We present the results of lattice QCD calculations of the magnetic moments of the lightest nuclei, the deuteron, the triton, and 3He, along with those of the neutron and proton. These calculations, performed at quark masses corresponding to $m_q \sim 800$ MeV, reveal that the structure of these nuclei at unphysically heavy quark masses closely resembles that at the physical quark masses. In particular, we find that the magnetic moment of 3He differs only slightly from that of a free neutron, as is the case in nature, indicating that the shell-model configuration of two spin-paired protons and a valence neutron captures its dominant structure. Similarly a shell-model-like moment is found for the triton, $\mu_{1\text{He}} \sim \mu_p$. The deuteron magnetic moment is found to be close to the nucleon isoscalar moment within the uncertainties of the calculations. Furthermore, deviations from the Schmidt limits are also found to be similar to those in nature for these nuclei. These findings suggest that at least some nuclei at these unphysical quark masses are describable by a phenomenological nuclear shell model.

The electromagnetic interactions of nuclei have been used extensively to elucidate their structure and dynamics. In the early days of nuclear physics, the magnetic moments of the light nuclei helped to reveal that they behaved like a collection of “weakly” interacting nucleons that, to a very large degree, retained their identity, despite being bound together by the strong nuclear force. This feature, in part, led to the establishment of the nuclear shell model as a phenomenological tool with which to predict basic properties of nuclei throughout the periodic table. The success of the shell model is somewhat remarkable, given that nuclei are fundamentally bound states of quarks and gluons, the degrees of freedom of quantum chromodynamics (QCD). The strong nuclear force emerges from QCD as a by-product of confinement and chiral symmetry breaking. The fact that, at the physical values of the quark masses, nuclei are not simply collections of quarks and gluons, defined by their global quantum numbers, but have the structure of interacting protons and neutrons, remains to be understood at a deep level. In this Letter, we continue our exploration of nuclei at unphysical quark masses, and calculate the magnetic moments of the lightest few nuclei using lattice QCD. We find that they are close to those found in nature, and also close to the sum of the constituent nucleon magnetic moments in the simplest shell model configuration. This second finding, in particular, is remarkable and suggests that a phenomenological nuclear shell model is applicable for at least some nuclei at these unphysical quark masses.

Our lattice QCD calculations were performed on one ensemble of gauge-field configurations generated with a $N_f = 3$ clover-improved fermion action [1] and a Lüscher-Weisz gauge action [2]. The configurations have $L = 32$ lattice sites in each spatial direction, $T = 48$ sites in the temporal direction, and a lattice spacing of $a \sim 0.12$ fm. All three light-quark masses were set equal to that of the physical strange quark, producing a pion of mass $m_\pi \sim 806$ MeV. A background electromagnetic $[U_0(1)]$ gauge field giving rise to a uniform magnetic field along the z axis was multiplied onto each QCD gauge field in the ensemble (separately for each quark flavor), and these combined gauge fields were used to calculate up- and down-quark propagators, which were then contracted to form the requisite nuclear correlation functions using the...
techniques of Ref. [3]. Calculations were performed on \( \sim 750 \) gauge-field configurations, taken at uniform intervals from \( \sim 10000 \) trajectories. On each configuration, quark propagators were generated from 48 uniformly distributed Gaussian-smeared sources for each of four magnetic field strengths (for further details of the production, see Refs. [4,5]).

Background electromagnetic fields have been used extensively to calculate electromagnetic properties of single hadrons, such as the magnetic moments of the lowest-lying baryons [6–14] and electromagnetic polarizabilities of mesons and baryons [9,12–17]. In order that the quark fields, with electric charges \( Q_a = +(2/3) \) and \( Q_{d,s} = -(1/3) \) for the up, down, and strange quarks, respectively, satisfy spatially periodic boundary conditions in the presence of a background magnetic field, it is well known [18] that the lattice links \( U_q(x) \) associated with the \( U_Q(1) \) gauge field are of the form

\[
U_q(x) = e^{i(6\pi Q_a\vec{n}/L)\cdot \vec{r}_1} e^{-i(6\pi Q_q\vec{n}/L)\cdot \vec{r}_2} e^{-i(6\pi Q_q\vec{n}/L)\cdot \vec{r}_3} e^{-i(6\pi Q_q\vec{n}/L)\cdot \vec{r}_4},
\]

for quark of flavor \( q \), where \( \vec{n} \) must be an integer. The uniform magnetic field \( \vec{B} \) resulting from these links is

\[
e_{\vec{B}} = \frac{6\pi \vec{n}}{L^2} \hat{z},
\]

where \( e \) is the magnitude of the electric charge and \( \hat{z} \) is a unit vector in the \( x_3 \) direction. In physical units, the background magnetic fields exploited with this ensemble of gauge-field configurations are \( e|\vec{B}| \sim 0.046|\vec{n}| \) GeV\(^2\). To optimize the reuse of light-quark propagators in the production, calculations were performed for \( U_Q(1) \) fields with \( \vec{n} = 0, 1, -2, +4 \). Four field strengths were found to be sufficient for this initial investigation. With three degenerate flavors of light quarks, and a traceless electric-charge matrix, there are no contributions from coupling of the \( \vec{B} \) field to sea quarks at leading order in the electric charge. Therefore, the magnetic moments presented here are complete calculations (there are no missing disconnected contributions).

The ground-state energy of a nonrelativistic hadron of mass \( M \) and charge \( Qe \) in a uniform magnetic field is

\[
E(\vec{B}) = M + \frac{|Qe|\vec{B}|}{2M} - \mu \cdot \vec{B} - 2\pi \beta_{M0} |\vec{B}|^2 - 2\pi \beta_{M2} T_{ij} B_i B_j + \ldots,
\]

where the ellipses denote terms that are cubic and higher in the magnetic field, as well as terms that are \( 1/M \) suppressed [19,20]. The first contribution in Eq. (3) is the hadron’s rest mass, the second is the energy of the lowest-lying Landau level, the third is from the interaction of its magnetic moment \( \mu \), and the fourth and fifth terms are from its scalar and quadrupole magnetic polarizabilities \( \beta_{M0,M2} \), respectively (\( T_{ij} \) is a traceless symmetric tensor [21]). The magnetic moment term is only present for particles with spin, and \( \beta_{M2} \) is only present for \( j \geq 1 \). In order to determine \( \mu \) using lattice QCD calculations, two-point correlation functions associated with the hadron or nucleus of interest in the \( j_z = \pm j \) magnetic substates \( \epsilon^{(R)}(t) \) can be calculated in the presence of background fields of the form given in Eq. (1) with \( B = \pm \hat{z} \cdot \vec{B} \). The energies of ground states aligned and antialigned with the magnetic field \( E^{(B)}_{+\pm j} \) will be split by spin-dependent interactions, and the difference \( \delta E^{(B)} = E^{(B)}_{+j} - E^{(B)}_{-j} \) can be extracted from the correlation functions that we consider. The component of \( \delta E^{(B)} \) that is linear in \( \vec{B} \) determines \( \mu \) via Eq. (3). Explicitly, the energy difference is determined from the large time behavior of

\[
R(B) = \frac{C^{(B)}_{+j}(t)C^{(0)}_{-j}(t)}{C^{(B)}_{-j}(t)C^{(0)}_{+j}(t)} e^{-\delta E^{(B)} t}.
\]

Each term in this ratio is a correlation function with the quantum numbers of the nuclear state that is being considered, which we compute using the methods of Ref. [3]. As discussed in Ref. [14], subtracting the contribution from the correlation functions calculated in the absence of a magnetic field reduces fluctuations in the ratio, enabling a more precise determination of the magnetic moment. The energy splitting is extracted from a correlated \( \chi^2 \) minimization of the functional form in Eq. (4) using a covariance matrix generated with the jackknife procedure. Fits are performed only over time ranges where all of the individual correlators in the ratio exhibit single exponential behavior and a systematic uncertainty is assigned from variation of the fitting window. Figure 1 shows the correlator ratios and associated fits for the various states that we consider: \( p, n, d, ^3\text{He}, \) and \( ^3\text{H} \), for \( \vec{n} = +1, -2, +4 \).

As mentioned above, the magnetic moments of the proton and neutron have been previously calculated with lattice QCD methods for a wide range of light-quark masses (in almost all cases omitting the disconnected contributions). The present work is the first QCD calculation of the magnetic moments of nuclei. In Figure 2, we show the energy splittings of the nucleons and nuclei as a function of \( |\vec{n}| \), and, motivated by Eq. (3), we fit these to a function of the form \( \delta E^{(B)} = -2\mu |\vec{B}| + \gamma |\vec{B}|^2 \), where \( \gamma \) is a constant encapsulating higher-order terms in the expansion. We find that the proton and neutron magnetic moments at this pion mass are \( \mu_p = 1.792(19)(37) \) N·m/\( \text{C} \) (nuclear magnetons) and \( \mu_n = -1.138(03)(10) \) N·m/\( \text{C} \), respectively, where the first uncertainty is statistical and the second uncertainty is from systematics associated with the fits to correlation functions and the extraction of the magnetic moment using the above form. These results agree with previous calculations [14] within the uncertainties. The
of time slice for the various states ($p$, $n$, $d$, $^3\text{He}$, and $^3\text{H}$) for $\bar{n} = +1, -2, +4$. Fits to the ratios are also shown.

In Figure 2, we also show $\delta\mathcal{E}^{(B)}$ as a function of $|\bar{n}|$ for the deuteron, $^3\text{He}$ and the triton ($^3\text{H}$). Fitting the energy splittings with a form analogous to that for the nucleons gives magnetic moments of $\mu_d^{\text{exp}} = 1.218(38)(87)$ nNM for the deuteron, $\mu_{^3\text{He}}^{\text{exp}} = -2.29(03)(12)$ nNM for $^3\text{He}$, and $\mu_{^3\text{H}}^{\text{exp}} = 3.56(05)(18)$ nNM for the triton. These can be compared with the experimental values of $\mu_d^{\text{exp}} = 0.8574382308(72)$ NM, $\mu_{^3\text{He}}^{\text{exp}} = -2.127625306(25)$ NM, and $\mu_{^3\text{H}}^{\text{exp}} = 2.978962448(38)$ NM. The magnetic moments calculated with lattice QCD, along with their experimental values, are presented in Fig. 3. The naive shell-model predictions for the magnetic moments of these light nuclei are $\mu_d^{\text{SM}} = \mu_p + \mu_n$, $\mu_{^3\text{He}}^{\text{SM}} = \mu_n$ (where the two protons in the 1s state are spin paired to $j_p = 0$ and the neutron is in the 1s state) and $\mu_{^3\text{H}}^{\text{SM}} = \mu_p$ (where the two neutrons in the 1s state are spin paired to $j_n = 0$ and the proton is in the 1s state). For these simple $s$-shell nuclei, the proton and neutron magnetic moments correspond to the Schmidt limits [22]. In nature, $^3\text{He}$ is one of the very few nuclei that lie outside the Schmidt limits [23]. In our calculations we also find that $^3\text{He}$ lies outside the Schmidt limits at this heavier pion mass, with $\delta\mu_{^3\text{He}} = \mu_{^3\text{He}}^{\text{exp}} - \mu_n = -0.340(24)(93)$ nNM (compared to the experimental difference of $\delta\mu_{^3\text{He}}^{\text{exp}} = -0.215$ nNM), and similarly for the triton $\delta\mu_{^3\text{H}} = \mu_{^3\text{H}}^{\text{exp}} - \mu_p = +0.45(04)(16)$ nNM (compared to the experimental difference of $\delta\mu_{^3\text{H}}^{\text{exp}} = +0.186$ nNM), corresponding to $\sim 10\%$ deviations from the naive shell-model predictions. These quantities are summarized in Fig. 4.

At a phenomenological level, it is not difficult to understand why the magnetic moments scale, to a large
MeV, and strange-quark mass of istic quarks, with up- and down-quark masses of
sum of contributions from three weakly bound nonrelativ-
magnetic moments of the lowest-lying baryons as the
relativistic quark model (NRQM) in describing the
degree, with the nucleon mass. The success of the non-
nonrelativistic quark model (NRQM) in describing the
magnetic moments of the lowest-lying baryons as the
magnetic moments using the sum of the
systematic uncertainties into our results. Chiral perturba-
continuum and infinite volume extrapolations introduces
lattice spacing and in one lattice volume, and the lack of
included as various contact interactions among nucleons
and heavier meson-exchange-type contributions are
pions and nucleons are the effective degrees of freedom,
the context of nuclear chiral effective field theory, where
nuclei at the flavor SU(3) symmetric point. We find that,
small compared to the other systematic uncertainties, but
3% on all the extracted moments. For the nuclei, this is
assess an overall multiplicative systematic uncertainty of
for $\Lambda_{QCD} = 300$ MeV. To account for these effects, we
combine the two sources of uncertainty in quadrature and
assess an overall multiplicative systematic uncertainty of
3% on all the extracted moments. For the nuclei, this is
small compared to the other systematic uncertainties, but
for the neutron, in particular, it is the dominant uncertainty.

In conclusion, we have presented the results of lattice
QCD calculations of the magnetic moments of the lightest
nuclei at the flavor SU(3) symmetric point. We find that,
when rescaled by the mass of the nucleon, the magnetic
moments of the proton, neutron, deuteron, $^3$He, and triton
are remarkably close to their experimental values. The
magnetic moment of $^3$He is very close to that of a free
neutron, consistent with the two protons in the 1s state spin
paired to $j_p = 0$ and the valence neutron in the 1s.
Analogous results are found for the triton, and the magnetic
moment of the deuteron is consistent with the sum of the
neutron and proton magnetic moments. This work demon-
strates for the first time that QCD can be used to calculate
the structure of nuclei from first principles. Calculations
using these techniques at lighter quark masses and for

degree, with the nucleon mass. The success of the non-
relativistic quark model (NRQM) in describing the
magnetic moments of the lowest-lying baryons as the
sum of contributions from three weakly bound nonrelativ-
istic quarks, with up- and down-quark masses of $M_{u,d} \sim$
300 MeV and strange-quark mass of $M_S \sim$ 500 MeV,
suggests that naive scaling with the hadron mass should
capture most of the quark-mass dependence. From the
perspective of chiral perturbation theory ($\chi$PT), the leading
contributions to the nucleon magnetic moments are from
dimension-five operators, with the leading quark-mass
dependence arising from mesons loops that are suppressed
in the chiral expansion, and scaling linearly with the mass
of the pion. Consistency of the magnetic moments calcu-
lated in the NRQM and in $\chi$PT suggests that the nucleon
mass scales linearly with the pion mass, which is inconsis-
tent with chiral power counting, but consistent with the
results obtained from analysis of lattice QCD calculations
[24]. It should be emphasized that the magnetic moments of
the light nuclei that we study here are well understood in
the context of nuclear chiral effective field theory, where
pions and nucleons are the effective degrees of freedom,
and heavier meson-exchange-type contributions are
included as various contact interactions among nucleons
(see, for instance, Ref. [25]).

The present calculations have been performed at a single
lattice spacing and in one lattice volume, and the lack of
continuum and infinite volume extrapolations introduces
systematic uncertainties into our results. Chiral perturba-
tion theory can be used to estimate the finite volume (FV)
effects in the magnetic moments, using the sum of the
known [26] effects on the constituent nucleons. These
contributions are $\lesssim 1\%$ in all cases. There may be additional
effects beyond the single particle contributions; however,
the binding energies of light nuclei calculated previously in
multiple volumes at this quark mass [4] demonstrate that
the current lattice volume is large enough for such FV
effects to be negligible. In contrast, calculations with
multiple lattice spacings have not been performed at this
heavier pion mass, and, consequently, this systematic
uncertainty remains to be quantified. However, electro-
magnetic contributions to the action are perturbatively
improved as they are included as a background field in the
link variables. Consequently, the lattice spacing arti-
facts are expected to be small, entering at $O(\Lambda_{QCD}^3)$
$\sim 3\%$ for $\Lambda_{QCD} = 300$ MeV. To account for these effects, we
combine the two sources of uncertainty in quadrature and
assess an overall multiplicative systematic uncertainty of
3% on all the extracted moments. For the nuclei, this is
small compared to the other systematic uncertainties, but
for the neutron, in particular, it is the dominant uncertainty.

In conclusion, we have presented the results of lattice
QCD calculations of the magnetic moments of the lightest
nuclei at the flavor SU(3) symmetric point. We find that,
when rescaled by the mass of the nucleon, the magnetic
moments of the proton, neutron, deuteron, $^3$He, and triton
are remarkably close to their experimental values. The
magnetic moment of $^3$He is very close to that of a free
neutron, consistent with the two protons in the 1s state spin
paired to $j_p = 0$ and the valence neutron in the 1s.
Analogous results are found for the triton, and the magnetic
moment of the deuteron is consistent with the sum of the
neutron and proton magnetic moments. This work demon-
strates for the first time that QCD can be used to calculate
the structure of nuclei from first principles. Calculations
using these techniques at lighter quark masses and for

FIG. 3 (color online). The magnetic moments of the proton, neutron, deuteron, $^3$He, and triton. The results of the lattice QCD calculation at a pion mass of $m_\pi \sim 300$ MeV, in units of natural nuclear magnetons ($e/2M_N^\text{MU}$), are shown as the solid bands. The inner bands correspond to the statistical and systematic uncertainties combined in quadrature, and include our estimates of the uncertainties from lattice spacing and volume. The red dashed lines show the experimentally measured values at the physical quark masses.

FIG. 4 (color online). The differences between the nuclear magnetic moments and the predictions of the naive shell model. The results of the lattice QCD calculation at a pion mass of $m_\pi \sim 300$ MeV, in units of natural nuclear magnetons ($e/2M_N^\text{MU}$), are shown as the solid bands. The inner band corresponds to the statistical uncertainties, while the outer bands correspond to the statistical and systematic uncertainties combined in quadrature, including estimates of the uncertainties from lattice spacing and volume. The red dashed lines show the experimentally measured differences.
larger nuclei are ongoing and will be reported in future work. Perhaps even more importantly, these results reveal aspects of the nature of nuclei, not at the physical quark masses, but in a more general setting where standard model parameters are allowed to vary. In particular, they indicate that the phenomenological successes of the nuclear shell model in nature may extend over a broad range of quark masses.
