemical and physical perturbation. We consider three distinct, model cell types: 1), the adult human bone-marrow-derived mesenchymal stem or stromal cell (hMSC), which undergoes the attached-to-suspended transition repeatedly during passaging, most notably at the last detachment immediately before reimplantation for therapeutic purposes; 2), the transformed—or immortalized—murine fibroblast (3T3), which is relatively easy to culture due to rapid proliferation and is commonly used as a model cell in rheology studies (12,13,44); and 3), the transformed and nonadherent murine lymphoma cell (CH27), which exhibits no substratum attachment response and thus does not exhibit contractile stress fibers before optical stretching.

FIGURE 1 Optical stretching measures the stiffness of cells in the suspended state, absent physical contact, and absent the direct influence of substratum chemomechanical properties. (a) Scanning electron micrograph of opposing optical fibers positioned to direct laser emission toward a hollow glass capillary filled with cell suspension. (During operation, fibers are surrounded by index-matching gel and positioned ~100 μm away from the capillary wall.) (Inset) Edge detection applied to a phase-contrast image to quantify cell deformation upon photonic loading; scale bar, 10 μm. (b) From one eukaryotic cell type (CH27 lymphoma, n = 121 cells), thin solid lines show deformation and creep compliance, J(t), for single cells in response to a step increase in laser power from time t = 0–4 s. The thick solid line shows the geometric mean, well fit during stretching by the relationship J(t) = J₀tᵃ, where a is a measure of cell fluidity. Dotted lines contrast the behaviors of perfectly elastic (a = 0) and viscous (a = 1) materials in creep compliance stretching and recovery (vertical positioning of these lines is arbitrary). (c) Oscillatory deformation (minus baseline; see Fig. S1) of a single cell in response to sinusoidal loading with angular frequency ω. (Inset) Symmetric and elliptical Lissajous figure indicates linear viscoelasticity. The viscoelastic phase lag, φ, of the cell in radians is also a measure of cell fluidity as a = 2π/φ; thus, fluidity can be estimated through experiments in both the time and frequency domains. To see this figure in color, go online.
Testing in both the time and frequency domains allows estimation of the fluidity by three methods—the slope of the creep compliance response versus time on a log-log scale, the phase lag under an oscillatory load, and the slope of the complex modulus response versus frequency on a log-log scale—to reduce the role of chance and experimental artifacts when testing the predictions of various viscoelastic models. We find that fluidity is frequency-independent for multiple cell types and also upon depletion of ATP and, further, that fluidity increases as a function of cell temperature. Consideration of this nondimensional rheological characteristic of single cells thus offers the possibility of rapid measurements and new predictions relevant to mechanisms of single-cell deformation; obtaining this parameter in the suspended state further adds to our understanding relevant to physical sorting and delivery of suspended cells.

MATERIALS AND METHODS

Cell culture

Primary adult human mesenchymal stem cells (hMSCs) were isolated from the bone marrow of four adult donors via Stem Cell Technologies (Vancouver, BC, Canada), ReachBio (Seattle, WA), or Lonza Group (Basel, Switzerland). Cells were cultured in proprietary media (basal with 10% supplements; 5401 and 5402, Stem Cell Technologies), and used between passages 1 and 9, as described previously (17). Transformed murine NIH 3T3 fibroblasts were obtained from American Type Culture Collection (CRL-1658) and cultured in Dulbecco’s modified Eagle’s medium (DMEM) (11885, Gibco, Langley, OK) with 10% fetal bovine serum (S11550, Atlanta Biologicals, Flowery Branch, GA). Immortalized murine CH27 lymphoma cells (48) were obtained courtesy of D. J. Irvine (Massachusetts Institute of Technology, Cambridge, MA) and cultured in Roswell Park Memorial Institute medium (RPMI) (11875, Gibco) with 10% fetal bovine serum (S11550, Atlanta Biologicals).

Chemical fixation was accomplished by incubating suspended cells at a concentration of ~100,000 cells mL⁻¹ in a 25% glutaraldehyde-water solution diluted in phosphate-buffered saline (PBS) complete media for 10 min at 37°C. The suspensions were then diluted 50×, centrifuged, and resuspended in PBS for optical stretching.

ATP was depleted by exposing 3T3 fibroblasts to the standard cocktail of ATP (i.e., 1 W peak to peak/fiber) unless otherwise specified, with a 1 s trapping period at 1 W/fiber before and after exposure (Fig. 1 c). For oscillation frequencies of ≥10 Hz, a load amplitude of 1 W/fiber was used. Images were recorded at 10–50 frames s⁻¹. Amplitudes and phase angles were extracted from deformation signals by subtracting a moving average across one or more periods and fitting the expression F sin(ωt − t₀ − θ) by nonlinear regression (Mathematica, Wolfram Research, Oxfordshire, United Kingdom), where F is the deformation amplitude, ω is the applied angular frequency, t₀ is the measured lag of the tool (collection, processing, and transmission time of laser data and image frames, see Supporting Material) and θ is the phase angle. (Alternatively, fluidity and amplitude can be estimated by fitting the deformation to a quadratic function plus a sinusoid, with similar results (see Fig. S1.) The signal/noise ratio was calculated by dividing the root mean-square magnitude of the fitted sinusoid by the root mean-square magnitude of the flattened deformation with the signal subtracted. During fixation experiments, 16% of the chemically cross-linked cells exhibited signal/noise ratios of <1 or unphysical values of fluidity of a < 0 or a > 1; these cells were excluded from further analysis.

Microfluidic optical stretching and data analysis

Optical stretching and subsequent data analysis in the time domain were conducted generally as described previously (17,47,49), with differences noted here. Briefly, adherent cells were detached by trypsinization, centrifuged, and resuspended in complete media (these steps were omitted for the nonadherent CH27 cells), serially injected into a hollow glass capillary positioned between two optical fibers (Fig. 1 a), and exposed to two 0.2 W counterpropagating 1064 nm laser beams to center each cell and allow it to rotate into an equilibrium orientation before stretching. Deformation was characterized by the edge-to-edge distance, along the laser axis, of a phase-contrast image of the cell, normalized to the distance measured during the 0.2 W trapping period (Fig. 1 a, inset). In the study presented here, this deformation was ~1% of the cell diameter.

In time-domain experiments, stretching power (0.9 W/fiber, unless otherwise specified, for 4 s) and trapping power (0.2 W/fiber for 2 s) were applied to stretch the cell and allow recovery, respectively (Fig. 1 b). Simultaneously, cell images were recorded by phase contrast microscopy at 15–20 frames s⁻¹. The photonic surface stress on a cell at the center of the beam, used to determine nominal creep compliance and complex modulus, was calculated via previously published models (47) to equal ~0.3 Pa/W laser power/fiber (see Supporting Material) for the two optical stretching chambers used in this study.

In frequency-domain experiments, cells were exposed to a sinusoidal laser profile for 8 s, with a mean power of 1 W/fiber and a load amplitude of 0.5 W/fiber (i.e., 1 W peak to peak/fiber) unless otherwise specified, with a 1 s trapping period at 1 W/fiber before and after exposure (Fig. 1 c). For oscillation frequencies of ≥10 Hz, a load amplitude of 1 W/fiber was used. Images were recorded at 10–50 frames s⁻¹. Amplitudes and phase angles were extracted from deformation signals by subtracting a moving average across one or more periods and fitting the expression F sin(ωt − t₀ − θ) by nonlinear regression (Mathematica, Wolfram Research, Oxfordshire, United Kingdom), where F is the deformation amplitude, ω is the applied angular frequency, t₀ is the measured lag of the tool (collection, processing, and transmission time of laser data and image frames, see Supporting Material) and θ is the phase angle. (Alternatively, fluidity and amplitude can be estimated by fitting the deformation to a quadratic function plus a sinusoid, with similar results (see Fig. S1.) The signal/noise ratio was calculated by dividing the root mean-square magnitude of the fitted sinusoid by the root mean-square magnitude of the flattened deformation with the signal subtracted. During fixation experiments, 16% of the chemically cross-linked cells exhibited signal/noise ratios of <1 or unphysical values of fluidity of a < 0 or a > 1; these cells were excluded from further analysis.

The differences between structural-damping and lumped-component viscoelastic models are summarized in the Supporting Material. In this work, optical stretching data were fitted to constitutive models of both types. The structural-damping model in creep compliance took the form of A(t/t₀)² (with reference time t₀ = 1 s), with different values of A and a used in stretching and recovery, yielding four parameters to fit. (Recovery was quantified as time-dependent contraction relative to the time and deformation at the end of the stretching period.) In this model, the phase lag is frequency-independent, ϕ = πa/2. The lumped-component models contained four parameters, to offer equal complexity, and these were assigned to the two springs (E₁ and E₂) and two dashpots (η₁ and η₂) of a standard linear solid, which consists of a series spring-dashpot pair (E₁, η₁) in series with a parallel spring-dashpot pair (E₂, η₂). This model is most easily described by its deformation-versus-load-transfer function,

\[ D(s) = \frac{1}{E₁} + \frac{1}{s(\eta₁)} + \frac{1}{(E₂ + s\eta₂)}. \]

The phase lag is \( \phi(\omega) = \frac{\tan^{-1}\text{Im}[D(\omega)]}{\text{Re}[D(\omega)]} \).

Optical stretcher operation provides cell diameter via video image capture and analysis in the course of conducting an experiment. Cell diameter was found to be log-normally distributed with a geometric mean of 23 μm for the hMSCs and 18 μm for both the 3T3s and CH27s and a geometric standard deviation of ~1.1–1.2 for each cell type (Fig. S2); a geometric standard deviation of 1 would correspond to a single uniform cell diameter. The error (standard deviation) in repeated measurements of single cells was found to be 0.1 μm. Error bars in all figures represent the mean ± SE unless otherwise noted.
Temperature characterization and control during optical stretching

In optical stretching, laser beam absorption increases the temperature of the surrounding medium and trapped object (here, the cell); this temperature increase has previously been approximated as a constant value (50–52). Here, we revise that estimate by developing a thermal model of time-dependent laser-induced heating (Fig. S3), deriving a constitutive relationship that follows an approximate ln(t) form: \( T(t) = T_0 + C_1 \ln(1 + C_2 t) \), where \( C_1 \) and \( C_2 \) are constants representing the geometry and thermal characteristics of the system.

During external heating experiments, optical stretcher chamber temperature was controlled with two 10 cm \( \times 7 \) W cm\(^{-2} \) strip resistance heaters that were clamped to the microscope stage. Cells were stored in a rotating syringe at room temperature (17) and were not exposed to elevated temperatures until they were injected into the capillary several seconds before stretching. A moving average was applied to external heating data to clarify that cell deformation behavior could not be described accurately with more elements; power-law rheology is equivalent to an infinite number of spring-dashpot assemblies with a power-law distribution of fluidity, in agreement with previous studies of attached cells (2,12,54). The fluidity of the primary hMSCs was independent of the number of population doublings since explantation and isolation (see Fig. S5).

RESULTS AND DISCUSSION

Structural damping/power-law rheology behavior is consistent across time and frequency domains, in contrast to spring-dashpot parameterization of equivalent complexity

We conducted creep compliance (time-domain) analysis by applying unit-step laser-induced photonic stresses on single whole cells from three eukaryotic cell populations: hMSCs, murine fibroblasts (3T3 FBs), and CH-27 cells ((Fig. 2, a, d, and g)), which constitute a selection of adherent and nonadherent and primary and transformed cell populations. The hMSCs are primary and adherent; the 3T3 fibroblasts are transformed and adherent; and the CH27 are transformed and nonadherent under typical in vitro culture conditions. The full stretching and recovery periods generally resembled those shown in Fig. 1b; in Fig. 2, a, d, and g, we show the recovery as a contraction relative to the time and deformation at the end of the stretching period.

The appearance of the stretching and recovery data on a log-log scale of creep compliance \( J(t) \) versus time suggests a power-law fit \( J(t) \propto t^\alpha \) with different exponents (i.e., different fluidity values) for the stretching and recovery periods, where \( \alpha = 0.4 \) and 0.2, respectively. For comparison with a lumped-component model of equal complexity, we also fit a four-parameter standard linear solid to the creep compliance data for each cell type (Fig. S4). Both models predict certain behavior in the frequency domain (e.g., the appearance, or lack thereof, of phase lag transitions at characteristic frequencies) that can then be compared to actual behavior in that domain.

To enable this comparison, we measured rheological parameters (stiffness and fluidity) in the frequency domain by applying sinusoidal photonic loads and recording the amplitude and phase lag of the sinusoidal portion of the resulting deformation (Fig. 1c). Shown in Fig. 2, b, e, and h, are the average fluidity measurements; histograms of these values are shown in Fig. 2, c, f, and i. (We observed an approximate Gaussian distribution of fluidity, in agreement with previous studies of attached cells (2,12,54). The fluidity of the primary hMSCs was independent of the number of population doublings since explantation and isolation (see Fig. S5).

Lumped-component models predicted time constants of \( \sim 0.1–3 \) s (Fig. S4) (the viscosity-stiffness ratios of the spring-dashpot pairs, corresponding to characteristic frequencies of 0.06–1.6 Hz), where one would expect fluidity to be altered strongly by changing frequency; however, these transitions were not observed (Fig. 2, b, e, and h). We also did not see convincing evidence of a transition between multiple power laws (4,31) over the frequency range of interest here, nor did we detect the onset of poroelastic, or decoupled solid-liquid, behavior that is expected to dominate at higher frequencies (1,32). Rather, fluidity was independent of frequency, within error, over two decades centered around 1 Hz, and furthermore, the magnitudes were in good agreement with those estimated by using the stretching portions of the creep compliance curves. The structural damping, or power-law, model was thus found to be viscoelastically consistent in the sense that predictions generated from the time domain were validated by measurements in the frequency domain. A lumped-component model of equal complexity consisting of springs and dashpots did not share this consistency and therefore appeared to be not only a poorer fit but also misleading at the time-scale investigated here. (Our findings do not imply, however, that cell deformation behavior could not be described accurately with more elements; power-law rheology is equivalent to an infinite number of spring-dashpot assemblies with a power-law distribution of relaxation times (2). Nevertheless, the principle of model parsimony argues against arbitrarily large collections of lumped components (1,41,55).)

We also acquired additional estimates of fluidity within the structural damping framework by fitting the complex modulus magnitude, \( |G'(\omega)| \propto \omega^\alpha \). These estimates, shown in Fig. S6 and tabulated in Table S1, agreed with our other estimates. Taken as a whole, the results reinforce our earlier conclusion (17) that the stress fibers often observed in the attached state are not a necessity for manifestation of structural-damping or power-law rheological behavior. In summary, we reject a lumped-component parameterization of several springs and dashpots due not only to poor
performance by fitting metrics (17) (see also Rocha-Cusachs et al. (16), Hemmer et al. (43), and Zhou et al. (44)) but also to inconsistency between predictions in the time and frequency domains. That fundamental inconsistency, under the reasoning that extracted time constants simply reflect the experiment duration, has itself been predicted (41), but to our knowledge, has not been previously demonstrated.

Fluidity modulated by applied load

To determine the sensitivity of fluidity values against changes in applied photonic load, we stretched cells in the frequency domain (1 Hz) with multiple mean and amplitude laser power values. We observed fluidity values to increase with increasing mean laser power (Fig. 3 a). In addition, a sufficiently large load amplitude caused fluidity to deviate detectably from a constant small-load-amplitude value (Fig. 3 b); a possible origin for this decrease is discussed in the Supporting Material. Smaller-load amplitudes, in contrast, were correlated with a relatively small signal/noise ratio, such that it was difficult to discern signals arising from load amplitudes of $<0.2$ W/fiber, at least for the 1 Hz, 8 s stretching settings employed here. We thus selected a sinusoidal amplitude of 0.5 W/fiber (overlaid on a constant power of 1 W/fiber) to evaluate the influence of chemicals on cell fluidity, as discussed in the next section. This condition provided a suitable range of load amplitudes that produced sufficiently high signal/noise ratios from
deformation signals while minimally altering the extracted magnitudes of fluidity. Note that for all load amplitudes employed, Lissajous figures of load versus deformation remained generally elliptical and symmetric. In our observations, all whole-cell deformations (with magnitudes of up to 2% and deformation rates of up to 20% s⁻¹) remained in the linear viscoelastic regime (for comparison, see reports of mechanical nonlinearity for eukaryotic or red blood cells under other loading conditions (56–58)).

Impact on fluidity of chemical fixation and ATP depletion

We investigated chemical perturbation of fluidity with two approaches: glutaraldehyde fixation, which covalently cross-links the cytoskeleton and kills the cell in the process; and ATP depletion, which generally slows metabolic processes and blocks actomyosin contraction to possibly alter whole-cell deformation. We extracted fluidity values from frequency-domain (phase-lag) measurements of CH27 cells exposed to various glutaraldehyde concentrations for 10 min at 37°C. Fig. 4 a illustrates a dose-dependent reduction in fluidity, a, from 0.35 to 0.18 with cross-linking extent. (Note that increased incubation time did not detectably reduce fluidity further: a = 0.17 ± 0.02 for 30 min vs. a = 0.18 ± 0.01 for 10 min.)

Experiments at 0.1 Hz and 10 Hz showed that the reduction of fluidity occurred evenly across this frequency range. Insensitivity of cell size to glutaraldehyde treatment excluded volumetric changes as an origin for fluidity alteration. The gradual transition over at least three decades of fixative concentration represents a decrease in the rate of cytoskeletal rearrangement processes, as transient

deposited

FIGURE 3 Effects of thermomechanical loading on suspended-cell fluidity. (a) In frequency-domain optical stretcher experiments, fluidity increases with mean incident laser power (n = 40–324 cells/power setting). (b, Upper) At a mean power of 1 W/fiber, the estimated mean cell fluidity is minimally dependent on load at sufficiently low load amplitudes (n = 10–165 cells/power setting). (Lower) Increase in signal/noise ratio to >10 for a load amplitude of 0.3 W/fiber and above suggests a window for obtaining relatively low-noise data without drastically changing the parameter of interest through loading. Arrows show the 0.5 W amplitude setting used for chemical-fixation and ATP-depletion investigations. (Insets) Symmetric and elliptical Lissajous figures show that cells do not exhibit noticeably nonlinear effects, such as strain stiffening or softening, at the settings used. To see this figure in color, go online.

FIGURE 4 Suspended-cell fluidity is reduced by chemical fixation but not detectably altered by ATP depletion. (a) Glutaraldehyde fixation reduces fluidity in a dose-dependent but frequency-independent manner, in agreement with previous reports that chemical cross-linking hinders network rearrangement that enables fluidity in the cell, but cell diameter is unaffected (n = 11–123 CH27 cells/concentration, n = 29 cells for control). (b) Fluidity is consistent between time- and frequency-domain measurements when ATP is depleted, similar to controls (untreated cells) (n = 102–249 3T3 fibroblasts/condition and domain). (Inset) Photographs of cells that have undergone ATP depletion (i) before and (ii) after trypsinization show that contractile machinery is hindered after depletion and that the cell is unable to remodel from an attached-state to a suspended-state morphology. To see this figure in color, go online.
protein-protein interactions are replaced by covalent bonds (4). This modulation of fluidity via cross-linking constitutes a positive control for tracking changes in this parameter, to be compared to similar reductions in fluidity by similar treatment of attached cells (4).

It has been suggested that ATP hydrolysis enables a nonzero fluidity value in cells (14,59–61). Previous investigations of ATP depletion effects on (power-law) rheology have been reported for cells in the attached state (see, e.g., Hoffman et al. (3), Chowdhury et al. (4), and Bursac et al. (14)); we here test this hypothesis with cells in the suspended state in which ATP synthesis is inhibited and ATP stores are depleted by chemical means. Interestingly, ATP depletion in these experiments, confirmed by chemical assay and cell morphology (Fig. 4 b, i and ii), did not alter whole-cell mean fluidity, a, within error, in 3T3 fibroblasts. (See Fig. 4 b, where fluidity values are obtained from, and are in agreement with, both time- and frequency-domain measurements.) Equivalent results were obtained from CH27 cells: a = 0.39 ± 0.02 after ATP depletion versus a = 0.39 ± 0.01 for control, via frequency-domain testing of 25 cells/condition.

These findings have important implications when investigating the origin of nonzero fluidity that is also conserved over multiple frequency decades (Figs. 2 and 4 a). The fluidity, a, of soft glassy materials has been proposed to represent (through a noise-temperature equivalent to a + 1) an effective mean-field energy (>>kT) that describes jostling from the mechanical yielding of neighboring regions in the material (62). It has been in turn noted that ATP is an effective energy carrier that the cell employs for actomyosin contraction, leading to the proposal that ATP hydrolysis provides the agitation needed to enable power-law rheology in cells (15,63–65). However, others have reported from experiments that in adherent, contractile cells, fluidity is minimally altered even when ATP is depleted (3,4,14,61,66). Now shown in suspended cells as well, we find that the absence of ATP leaves the cytoskeleton in a rigor state that nevertheless remains susceptible to other sources of structural jostling or agitation and—like inanimate soft glassy materials—continues to exhibit power-law rheology with nonzero fluidity.

**Fluidity increases with temperature**

Finally, we extend the relatively small number of studies addressing temperature-dependent cell rheology (14,52,67,68). Temperature adjustment provides a powerful tool to characterize viscoelastic materials and to evaluate models of such materials, and photonic tools such as the optical stretcher provide a means to alter local temperature rapidly (50,51,69). Because laser power is coupled to both increased applied stress and increased temperature of cells (the second effect being an unintended and generally undesirable consequence of irradiation during optical stretching (51)), we decoupled these cues by externally heating the optical stretcher chamber with resistance heaters attached to the microscope stage as the cells were injected into the chamber from an off-stage syringe.

We began by characterizing the temperature increase from laser heating alone. The temperature-sensitive fluorescent dye Rhodamine B was used to measure the optical stretcher chamber temperature during these experiments; heat-map coloration of the resulting fluorescence intensity allows visualization of the temperature field (Fig. 5 a) (50). In the Supporting Material, we develop a thermal model of the time response of temperature changes in response to laser heating; a comparison of predicted and measured temperature changes is shown in Fig. 5 b. When set to dissipate ~20 W in $\text{C}_0^2$, the stage-mounted external heaters raised the capillary and medium temperature by several tens of degrees in the manner of a first-order thermal system with a time constant of approximately half an hour, verified by dye measurements (Fig. 5 c).

![Temperature measurement via fluorescent dye](image)

**FIGURE 5** Whole-cell fluidity increases with temperature, according to optical stretching measurements in the time and frequency domains, in which temperature was controlled via external heating and/or laser absorption. (a) A temperature-sensitive fluorescent dye allows local laser-induced heating to be quantified. (b) A temperature increase with a ln(t) form over time t in response to a laser power unit step is derived (Fig. S3) and used to predict temperature response from arbitrary laser power profiles. (c) Resistance heaters clamped to the microscope stage enable external heating (with the thermal characteristics of a first-order system), decoupling cell temperature from photonic load. (d) Enabled by fluorescent-dye temperature quantification and fluidity obtained from different rheological techniques ($J(t)$ versus $t$, $G(\omega)$ versus $\omega$, and phase lag, $\delta$) at different laser powers, along with external heating, fluidity is found to increase with temperature at an approximate rate of 0.01 °C$^{-1}$. External heating values show a 100-cell moving average of fluidity from 860 individual cells with 95% confidence interval during the heating and cooling cycle shown in c. To see this figure in color, go online.
After this characterization of laser-induced and external heating, we stretched CH27 cells for 1 h, then heated and (passively) cooled the stage with the temperature profile shown in Fig. 5c by turning the heaters on at 60 min and off at 120 min. We stretched cells by using a 1 Hz sinusoidal laser power amplitude of 0.5 W/fiber overlaid on a constant power of 0.5 W/fiber. As a result, cells were stretched at average temperatures ranging from 31°C to 47°C, providing individual fluidity values cross-referenced to cell temperature (Fig. S7). As shown in Fig. 5d, a 100-cell moving average over >800 cells displays a trend of increasing fluidity with increasing temperature, and vice versa, during this cycle of external heating.

Also shown in Fig. 5d are summarized fluidity measurements acquired from CH27 cells in the time and frequency domains, including the data shown in Fig. 2, g–i. This collection of results, now shown as a function of cell temperature, enables us to draw two important conclusions. First, the increase in fluidity with laser power is linked with laser-induced heating, as the trend observed with external heating is in good agreement with that observed with laser-induced heating. Second, the different fluidity values obtained during creep-compliance stretching and recovery can now be interpreted as a single, temperature-dependent parameter. (These conclusions also hold for the two other cell types studied here (see Fig. S8).

We conclude that for measurements at different temperatures, it is appropriate to use the more general constitutive equation \( G^*(\omega, T) = g_0(T)(i\omega/\omega_0)^{a(T)} \) for a fixed temperature, or a convolution approach, for example, when the temperature changes during an experiment, as is the case with optical stretching. (The relationship between whole-cell stiffness, \( g_0(T) \), and temperature, \( T \), is shown in Fig. S9, where creep-compliance values were converted to stiffness, \( g_0 \), in \( G^*(\omega) = g_0(i\omega/\omega_0)^{a(T)} \) by using \( g_0 = [J/(1s)](2\pi)^3(c1+a)^{-1} \), where \( c \) is the gamma function (2). Here also, results from external heating and laser-induced heating are in good agreement.) This interpretation supersedes the offset-power-law constitutive relation that we considered previously (17).

Such findings clarify a relationship that has rarely been examined—and even then has been complicated by the influence of contraction-induced prestress when fluidity is measured in attached cells. For example, Bursac et al. reported a monotonic increase in fluidity (or, equivalently, power-law exponent) with temperature (14) for cells in the attached state. In contrast, Sunyer et al. measured a decrease in fluidity with increasing temperature (68), which (with the use of pharmacological inhibition) was attributed to substratum-promoted contraction, an effect absent in the suspended state. Kießling et al. recently studied the thermorheology of single suspended cells at deformation times near 1 s via an optical stretcher modified with a second set of fibers under the framework of simple time-temperature superposition (TTS) (52). Note that simple TTS is not strictly compatible with a power-law material (Fig. 2) that exhibits temperature-dependent fluidity (Fig. 5d), because constant time and deformation scaling factors cannot reproduce a creep-compliance relationship of \( J \propto e^{\alpha(T)} \). As we describe in the Supporting Material, however, if fluidity is assumed to be independent of temperature over small ranges, one can derive a time-scaling parameter in agreement with Kießling et al. It may ultimately be a matter of convenience whether one employs the approximation of simple TTS or not; in this work, we prefer to express the rheological behavior in terms of temperature-dependent fluidity and stiffness as a description of a linear viscoelastic material.

**Conclusion**

We expect that physical sorting approaches will continue to emerge that will test suspended cells at timescales of ~1 s or smaller, and that studies of single cell mechanics will provide robust parameterization while enabling theories of soft matter and complex fluids to be tested. Within this scope, our goals are to characterize the mechanical behavior of fully suspended cells, to extend familiarity with animate soft condensed matter and the origins of deformation, and to enable interpretation of cell deformation in cell-sorting devices to separate cell populations by leveraging deformation mechanisms relevant at the timescale of interest. The term fluidity generalizes a parameter that can be estimated from phase lag or power-law exponent (with the most robust results obtained here using phase lag), without committing to any specific model of cell deformation and without the need to calibrate stiffness and compliance to absolute values—a special advantage with optical stretching, where optical coupling means that deformation amplitude varies with refractive index and individual chamber geometry.

We thus devoted part of this study to examining the advantages (and the potential pitfalls) of applying one viscoelastic framework or another. Although there is no guarantee that fitted models will extrapolate accurately outside the range to which they are fit, and we therefore emphasize that our parameterization is applicable specifically to suspended whole cells at the timescale studied here, it is certainly reasonable to expect fitted models to be internally consistent between time and frequency domains. However, we found that time constants predicted from lumped-component fits in the time domain were not observed in the frequency domain. Spring-dashpot models of equivalent complexity therefore appear to be viscoelastically inconsistent between time and frequency domains, producing predictions of system time constants that are apparently artifactual.

Based on these conclusions, we examined fluidity as a parameter with which to characterize cells and cell populations and the effects of chemical and environmental perturbations. We tested the hypothesis that ATP hydrolysis is specifically the source of athermal agitation that enables
structural damping or power-law rheology in cells. However, we found that ATP depletion (visibly confirmed to inhibit remodeling in recently suspended cells) did not transform suspended cells into elastic solids or even alter their fluidity within error. Therefore, ATP appears not to be crucial in enabling power-law rheology during linear viscoelastic deformation of cells, though ATP hydrolysis is plausibly linked to cytoskeletal network remodeling after large fluidizing deformations. It is emphasized that this conclusion needs to be expressed precisely, as ATP plays a part in cytoskeletal resolidification after disruption, and it is thus too vague to say that ATP hydrolysis is or is not responsible for power-law rheology. The findings of this study are specifically that ATP hydrolysis played no detectable part in the average fluidity or hysteresis (as quantified by phase lag) during oscillatory measurements in the linear regime.

The temperature dependence of fluidity in the suspended cell has now been established. For sufficiently small load amplitudes, fluidity was essentially constant; however, we found that its value increased with the mean photonic power used to deform the cell. We decoupled laser-induced stress and temperature to show that whole-cell fluidity depended on temperature, a finding relevant for biophysical understanding of the cell and its position in the framework of animate and inanimate soft condensed matter. A collection of fluidity estimates from the time and frequency domains contributes to a quantitative understanding of temperature dependence and further explains rheological differences between stretching and recovery portions of creep compliance data. Optical stretching changes the temperature of the cell, specifically between stretching and recovery segments of creep-compliance experiments; it is now possible to explain the difference in fluidity estimates during these segments as manifestations of a general temperature dependence.

In summary, the fluidity, $a$, of cells can be measured rigorously and compared as a function of cell type, chemical state, and physical environment—without potential artifacts of cell-substratum and cell-tool contact. Measurement of this nondimensional rheological parameter suggests that the structural damping model best predicts cell mechanical response. Such parameterization supports rapid and accurate assays of cell mechanics in contexts relevant to sorting, delivery, and study of suspended cells.

SUPPORTING MATERIAL

One table, nine figures, references (70–72) and details of calculations and fitting estimates are available at http://www.biophysj.org/biophysj/supplemental/S0006-3495(13)00987-9.

We gratefully acknowledge guidance from J. Guck et al. (Cambridge University, Cambridge, United Kingdom, and Technical University of Dresden, Dresden, Germany) on optical stretcher construction and image analysis. We appreciate the donation of CH27 lymphoma cells by S. H. Um and D. J. Irvine (Massachusetts Institute of Technology (MIT), Cambridge, MA).
