PIVOTAL ESTIMATION VIA SQUARE-ROOT LASSO IN NONPARAMETRIC REGRESSION

BY ALEXANDRE BELLONI, VICTOR CHERNOZHUKOV AND LIE WANG

Duke University, Massachusetts Institute of Technology and Massachusetts Institute of Technology

We propose a self-tuning $\sqrt{\text{Lasso}}$ method that simultaneously resolves three important practical problems in high-dimensional regression analysis, namely it handles the unknown scale, heteroscedasticity and (drastic) non-Gaussianity of the noise. In addition, our analysis allows for badly behaved designs, for example, perfectly collinear regressors, and generates sharp bounds even in extreme cases, such as the infinite variance case and the noiseless case, in contrast to Lasso. We establish various nonasymptotic bounds for $\sqrt{\text{Lasso}}$ including prediction norm rate and sparsity. Our analysis is based on new impact factors that are tailored for bounding prediction norm. In order to cover heteroscedastic non-Gaussian noise, we rely on moderate deviation theory for self-normalized sums to achieve Gaussian-like results under weak conditions. Moreover, we derive bounds on the performance of ordinary least square (ols) applied to the model selected by $\sqrt{\text{Lasso}}$ accounting for possible misspecification of the selected model. Under mild conditions, the rate of convergence of ols post $\sqrt{\text{Lasso}}$ is as good as $\sqrt{\text{Lasso}}$’s rate. As an application, we consider the use of $\sqrt{\text{Lasso}}$ and ols post $\sqrt{\text{Lasso}}$ as estimators of nuisance parameters in a generic semiparametric problem (nonlinear moment condition or $Z$-problem), resulting in a construction of $\sqrt{n}$-consistent and asymptotically normal estimators of the main parameters.

1. Introduction. We consider a nonparametric regression model:

\begin{equation}
    y_i = f(z_i) + \sigma \varepsilon_i, \quad i = 1, \ldots, n,
\end{equation}

where $y_i$’s are the outcomes, $z_i$’s are vectors of fixed basic covariates, $\varepsilon_i$’s are independent noise, $f$ is the regression function and $\sigma$ is an unknown scaling
parameter. The goal is to recover the values \((f_i)_{i=1}^n = (f(z_i))_{i=1}^n\) of the regression function \(f\) at \(z_i\)'s. To achieve this goal, we use linear combinations of technical regressors \(x_i = P(z_i)\) to approximate \(f\), where \(P(z_i)\) is a dictionary of \(p\)-vector of transformations of \(z_i\). We are interested in the high dimension low sample size case, where we potentially use \(p > n\), to obtain a flexible approximation. In particular, we are interested in cases where the regression function can be well approximated by a sparse linear function of \(x_i\).

The model above can be written as \(y_i = x_i'\beta_0 + r_i + \sigma \varepsilon_i\), where \(f_i = f(z_i)\) and \(r_i := f_i - x_i'\beta_0\) is the approximation error. The vector \(\beta_0\) is defined as a solution of an optimization problem to compute the oracle risk, which balances bias and variance (see Section 2). The cardinality of the support of \(\beta_0\) is denoted by \(s := \|\beta_0\|_0\). It is well known that ordinary least squares (ols) is generally inconsistent when \(p > n\). However, the sparsity assumption, namely that \(s \ll n\), makes it possible to estimate these models effectively by searching for approximately the right set of the regressors. In particular, \(\ell_1\)-penalization has played a central role \([14, 15, 18, 35, 40, 47, 52, 54]\). It was demonstrated that \(\ell_1\)-penalized least squares estimators can achieve the rate \(\sigma \sqrt{s/n} \sqrt{\log p}\), which is very close to the oracle rate \(\sigma \sqrt{s/n}\) achievable when the true model is known. Importantly, in the context of linear regression, these \(\ell_1\)-regularized problems can be cast as convex optimization problems which make them computationally efficient (computable in polynomial time). We refer to \([14–17, 27, 38, 39, 42, 47]\) for a more detailed review of the existing literature which has focused on the homoscedastic case.

In this paper, we attack the problem of nonparametric regression under non-Gaussian, heteroscedastic errors \(\varepsilon_i\), having an unknown scale \(\sigma\). We propose to use a self-tuning \(\sqrt{\text{Lasso}}\) which is pivotal with respect to the scaling parameter \(\sigma\), and which handles non-Gaussianity and heteroscedasticity in the errors. The resulting rates and performance guarantees are very similar to the Gaussian case, due to the use of self-normalized moderate deviation theory. Such results and properties, particularly the pivotality with respect to the scale, are in contrast to the previous results and methods on others \(\ell_1\)-regularized methods, for example, Lasso and Dantzig selector that use penalty levels that depend linearly on the unknown scaling parameter \(\sigma\).

There is now a growing literature on high-dimensional linear models allowing for unknown scale \(\sigma\). Städler et al. \([43]\) propose a \(\ell_1\)-penalized max-

---

1Earlier literature, for example, in bounded designs \([15]\), provides bounds using refinements of Nemirovski's inequality; see \([26]\). These results provide rates as good as in the Gaussian case. However, when the design is unbounded (e.g., regressors generated as realizations of independent Gaussian random variables), the rates of convergence provided by these techniques are no longer sharp. The use of self-normalized moderate deviations in the present context allows to handle the latter cases, with sharp rates.

2There is also a literature on penalized median regression, which can be used in the case of symmetric errors, since these methods are independent of the unknown \(\sigma\), cf. \([5, 53]\).
minimum likelihood estimator for parametric Gaussian regression models. Belloni et al. [12] consider \( \sqrt{\text{Lasso}} \) for a parametric homoscedastic model with both Gaussian and non-Gaussian errors and establish that the choice of the penalty parameter in \( \sqrt{\text{Lasso}} \) becomes pivotal with respect to \( \sigma \). van de Geer [49] considers an equivalent formulation of the (homoscedastic) \( \sqrt{\text{Lasso}} \) to establish finite sample results and derives results in the parametric homoscedastic Gaussian setting. Chen and Dalalyan [21] consider scaled fused Dantzig selector to allow for different sparsity patterns and provide results under homoscedastic Gaussian errors. Belloni and Chernozhukov [6] study Lasso with a plug-in estimator of the noise level based on Lasso iterations in a parametric homoscedastic setting. Chrétien and Darses [24] study plug-in estimators and a trade-off penalty choice between fit and penalty in the parametric case with homoscedastic Gaussian errors under random support assumption (similar to [19]) using coherence condition. In a trace regression model for recovery of a matrix, [34] proposes and analyses a version of the \( \sqrt{\text{Lasso}} \) under homoscedasticity. A comprehensive review is given in [30]. All these works rely essentially on the restricted eigenvalue condition [14] and homoscedasticity and do not differentiate penalty levels across components.

In order to address the nonparametric, heteroscedastic and non-Gaussian cases, we develop covariate-specific penalty loadings. To derive a practical and theoretically justified choice of penalty level and loadings, we need to account for the impact of the approximation error. We rely on moderate deviation theory for self-normalized sums of [33] to achieve Gaussian-like results in many non-Gaussian cases provided \( \log p = o(n^{1/3}) \), improving upon results derived in the parametric case that required \( \log p \lesssim \log n \), see [12]. (In the context of standard Lasso, the self-normalized moderate deviation theory was first employed in [3].)

Our first contribution is the proposal of new design and noise impact factors, in order to allow for more general designs. Unlike previous conditions, these factors are tailored for establishing performance bounds with respect to the prediction norm, which is appealing in nonparametric problems. In particular, collinear designs motivate our new condition. In studying their properties, we further exploit the oracle based definition of the approximating function. The analysis based on these impact factors complements the analysis based on restricted eigenvalue proposed in [14] and compatibility condition in [48], which are more suitable for establishing rates for \( \ell_k \)-norms.

The second contribution is a set of finite sample upper bounds and lower bounds for estimation errors under prediction norm, and upper bounds on the sparsity of the \( \sqrt{\text{Lasso}} \) estimator. These results are “geometric,” in that they hold conditional on the design and errors provided some key events occur. We further develop primitive sufficient conditions that allow for these results to be applied to heteroscedastic non-Gaussian errors. We also give results for other norms in the supplementary material [2].
The third contribution develops properties of the estimator that applies ordinary least squares (ols) to the model selected by $\sqrt{\text{Lasso}}$. Our focus is on the case that $\sqrt{\text{Lasso}}$ fails to achieve perfect model selection, including cases where the oracle model is not completely selected by $\sqrt{\text{Lasso}}$. This is usually the case in a nonparametric setting. This estimator intends to remove the potentially significant bias toward zero introduced by the $\ell_1$-norm regularization employed in the $\sqrt{\text{Lasso}}$ estimator.

The fourth contribution is to study two extreme cases: (i) parametric noiseless case and (ii) nonparametric infinite variance case. $\sqrt{\text{Lasso}}$ has interesting theoretical properties for these two extreme cases. For case (i), $\sqrt{\text{Lasso}}$ can achieve exact recovery in sharp contrast to Lasso. For case (ii), $\sqrt{\text{Lasso}}$ estimator can still be consistent with penalty choice that does not depend on the scale of the noise. We develop the necessary modifications of the penalty loadings and derive finite-sample bounds for the case of symmetric noise. When noise is Student's $t$-distribution with 2 degrees of freedom, we recover Gaussian-noise rates up to a multiplicative factor of $\log^{1/2} n$.

The final contribution is to provide an application of $\sqrt{\text{Lasso}}$ methods to a generic semiparametric problem, where some low-dimensional parameters are of interest and $\sqrt{\text{Lasso}}$ methods are used to estimate nonparametric nuisance parameters. These results extend the $\sqrt{n}$ consistency and asymptotic normality results of [3, 8] on a rather specific linear model to a generic nonlinear problem, which covers smooth frameworks in statistics and in econometrics, where the main parameters of interest are defined via nonlinear instrumental variable/moment conditions or $Z$-conditions containing unknown nuisance functions (as in [20]). This and all the above results illustrate the wide applicability of the proposed estimation procedure.

**Notation.** To make asymptotic statements, we assume that $n \to \infty$ and $p = p_n \to \infty$, and we allow for $s = s_n \to \infty$. In what follows, all parameters are indexed by the sample size $n$, but we omit the index whenever it does not cause confusion. We work with i.n.i.d., independent but not necessarily identically distributed data, $(w_i)_{i=1}^n$, with $k$-dimensional real vectors $w_i$ containing $y_i \in \mathbb{R}$ and $z_i \in \mathbb{R}^p$, the latter taking values in a set $Z$. We use the notation $(a)_+ = \max\{a, 0\}$, $a \lor b = \max\{a, b\}$ and $a \land b = \min\{a, b\}$. The $\ell_2$-norm is denoted by $\|\cdot\|$, the $\ell_1$-norm is denoted by $\|\cdot\|_1$, the $\ell_\infty$-norm is denoted by $\|\cdot\|_\infty$, and the $\ell_0$-“norm” $\|\cdot\|_0$ denotes the number of nonzero components of a vector. The transpose of a matrix $A$ is denoted by $A'$. Given a vector $\delta \in \mathbb{R}^p$, and a set of indices $T \subset \{1, \ldots, p\}$, we denote by $\delta_T$ the vector in which $\delta_{T_j} = \delta_j$ if $j \in T$, $\delta_{T_j} = 0$ if $j \notin T$, and by $|T|$ the cardinality of $T$. For a measurable function $f : \mathbb{R}^k \to \mathbb{R}$, the symbol $E[f(w_i)]$ denotes the expected value of $f(w_i)$; $\mathbb{E}_n[f(w)]$ denotes the average $n^{-1} \sum_{i=1}^n f(w_i)$; $\mathbb{E}[f(w)]$ denotes the average expectation $n^{-1} \sum_{i=1}^n E[f(w_i)]$; and $\mathbb{G}_n(f(w))$ denotes $n^{-1/2} \sum_{i=1}^n (f(w_i) - \mathbb{E}[f(w_i)])$. We will work with regressor values
$(x_i)_{i=1}^n$ generated via $x_i = P(z_i)$, where $P(\cdot): Z \rightarrow \mathbb{R}^p$ is a measurable dictionary of transformations, where $p$ is potentially larger than $n$. We define the prediction norm of a vector $\delta \in \mathbb{R}^p$ as $\|\delta\|_{2,n} = \{\mathbb{E}_n[(x'_i \delta)^2]\}^{1/2}$, and given values $y_1, \ldots, y_n$ we define $\hat{Q}(\beta) = \mathbb{E}_n[(y - x' \beta)^2]$. We use the notation $a \lesssim b$ to denote $a \leq Cb$ for some constant $C > 0$ that does not depend on $n$ (and, therefore, does not depend on quantities indexed by $n$ like $p$ or $s$); and $a \lesssim_P b$ to denote $a = O_P(b)$. $\Phi$ denotes the cumulative distribution of a standard Gaussian distribution and $\Phi^{-1}$ its inverse function.

2. Setting and estimators. Consider the nonparametric regression model:

$$y_i = f(z_i) + \sigma \varepsilon_i, \quad \varepsilon_i \sim F_i,$$

(2.1) 

$$\mathbb{E}[\varepsilon_i] = 0, \quad i = 1, \ldots, n, \quad \mathbb{E}[\varepsilon_i^2] = 1,$$

where $z_i$ are vectors of fixed regressors, $\varepsilon_i$ are independent errors, and $\sigma$ is the scaling factor of the errors. In order to recover the regression function $f$, we consider linear combinations of the covariates $x_i = P(z_i)$ which are $p$-vectors of transformation of $z_i$ normalized so that $\mathbb{E}_n[x_j^2] = 1$ ($j = 1, \ldots, p$).

The goal is to estimate the value of the nonparametric regression function $f$ at the design points, namely the values $(f_i)_{i=1}^n := (f(z_i))_{i=1}^n$. In the nonparametric settings, the regression functions $f$ are generically nonsparse. However, often they can be well approximated by a sparse model $x' \beta_0$. One way to find such approximating model is to let $\beta_0$ be a solution of the following risk minimization problem:

$$\min_{\beta \in \mathbb{R}^p} \mathbb{E}_n[(f - x' \beta)^2] + \frac{\sigma^2 \|\beta\|_0}{n}.$$  

(2.2)

The problem (2.2) yields the so called oracle risk—an upper bound on the risk of the best $k$-sparse least squares estimator in the case of homoscedastic Gaussian errors, that is, the best estimator among all least squares estimators that use $k$ out of $p$ components of $x_i$ to estimate $f_i$. The solution $\beta_0$ achieves a balance between the mean square of the approximation error $r_i := f_i - x'_i \beta_0$ and the variance, where the latter is determined by the complexity $\|\beta_0\|_0$ of the model (number of nonzero components of $\beta_0$).

In what follows, we call $\beta_0$ the target parameter value, $T := \text{supp}(\beta_0)$ the oracle model, $s := |T| = \|\beta_0\|_0$ the dimension of the oracle model, and $x'_i \beta_0$ the oracle or the best sparse approximation to $f_i$. We note that $T$ is generally unknown. We summarize the preceding discussion as follows.

**Condition ASM.** We have data $\{(y_i, z_i): i = 1, \ldots, n\}$ that for each $n$ obey the regression model (2.1), where $y_i$ are the outcomes, $z_i$ are vectors of fixed basic covariates, the regressors $x_i := P(z_i)$ are transformations of $z_i$, and $\varepsilon_i$ are i.n.i.d. errors. The vector $\beta_0$ is defined by (2.2) where the
regressors \( x_i \) are normalized so that \( \mathbb{E}_n[x_j^2] = 1, \ j = 1, \ldots, p \). We let

\[
T := \text{supp}(\beta_0), \quad s := |T|, \quad r_i := f_i - x_i'\beta_0 \quad \text{and} \quad c_s^2 := \mathbb{E}_n[r^2].
\]

**Remark 1** (Targeting \( x_i'\beta_0 \) is the same as targeting \( f_i \)'s). We focus on estimating the oracle model \( x_i'\beta_0 \) using estimators of the form \( x_i'\hat{\beta} \), and we seek to bound estimation errors with respect to the prediction norm \( \| \hat{\beta} - \beta_0 \|_{2,n} \). The bounds on estimation errors for the ultimate target \( f_i \) then follow from the triangle inequality, namely

\[
\sqrt{\mathbb{E}_n[(f - x'\hat{\beta})^2]} \leq \| \hat{\beta} - \beta_0 \|_{2,n} + c_s.
\]

**Remark 2** (Bounds on the approximation error). The approximation errors typically satisfy \( c_s \leq K\sigma \sqrt{(s \vee 1)/n} \) for some fixed constant \( K \), since the optimization problem (2.2) balances the (squared) norm of the approximation error (the norm of the bias) and the variance; see [4, 6, 45]. In particular, this condition holds for wide classes of functions; see Example S of Section 4 dealing with Sobolev classes and Section C.2 of supplementary material [2].

### 2.1. Heteroscedastic \( \sqrt{\text{Lasso}} \)

In this section, we formally define the estimators which are tailored to deal with heteroscedasticity.

We propose to define the \( \sqrt{\text{Lasso}} \) estimator as

\[
\hat{\beta} \in \arg \min_{\beta \in \mathbb{R}^p} \sqrt{\hat{Q}(\beta)} + \frac{\lambda}{n} \| \Gamma \beta \|_1,
\]

where \( \hat{Q}(\beta) = \mathbb{E}_n[(y - x'\beta)^2] \), \( \Gamma = \text{diag}(\gamma_1, \ldots, \gamma_p) \) is a diagonal matrix of penalty loadings. The scaled \( \ell_1 \)-penalty allows component specific adjustments to more efficiently deal with heteroscedasticity.\(^3\) Throughout, we assume \( \gamma_j \geq 1 \) for \( j = 1, \ldots, p \).

In order to reduce the shrinkage bias of \( \sqrt{\text{Lasso}} \), we consider the post model selection estimator that applies ordinary least squares (ols) to a model \( \hat{T} \) that contains the model selected by \( \sqrt{\text{Lasso}} \). Formally, let \( \hat{T} \) be such that

\[
\text{supp}(\hat{\beta}) = \{ j \in \{1, \ldots, p\} : |\hat{\beta}_j| > 0 \} \subseteq \hat{T},
\]

and define the ols post \( \sqrt{\text{Lasso}} \) estimator \( \tilde{\beta} \) associated with \( \hat{T} \) as

\[
\tilde{\beta} \in \arg \min_{\beta \in \mathbb{R}^p} \sqrt{\hat{Q}(\beta)} : \beta_j = 0 \quad \text{if} \ j \notin \hat{T}.
\]

\(^3\) When errors are homoscedastic, we can set \( \Gamma = I_p \). In the heteroscedastic case, using \( \Gamma = I_p \) may require setting \( \lambda \) too conservatively, leading to over-penalization and worse performance bounds. In the paper, we develop data-dependent choice of \( \Gamma \) that allows us to avoid over-penalization thereby improving the performance.
A sensible choice for $\hat{T}$ is simply to set $\hat{T} = \text{supp}(\hat{\beta})$. Moreover, we allow for additional components (potentially selected through an arbitrary data-dependent procedure) to be added, which is relevant for practice.

### 2.2. Typical conditions on the Gram matrix.

The Gram matrix $E_n[xx']$ plays an important role in the analysis of estimators in this setup. When $p > n$, the smallest eigenvalue of the Gram matrix is 0, which creates identification problems. Thus, to restore identification, one needs to restrict the type of deviation vectors $\delta$ corresponding to the potential deviations of the estimator from the target value $\beta_0$. Because of the $\ell_1$-norm regularization, the following restricted set is important:

$$\Delta_c = \{ \delta \in \mathbb{R}^p : \| \Gamma \delta_c \|_1 \leq c \| \Gamma \delta \|_1, \delta \neq 0 \} \quad \text{for } c \geq 1.$$  

The restricted eigenvalue $\kappa_c$ of the Gram matrix $E_n[xx']$ is defined as

$$\kappa_c := \min_{\delta \in \Delta_c} \frac{\sqrt{\| \delta \|_2^2}}{\| \Gamma \delta \|_1}.$$  

(2.7)

The restricted eigenvalues can depend on $n$, $T$, and $\Gamma$, but we suppress the dependence in our notation. The restricted eigenvalues (2.7) are variants of the restricted eigenvalue introduced in [14] and of the compatibility condition in [48] that accommodate the penalty loadings $\Gamma$. They were proven to be useful for many designs of interest specially for establishing $\ell_k$-norm rates. Below we suggest their generalizations that are useful for deriving rates in prediction norm.

The minimal and maximal $m$-sparse eigenvalues of a matrix $M$,

$$\phi_{\min}(m, M) := \min_{\| \delta \|_0 \leq m, \delta \neq 0} \frac{\delta^T M \delta}{\| \delta \|_2^2},$$  

$$\phi_{\max}(m, M) := \max_{\| \delta \|_0 \leq m, \delta \neq 0} \frac{\delta^T M \delta}{\| \delta \|_2^2}.$$  

(2.8)

Typically, we consider $M = E_n[xx']$ or $M = \Gamma^{-1} E_n[xx'] \Gamma^{-1}$. When $M$ is not specified, we mean $M = E_n[xx']$, that is, $\phi_{\min}(m) = \phi_{\min}(m, E_n[xx'])$ and $\phi_{\max}(m) = \phi_{\max}(m, E_n[xx'])$. These quantities play an important role in the sparsity and post model selection analysis. Moreover, sparse eigenvalues provide a simple sufficient condition to bound restricted eigenvalues; see [14].

### 3. Finite-sample analysis of $\sqrt{\text{Lasso}}$.

Next, we establish several finite-sample results regarding the $\sqrt{\text{Lasso}}$ estimator. Importantly, these results are based on new impact factors that can be very well behaved under repeated (i.e., collinear) regressors, and which strictly generalize the restricted eigenvalue (2.7) and compatibility constants.
The following event plays a central role in the analysis:

\[(3.1) \quad \lambda/n \geq c \|\Gamma^{-1}\widetilde{S}\|_\infty \quad \text{where } \widetilde{S} := E_n[x(\sigma_0 + r)]/\sqrt{E_n[(\sigma_0 + r)^2]} \]

is the score of \(\widehat{Q}^{1/2}\) at \(\beta_0\) (\(\widetilde{S} = 0\) if \(E_n[(\sigma_0 + r)^2] = 0\)). Throughout the section, we assume such event holds. Later we provide choices of \(\lambda\) and \(\Gamma\) based on primitive conditions such that the event in (3.1) holds with a high probability.

3.1. New noise and design impact factors. We define the following noise and design impact factors for a constant \(c > 1\):

\[(3.2) \quad q_c := \sup_{\|\delta\|_{2,n} > 0, \delta \in R_c} \frac{|\widetilde{S}\delta|}{\|\delta\|_{2,n}}, \]

\[(3.3) \quad \bar{\kappa} := \inf_{\|\Gamma(\beta_0 + \delta)\|_1 < \|\Gamma\beta_0\|_1} \frac{\sqrt{s}\|\delta\|_{2,n}}{\|\Gamma\delta_T\|_1 - \|\Gamma\delta_T\|_1}, \]

where \(R_c := \{\delta \in \mathbb{R}^p : \|\Gamma\delta\|_1 \geq c(\|\Gamma(\beta_0 + \delta)\|_1 - \|\Gamma\beta_0\|_1)\}\). For the case \(\beta_0 = 0\), we define \(q_c = 0\) and \(\bar{\kappa} = \infty\). These quantities depend on \(n, \beta_0\) and \(\Gamma\), albeit we suppress this when convenient.

An analysis based on the quantities \(q_c\) and \(\bar{\kappa}\) will be more general than the one relying only on restricted eigenvalues (2.7). This follows because (2.7) yields one possible way to bound both \(\bar{\kappa}\) and \(q_c\), namely,

\[
\bar{\kappa} \geq \kappa := \inf_{\delta \in \text{int}(\Delta_1)} \frac{\sqrt{s}\|\delta\|_{2,n}}{\|\delta\|_{2,n}} \geq \min_{\delta \in \Delta_1} \frac{\sqrt{s}\|\delta\|_{2,n}}{\|\Gamma\delta_T\|_1 - \|\Gamma\delta_T\|_1} = \kappa_c,
\]

\[
q_c \leq \sup_{\delta \in \Delta_c} \frac{\|\Gamma^{-1}\widetilde{S}\|_\infty \|\delta\|_1}{\|\delta\|_{2,n} \|\Gamma\delta_T\|_1} \leq \sup_{\delta \in \Delta_c} \frac{\|\Gamma^{-1}\widetilde{S}\|_\infty (1 + \varepsilon) \|\Gamma\delta_T\|_1}{\|\delta\|_{2,n}} \leq \frac{(1 + \varepsilon)\sqrt{s}}{\kappa_c} \|\Gamma^{-1}\widetilde{S}\|_\infty,
\]

where \(c > 1\) and \(\varepsilon := (c + 1)/(c - 1) > 1\). The quantities \(\bar{\kappa}\) and \(q_c\) can be well behaved (i.e., \(\bar{\kappa} > 0\) and \(q_c < \infty\) even in the presence of repeated (i.e., collinear) regressors (see Remark 4 for a simple example), while restricted eigenvalues and compatibility constants would be zero in that case.

The design impact factor \(\bar{\kappa}\) in (3.3) strictly generalizes the original restricted eigenvalue (2.7) proposed in [14] and the compatibility constants proposed in [48] and in [46].\(^4\) The design conditions based on these concepts are relatively weak, and hence (3.3) is a useful concept.

\(^4\)The compatibility condition defined in [46] is defined as: \(\exists \nu(T) > 0\) such that

\[
\inf_{\delta \in \Delta_3} \frac{\sqrt{s}\|\delta\|_{2,n}}{\|\delta\|_{2,n} + \nu(T)\|\delta_T\|_1 - \|\Gamma\delta_T\|_1} > 0.
\]
The noise impact factor $\varrho_c$ also plays an important role. It depends on the noise, design and approximation errors, and can be controlled via empirical process methods. Note that under (3.1), the deviation $\hat{\delta} = \hat{\beta} - \beta_0$ of the $\sqrt{\text{Lasso}}$ estimator from $\beta_0$ obeys $\hat{\delta} \in R_c$, explaining its appearance in the definition of $\varrho_c$. The lemmas below summarize the above discussion.

**Lemma 1** (Bounds on and invariance of design impact factor). Under Condition \textit{ASM}, we have $\bar{\kappa} \geq \kappa \geq \kappa_1 \geq \kappa_c$. Moreover, if copies of regressors are included with the same corresponding penalty loadings, the lower bound $\kappa$ on $\bar{\kappa}$ does not change.

**Lemma 2** (Bounds on and invariance of noise impact factor). Under Condition \textit{ASM}, we have $\varrho_c \leq (1 + \bar{\kappa}) \sqrt{s} \| \Gamma^{-1} \tilde{S} \|_{\infty} / \kappa \bar{\kappa}$. Moreover, if copies of regressors with indices $j \in T^c$ are included with the same corresponding penalty loadings, $\varrho_c$ does not change (see also Remark 4).

**Lemma 3** (Estimators belong to restricted sets). Assume that for some $c > 1$ we have $\lambda / n \geq c \| \Gamma^{-1} \tilde{S} \|_{\infty}$, then $\hat{\delta} \in R_c$. The latter condition implies that $\hat{\delta} \in \Delta \bar{\kappa}$ for $\bar{\kappa} = (c + 1)/(c - 1)$.

3.2. Finite-sample bounds on $\sqrt{\text{Lasso}}$. In this section, we derive finite-sample bounds for the prediction norm of the $\sqrt{\text{Lasso}}$ estimator. These bounds are established under heteroscedasticity, without knowledge of the scaling parameter $\sigma$, and using the impact factors proposed in Section 3.1. For $c > 1$, let $\bar{c} = (c + 1)/(c - 1)$ and consider the conditions

\begin{equation}
\lambda / n \geq c \| \Gamma^{-1} \tilde{S} \|_{\infty} \quad \text{and} \quad \bar{\zeta} := \lambda \sqrt{s} / (n \bar{\kappa}) < 1.
\end{equation}

**Theorem 1** (Finite sample bounds on estimation error). Under Condition \textit{ASM} and (3.4), we have

$$
\| \hat{\beta} - \beta_0 \|_{2,n} \leq 2 \sqrt{Q(\beta_0)B_n}, \quad B_n := \frac{\varrho_c + \bar{\zeta}}{1 - \bar{\zeta}^2}.
$$

We recall that the choice of $\lambda$ does not depend on the scaling parameter $\sigma$. The impact of $\sigma$ in the bound of Theorem 1 comes through the factor $\hat{Q}^{1/2}(\beta_0) \leq \sigma \sqrt{E_n[\varepsilon^2]} + c_s$ where $c_s$ is the size of the approximation error defined in Condition \textit{ASM}. Moreover, under typical conditions that imply $\kappa_c$
to be bounded away from zero, for example, under Condition \( P \) of Section 4 and standard choice of penalty, we have with a high probability

\[
B_n \lesssim \sqrt{\frac{s \log (p \vee n)}{n}} \implies \|\hat{\beta} - \beta_0\|_{2,n} \lesssim \sigma \sqrt{\frac{s \log (p \vee n)}{n}}.
\]

Thus, Theorem 1 generally leads to the same rate of convergence as in the case of the Lasso estimator that knows \( \sigma \) since \( \mathbb{E}_n[\varepsilon^2] \) concentrates around 1 under (2.1) and provided a law of large numbers holds. We derive performance bounds for other norms of interest in the supplementary material [2].

The next result deals with \( \hat{Q}(\hat{\beta}) \) as an estimator for \( \hat{Q}(\beta_0) \) and \( \sigma^2 \).

**Theorem 2 (Estimation of \( \sigma \)).** Under Condition ASM and (3.4)

\[
-2\bar{c}\sqrt{\hat{Q}(\beta_0)}B_n \leq \sqrt{\hat{Q}(\hat{\beta})} - \sqrt{\hat{Q}(\beta_0)} \leq 2\bar{\zeta} \sqrt{\hat{Q}(\beta_0)}B_n.
\]

Under only Condition ASM, we have

\[
|\sqrt{\hat{Q}(\hat{\beta})} - \sigma| \leq \|\hat{\beta} - \beta_0\|_{2,n} + c_\ast + \sigma|\mathbb{E}_n[\varepsilon^2] - 1|.
\]

We note that further bounds on \( |\mathbb{E}_n[\varepsilon^2] - 1| \) are implied by von Bahr–Esseen’s and Markov’s inequalities, or by self-normalized moderate deviation (SNMD) theory as in Lemma 4. As a result, the theorem implies consistency \( |\hat{Q}^{1/2}(\hat{\beta}) - \sigma| = o_P(1) \) under mild moment conditions; see Section 4. Theorem 2 is also useful for establishing the following sparsity properties.

**Theorem 3 (Sparsity bound for \( \sqrt{\text{Lasso}} \)).** Suppose Condition ASM, (3.4), \( \hat{Q}(\beta_0) > 0 \), and \( 2\bar{c}B_n \leq 1/(c\bar{c}) \). Then we have

\[
|\text{supp}(\hat{\beta})| \leq s \cdot 4\bar{c}^2(B_n/\bar{\zeta}\bar{c})^2 \min_{m \in \mathcal{M}} \phi_{\max}(m, \Gamma^{-1}\mathbb{E}_n[xx']\Gamma^{-1}),
\]

where \( \mathcal{M} = \{m \in \mathbb{N} : m > s\phi_{\max}(m, \Gamma^{-1}\mathbb{E}_n[xx']\Gamma^{-1}) \cdot 8\bar{c}^2(B_n/\bar{\zeta}\bar{c})^2\} \). Moreover, if \( \kappa_{\bar{c}} > 0 \) and \( \bar{\zeta} < 1/\sqrt{2} \) we have

\[
|\text{supp}(\hat{\beta})| \leq s \cdot (4\bar{c}^2/\kappa_{\bar{c}})^2 \min_{m \in \mathcal{M}^*} \phi_{\max}(m, \Gamma^{-1}\mathbb{E}_n[xx']\Gamma^{-1}),
\]

where \( \mathcal{M}^* = \{m \in \mathbb{N} : m > s\phi_{\max}(m, \Gamma^{-1}\mathbb{E}_n[xx']\Gamma^{-1}) \cdot 2(4\bar{c}^2/\kappa_{\bar{c}})^2\} \).

**Remark 3 (On the sparsity bound).** Section 4 will show that under minimal and maximal sparse eigenvalues of order \( s \log n \) bounded away from zero and from above, Theorem 3 implies that with a high probability

\[
|\text{supp}(\hat{\beta})| \lesssim s := |\text{supp}(\beta_0)|.
\]
That is, the selected model’s size will be of the same order as the size of
the oracle model. We note, however, that the former condition is merely a
sufficient condition. The bound $|\text{supp}(\hat{\beta})| \lesssim s$ will apply for other designs
of interest. This can be the case even if $\kappa_e = 0$ (e.g., in the aforementioned
design, if we change it by adding a single repeated regressor).

**Remark 4** (Maximum sparse eigenvalue and sparsity). Consider the
case of $f(z) = z$ with $p$ repeated regressors $x_i = (z_i, \ldots, z_i)'$ where $|z| \leq K$.
In this case, one could set $\Gamma = I \cdot K$. In this setting, there is a sparse solution
for $\sqrt{\text{Lasso}}$, but there is also a solution which has all $p$ nonzero coefficients.
Nonetheless, the bound for the prediction error rate will be well behaved
since $\bar{\kappa}$ and $\bar{\zeta}$ are invariant to the addition of copies of $z$ and

$$\bar{\kappa} \geq 1/K \quad \text{and} \quad \varrho_c = \frac{|E_n[\varepsilon z]|}{\{E_n[\varepsilon^2]E_n[z^2]\}^{1/2}} \lesssim P 1/\sqrt{n}$$

under mild moment conditions on the noise (e.g., $E[|\varepsilon|^3] \leq C$). In this case,
$\phi_{\max}(m, \Gamma^{-1}E_n[x x']\Gamma^{-1}) = (m + 1)E_n[z^2]/K^2$ and the set $\mathcal{M}$ only contains integers larger than $p$, leading to the trivial bound $\hat{m} \leq p$.

### 3.3. Finite-sample bounds on ols post $\sqrt{\text{Lasso}}$.

Next, we consider the ols estimator applied to the model $\hat{T}$ that was selected by $\sqrt{\text{Lasso}}$ or
includes such model (plus other components that the data analyst may wish
to include), namely $\text{supp}(\hat{\beta}) \subseteq \hat{T}$. We are interested in the case when model
selection does not work perfectly, as occurs in applications.

The following result establishes performance bounds for the ols post $\sqrt{\text{Lasso}}$
estimator. Following [6], the analysis accounts for the data-driven choice of
components and for the possibly misspecified selected model (i.e., $T \not\subseteq \hat{T}$).

**Theorem 4** (Performance of ols post $\sqrt{\text{Lasso}}$). Under Condition ASM
and (3.4), let $\text{supp}(\hat{\beta}) \subseteq \hat{T}$, and $\hat{m} = |\hat{T} \setminus T|$. Then we have that the ols post
$\sqrt{\text{Lasso}}$ estimator based on $\hat{T}$ satisfies

$$\|\hat{\beta} - \beta_0\|_{2,n} \leq \frac{\sigma \sqrt{s + \hat{m}} \|E_n[x \varepsilon]\|_\infty}{\phi_{\min}(\hat{m})} + 2c_n + 2\sqrt{Q(\beta_0)B_n}.$$  

The result is derived from the sparsity of the model $\hat{T}$ and from its
approximating ability. Note the presence of the new term $\|E_n[x \varepsilon]\|_\infty$. Bounds
on $\|E_n[x \varepsilon]\|_\infty$ can be derived using the same tools used to justify the
penalty level $\lambda$, via moderate deviation theory for self-normalized sums [33],
Gaussian approximations to empirical processes [22, 23] or empirical pro-
cess inequalities as in [5]. Under mild conditions, we have $\|E_n[x \varepsilon]\|_\infty \leq C \sqrt{\log(pn)/n}$ with probability $1 - o(1)$.
3.4. Two extreme cases. Case (i): Parametric noiseless case. Consider the case that \( \sigma = 0 \) and \( c_s = 0 \). Therefore, the regression function is exactly sparse, \( f(z_i) = x_i^t \beta_0 \). In this case, \( \sqrt{\text{Lasso}} \) can exactly recover the \( f \) and even \( \beta_0 \) under weak conditions under a broad range of penalty levels.

**Theorem 5** (Exact recovery for the parametric noiseless case). Under Condition ASM, let \( \sigma = 0 \) and \( c_s = 0 \). Suppose that \( \lambda > 0 \) obeys the growth restriction \( \zeta = \lambda \sqrt{s}/[n \bar{k}] < 1 \). Then we have \( \| \hat{\beta} - \beta_0 \|_{2,n} = 0 \), and if, moreover, \( \kappa_1 > 0 \), then \( \hat{\beta} = \beta_0 \).

**Remark 5** (Perfect recovery and Lasso). It is worth mentioning that for any \( \lambda > 0 \), unless \( \beta_0 = 0 \), Lasso cannot achieve exact recovery. Moreover, it is not obvious how to properly set the penalty level for Lasso even if we knew a priori that it is a parametric noiseless model. In contrast, \( \sqrt{\text{Lasso}} \) can automatically adapt to the noiseless case.

Case (ii): Nonparametric infinite variance. We conclude this section with the infinite variance case. The finite sample theory does not rely on \( E[\varepsilon^2] < \infty \). Instead it relies on the choice of penalty level and penalty loadings to satisfy \( \lambda/n \geq c\|\Gamma^{-1}S\|_\infty \). Under symmetric errors, we exploit the sub-Gaussian property of self-normalized sums \([25]\) to develop a choice of penalty level \( \lambda \) and loadings \( \Gamma = \text{diag}(\gamma_j, j = 1, \ldots, p) \), where

\[
\lambda = (1 + u_n)c\sqrt{n}\{1 + \sqrt{2\log(2p/\alpha)}\} \quad \text{and} \quad \gamma_j = \max_{1 \leq i \leq n} |x_{ij}|,
\]

where \( u_n \) is defined below and typically we can select \( u_n = o(1) \).

**Theorem 6** (\( \sqrt{\text{Lasso}} \) prediction norm for symmetric errors). Consider a nonparametric regression model with data \((y_i, z_i)_{i=1}^n\), \( y_i = f(z_i) + \sigma \varepsilon_i \), \( x_i = P(z_i) \) such that \( E_n[x_{ij}^2] = 1 \) \( (j = 1, \ldots, p) \), \( \varepsilon_i \)'s are independent symmetric errors, and \( \beta_0 \) defined as any solution to (2.2). Let the penalty level and loadings as in (3.5). Assume that there exist sequences of constants \( \eta_1 \geq 0 \) and \( \eta_2 \geq 0 \) both converging to 0 and a sequence of constants 0 \( \leq u_n \leq 1 \) such that \( P(E_n[\sigma \varepsilon^2] > (1 + u_n)E_n[(\sigma \varepsilon + r)^2]) \leq \eta_1 \) and \( P(E_n[\varepsilon^2] \leq \{1 + u_n\}^{-1}) \leq \eta_2 \) for all \( n \). If \( \zeta = \lambda \sqrt{s}/[n \bar{k}] < 1 \), then with probability at least \( 1 - \alpha - \eta_1 - \eta_2 \) we have \( \lambda/n \geq c\|\Gamma^{-1}S\|_\infty \) and

\[
\| \hat{\beta} - \beta_0 \|_{2,n} \leq 2B_n\left(c_s + \sqrt{E_n[\varepsilon^2]}\right).
\]

The rate of convergence will be affected by how fast \( E_n[\varepsilon^2] \) diverges. That is, the final rate will depend on the particular tail properties of the distribution of the noise. The rate also depends on \( u_n \) through \( \lambda \). In many
examples, $u_n$ can be chosen as a constant or even a sequence going to zero sufficiently slowly, as in the next corollary where $\varepsilon_i$ follows a $t$ distribution with $2$ degrees of freedom, that is, $\varepsilon_i \sim t(2)$.

**Corollary 1** [\sqrt{\text{Lasso}} prediction norm for $\varepsilon_i \sim t(2)$]. Under the setting of Theorem 6, suppose that $\varepsilon_i \sim t(2)$ and are i.i.d. for all $i$. Then for any $\tau \in (0, 1/2)$, with probability at least $1 - \alpha - 3\tau - \frac{2 \log(4n/\tau)}{nu_n/[1+u_n]} - \frac{72 \log^2 n}{n^{1/2}(\log n - 6)^2}$, we have $\lambda/n \geq c \| \Gamma^{-1} \tilde{S} \|_{\infty}$ and, if $\bar{\zeta} = \lambda \sqrt{s/[n \kappa]} < 1$, we have

$$
||\hat{\beta} - \beta_0||_{2,n} \leq 2(c_s + \sigma \sqrt{\log(4n/\tau)} + 2\sqrt{2/\tau}) B_n.
$$

**Remark 6** [Asymptotic performance in $t(2)$ case]. Provided that regressors are uniformly bounded and satisfy the sparse eigenvalues condition (4.3), we have that the restricted eigenvalue $\kappa_\hat{e}$ is bounded away from zero for the specified choice of $\Gamma$. Because Corollary 1 ensures $\lambda/n \geq c \| \Gamma^{-1} \tilde{S} \|_{\infty}$ with the stated probability, by Lemmas 1 and 2 we have

$$
\varrho_e + \bar{\zeta} \lesssim \frac{\lambda \sqrt{s}}{n \kappa_\hat{e}} \lesssim (1 + u_n) \sqrt{\frac{s \log(p \vee n)}{n}} \implies B_n \lesssim \sqrt{\frac{s \log(p \vee n)}{n}}.
$$

Therefore, under these design conditions, assuming that $s \log(p/\alpha) = o(n)$ and that $\sigma$ is fixed, and setting $1/\alpha = o(\log n)$, we can select $u_n = 1/2$ and $\tau = 1/\log n$ in Corollary 1, to conclude that the \sqrt{\text{Lasso}} estimator satisfies

$$
||\hat{\beta} - \beta_0||_{2,n} \lesssim \left( c_s + \sigma \sqrt{\log n} \right) \sqrt{\frac{s \log(p \vee n)}{n}},
$$

with probability $1 - \alpha(1 + o(1))$. Despite the infinite variance, the bound (3.6) differs from the Gaussian noise case only by a $\sqrt{\log n}$ factor.

4. Asymptotics analysis under primitive conditions. In this section, we formally state an algorithm to compute the estimators and we provide rates of convergence results under simple primitive conditions.

We propose setting the penalty level as

$$
\lambda = c \sqrt{n} \Phi^{-1}(1 - \alpha/2p),
$$

where $\alpha$ controls the confidence level, and $c > 1$ is a slack constant similar to [14], and the penalty loadings according to the following iterative algorithm.

**Algorithm 1** (Estimation of square-root Lasso loadings). Choose $\alpha \in (1/n, 1/2]$ and a constant $K \geq 1$ as an upper bound on the number of iterations. (0) Set $k = 0$, $\lambda$ as in (4.1), and $\tilde{\gamma}_{ij,0} = \max_{1 \leq i \leq n} |x_{ij}|$ for each
Compute the \( \sqrt{\text{Lasso}} \) estimator \( \hat{\beta} \) based on the current penalty loadings \( \Gamma = \hat{\Gamma}_k = \text{diag}\{\hat{\gamma}_{j,k}, j = 1, \ldots, p\}. \) (2) Set 
\[ \hat{\gamma}_{j,k+1} := 1 \lor \sqrt{\mathbb{E}_n[\epsilon^2]} / \sqrt{\mathbb{E}_n[(y - x'\hat{\beta})^2]} \] 
(3) If \( k > K \), stop; otherwise set \( k \leftarrow k + 1 \) and go to step 1.

Remark 7 (Parameters of the algorithm). The parameter \( 1 - \alpha \) is a confidence level which guarantees near-oracle performance with probability at least \( 1 - \alpha \); we recommend \( \alpha = 0.05 / \log n \). The constant \( c > 1 \) is the slack parameter used as in [14]; we recommend \( c = 1.01 \). In order to invoke moderate deviation theorem for self-normalized sums, we need to be able to bound with a high probability:

\[ \sqrt{\mathbb{E}_n[\epsilon^2]} / \sqrt{\mathbb{E}_n[\epsilon^2]} \leq \gamma_{j,0} \] 

The choice of \( \hat{\gamma}_{j,0} = \max_{1 \leq i \leq n} |x_{ij}| \) automatically achieves (4.2). Nonetheless, we recommend iterating the procedure to avoid unnecessary over-penalization, since at each iteration more precise estimates of the penalty loadings are achieved. These recommendations are valid either in finite or large samples under the conditions stated below. They are also supported by the numerical experiments (see Section G of supplementary material [2]).

Remark 8 (Alternative estimation of loadings). Algorithm 1 relies on the \( \sqrt{\text{Lasso}} \) estimator \( \hat{\beta} \). Another possibility is to use the ols post \( \sqrt{\text{Lasso}} \) estimator \( \hat{\beta} \). This leads to similar theoretical and practical results. Moreover, we can define the initial penalty loading as \( \hat{\gamma}_{j,0} = W \{ \mathbb{E}_n[|x_j^4|] \}^{1/4} \) where the kurtosis parameter \( W > \{ \mathbb{E}[|\epsilon|^4] \}^{1/4} / \{ \mathbb{E}[\epsilon^2] \}^{1/2} \) is pivotal with respect to the scaling parameter \( \sigma \), but we need to assume an upper bound for this quantity. The purpose of this parameter is to bound the kurtosis of the marginal distribution of errors, namely that of \( F_{\epsilon}(v) = n^{-1} \sum_{i=1}^n P(\epsilon_i \leq v) \). We recommend \( W = 2 \), which permits a wide class of marginal distributions of errors, in particular it allows \( F_{\epsilon} \) to have tails as heavy as those of \( t(a) \) with \( a > 5 \). This method also achieves (4.2); see Section C.1 of supplementary material [2].

The following is a set of simple sufficient conditions which yields practical corollaries. Let \( \ell_n / \phi_n \) be a sequence of positive constants.

Condition P. The noise and regressors obey \( \text{sup}_{n \geq 1} \mathbb{E}[|\epsilon|^q] < \infty, q > 4, \) \( \text{inf}_{n \geq 1} \min_{1 \leq j \leq p} \mathbb{E}_n[|x_j^2\epsilon|] > 0, \) \( \text{sup}_{n \geq 1} \max_{1 \leq j \leq p} \mathbb{E}_n[|x_j^3\epsilon|] < \infty \) and \( \text{sup}_{n \geq 1} \phi_{\max}(s\ell_n, \mathbb{E}_n[x'x]) / \phi_{\min}(s\ell_n, \mathbb{E}_n[x'x]) < \infty \).
Moreover, we have that \( \max_{i \leq n, j \leq p} |x_{ij}|^2/\ell_n = o(1) \), \( \log p \leq C(n / \log^2 n)^{1/3} \), \( \ell_n^2 s \log(p \vee n) \leq Cn / \log n \), \( s \geq 1 \), and \( c_s^2 \leq C\sigma^2(s \log(p \vee n)/n) \).

Condition \( P \) imposes conditions on moments that allow us to use results of the moderate deviation theory for self-normalized sums, weak requirements on \((s, p, n)\), well behaved sparse eigenvalues as a sufficient condition on the design to bound the impact factors and a mild condition on the approximation errors (see Remark 2 for a discussion and references).

The proofs in this section rely on the following result due to [33].

**Lemma 4** (Moderate deviations for self-normalized sums). Let \( X_1, \ldots, X_n \) be independent, zero-mean random variables and \( \delta \in (0, 1] \). Let \( S_{n,n} = n\mathbb{E}_n[X], V_{n,n} = n\mathbb{E}_n[X^2], M_n = \{ \mathbb{E}[|X|^{2+\delta}] / \{ \mathbb{E}[X^2] \}^{1/2} \} < \infty \) and \( J_n \leq n^{\delta/(2(2+\delta))} M_n^{-1} \). For some absolute constant \( A \), uniformly on \( 0 \leq |x| \leq n^{\delta/(2(2+\delta))} M_n^{-1}/J_n - 1 \), we have

\[
\left| P(S_{n,n}/V_{n,n} \geq x) - \left( 1 - \Phi(x) \right) \right| \leq A \frac{J_n^{2+\delta}}{n^{2+\delta}}.
\]

The following theorem summarizes the asymptotic performance of \( \sqrt{\text{Lasso}} \), based upon Algorithm 1, for commonly used designs.

**Theorem 7** (Performance of \( \sqrt{\text{Lasso}} \) and ols post \( \sqrt{\text{Lasso}} \) under Condition \( P \)). Suppose Conditions \( \text{ASM} \) and \( P \) hold. Let \( \alpha \in (1/n, 1/\log n) \), \( c \geq 1.01 \), the penalty level \( \lambda \) be set as in (4.1) and the penalty loadings as in Algorithm 1. Then for all \( n \geq n_0 \), with probability at least \( 1 - \alpha \{ 1 + \tilde{C} / \log n \} - \tilde{C} \{ n^{-1/2} \log n + n^{1-q/4} \} \) we have

\[
\| \hat{\beta} - \beta_0 \|_{2,n} \leq \sigma \tilde{C} \sqrt{\frac{s \log(n \vee (p/\alpha))}{n}},
\]

\[
\sqrt{\mathbb{E}_n[(f - x'\hat{\beta})^2]} \leq \sigma \tilde{C} \sqrt{\frac{s \log(n \vee (p/\alpha))}{n}},
\]

\[
\| \hat{\beta} - \beta_0 \|_1 \leq \sigma \tilde{C} \sqrt{\frac{s^2 \log(n \vee (p/\alpha))}{n}} \quad \text{and} \quad |\text{supp}(\hat{\beta})| \leq \tilde{C}s,
\]

where \( n_0 \) and \( \tilde{C} \) depend only on the constants in Condition \( P \). Moreover, the ols post \( \sqrt{\text{Lasso}} \) estimator satisfies with the same probability for all \( n \geq n_0 \),

\[
\| \hat{\beta} - \beta_0 \|_{2,n} \leq \sigma \tilde{C} \sqrt{\frac{s \log(n \vee (p/\alpha))}{n}},
\]

\[
\sqrt{\mathbb{E}_n[(f - x'\hat{\beta})^2]} \leq \sigma \tilde{C} \sqrt{\frac{s \log(n \vee (p/\alpha))}{n}} \quad \text{and}
\]
\[ \|\hat{\beta} - \beta_0\|_1 \leq \sigma \tilde{C} \sqrt{\frac{s^2 \log(n \vee (p/\alpha))}{n}}. \]

**Remark 9** (Gaussian-like performance and normalization assumptions). Theorem 7 yields bounds on the estimation errors that are “Gaussian-like,” namely the factor \( \sqrt{\log(p/\alpha)} \) and other constants in the performance bound are the same as if errors were Gaussian, but the probabilistic guarantee is not \( 1 - \alpha \) but rather \( 1 - \alpha + o(1) \), which together with mildly more restrictive growth conditions is the cost of non-Gaussianity. We also note that the normalization \( E_n[x_j^2] = 1, j = 1, \ldots, p \) is not used in the construction of the estimator, and the results of the theorem hold under the condition:

\[ C_1 \leq E_n[x_j^2] \leq C_2, j = 1, \ldots, p \] uniformly for all \( n \geq n_0 \), for some positive, finite constants \( C_1 \) and \( C_2 \).

The results above establish that \( \sqrt{\text{Lasso}} \) achieves the same near oracle rate of convergence as Lasso despite not knowing the scaling parameter \( \sigma \). They allow for heteroscedastic errors with mild restrictions on its moments. Moreover, it allows for an arbitrary number of iterations. The results also establish that the upper bounds on the rates of convergence of \( \sqrt{\text{Lasso}} \) and \( \text{ols post} \sqrt{\text{Lasso}} \) coincide under these conditions. This is confirmed also by Monte–Carlo experiments reported in the supplementary material [2], with \( \text{ols post} \sqrt{\text{Lasso}} \) performing no worse and often outperforming \( \sqrt{\text{Lasso}} \) due to having a much smaller bias. Notably, this theoretical and practical performance occurs despite the fact that \( \sqrt{\text{Lasso}} \) may in general fail to correctly select the oracle model \( T \) as a subset and potentially select variables not in \( T \).

**Example S** (Performance for Sobolev balls and \( p \)-rearranged Sobolev balls). In this example, we show how our results apply to an important class of Sobolev functions, and illustrates how modern selection drastically reduces the dependency on knowing the order of importance of the basis functions.

Suppose that \( z_i \)'s are generated as i.i.d. from Uniform(0, 1), \( x_i \)'s are formed as \( (x_{ij})_{j=1}^p \) with \( x_{ij} = P_j(z_i), \sigma = 1, \) and \( \varepsilon_i \sim N(0,1) \). Following [45], consider an orthonormal bounded basis \( \{P_j(\cdot)\}_{j=1}^{\infty} \) in \( L^2[0,1] \), consider functions \( f(z) = \sum_{j=1}^{\infty} \theta_j P_j(z) \) in a Sobolev space \( S(\alpha,L) \) for some \( \alpha \geq 1 \) and \( L > 0 \). This space consists of functions whose Fourier coefficients \( \theta \) satisfy \( \sum_{j=1}^{\infty} |\theta_j| < \infty \) and

\[ \theta \in \Theta(\alpha,L) = \left\{ \theta \in \ell^2(\mathbb{N}): \sum_{j=1}^{\infty} j^{2\alpha} |\theta_j|^2 \leq L^2 \right\}. \]

We also consider functions in a \( p \)-rearranged Sobolev space \( \mathcal{R}S(\alpha,p,L) \). These functions take the form \( f(z) = \sum_{j=1}^{\infty} \theta_j P_j(z) \) such that \( \sum_{j=1}^{\infty} |\theta_j| < \infty \)
and $\theta \in \Theta^R(\alpha,p,L)$, where

$$\Theta^R(\alpha,p,L) = \left\{ \theta \in \ell^2(N) : \exists \text{ permutation } \Upsilon : \{1,\ldots,p\} \to \{1,\ldots,p\}, \sum_{j=1}^p j^{2\alpha} \theta^2_{\Upsilon(j)} + \sum_{j=p+1}^{\infty} j^{2\alpha} \theta^2_j \leq L^2 \right\}.$$  

Note that $S(\alpha,L) \subset RS(\alpha,p,L)$.

In the supplementary material [2], we show that the rate-optimal choice for the size of the support of the oracle model $\beta_0$ is $s \lesssim n^{1/[2\alpha+1]}$. This rate can be achieved with the support consisting of indices $j$ that correspond to the $s$ largest coefficients $|\theta_j|$. The oracle projection estimator $\hat{\beta}^{\text{for}}$ that uses these “ideal” $s$ components achieves optimal prediction error rate uniformly over the regression functions $f \in S(\alpha,L)$ or $f \in RS(\alpha,p,L)$: $(E_n[(f - \sum_{j=1}^{\infty} \hat{\beta}^{\text{for}}_j P_j(z))^2])^{1/2} \lesssim_p n^{-\alpha/[2\alpha+1]}$. Under mild regularity conditions, as in Theorem 7, $\sqrt{\text{Lasso}}$ estimator $\hat{\beta}$ that uses $x_i = (P_1(z_i),\ldots,P_p(z))^\top$ achieves near-optimal rate uniformly over the regression functions $f \in S(\alpha,L)$ or $f \in RS(\alpha,p,L)$:

$$(E_n[(f - x^\top \hat{\beta})^2])^{1/2} \lesssim_p n^{-\alpha/[2\alpha+1]} \log(n \vee p),$$

without knowing the “ideal” $s$ components among $x_i$. The same statement also holds for the ols post $\sqrt{\text{Lasso}}$ estimator $\hat{\beta}$.

Therefore, the $\sqrt{\text{Lasso}}$ and ols post $\sqrt{\text{Lasso}}$ estimators achieve near oracle rates uniformly over rearranged Sobolev balls under mild conditions. As a contrast, consider the “naive oracle” series projection estimator that uses the first $s$ components of the basis, assuming that the parameter space is $S(\alpha,L)$. This estimator achieves the optimal rate for the Sobolev space $S(\alpha,L)$, but fails to be uniformly consistent over $p$-rearranged Sobolev space $RS(\alpha,p,L)$, since we can select a model $f \in RS(\alpha,p,L)$ such that its first $s$ Fourier coefficients are zero, and the remaining coefficients are nonzero, therefore, the “naive oracle” fit will be 0 plus a centered noise, and the estimator will be inconsistent for this $f$.

We proceed to state a result on estimation of $\sigma^2$ under the asymptotic framework.

**Corollary 2 (Estimation of $\sigma^2$ under asymptotics).** Suppose Conditions ASM and $P$ hold. Let $\alpha \in (1/n,1/\log n)$, $c \geq 1.01$, the penalty level $\lambda$ be set as in (4.1) and the penalty loadings as in Algorithm 1. Then for all $n \geq n_0$, with probability at least $1 - \alpha\{1 + C/\log n\} - C\{n^{-1/2} \log n + n^{1-q/4}\} - 2\delta$,

$$|\hat{Q}(\hat{\beta}) - \sigma^2| \leq \frac{\sigma^2 C s \log(n \vee (p/\alpha))}{n} + \frac{\sigma^2 C \sqrt{s \log(p \vee n)}}{\sqrt{\delta n^{1-1/q}}} + \frac{\sigma^2 C}{\sqrt{\delta n}}.$$
Moreover, provided further that $s^2 \log^2 (p \vee n) \leq Cn / \log n$, we have that

$$\{\sigma^2 \xi_n\}^{-1} n^{1/2} (\hat{Q}(\hat{\beta}) - \sigma^2) \Rightarrow N(0,1),$$

where $\xi_n^2 = \bar{E} [\{\varepsilon^2 - E[\varepsilon^2]\}^2]$.

This result extends [6, 44] to the heteroscedastic, non-Gaussian cases.

5. An application to a generic semi-parametric inference problem. In this section, we present a generic application of the methods of this paper to semiparametric problems, where some lower-dimensional structural parameter is of interest and the $\sqrt{\text{Lasso}}$ or ols post $\sqrt{\text{Lasso}}$ are used to estimate the high-dimensional nuisance function. We denote the true value of the target parameter by $\theta_0 \in \Theta \subset \mathbb{R}^d$, and assume that it satisfies the following moment condition:

$$E[\psi(w_i, \theta_0, h_0(z_i))] = 0, \quad i = 1, \ldots, n,$$

where $w_i$ is a random vector taking values in $W$, containing vector $z_i$ taking values in $Z$ as a subcomponent; the function $(w, \theta, t) \mapsto \psi(w, \theta, t) = (\psi_j(w, \theta, t))_{j=1}^d$ is a measurable map from an open neighborhood of $W \times \Theta \times T$, a subset of $\mathbb{R}^{d_w + d + d_t}$, to $\mathbb{R}^d$, and $z \mapsto h_0(z) = (h_{0m}(z))_{m=1}^M$ is the nuisance function mapping $Z$ to $T \subset \mathbb{R}^M$. We note that $M$ and $d$ are fixed and do not depend on $n$ in what follows.

Perhaps the simplest, that is linear, example of this kind arises in the instrumental variable (IV) regression problem in [3, 8], where $\psi(w_i, \theta_0, h_0(z_i)) = (u_i - \theta_0 d_i) h_0(z_i)$, where $u_i$ is the response variable, $d_i$ is the endogenous variable, $z_i$ is the instrumental variable, $h_0(z_i) = E[d_i | z_i]$ is the optimal instrument, and $E[(u_i - \theta_0 d_i) z_i] = 0$. Other examples include partially linear models, heterogeneous treatment effect models, nonlinear instrumental variable, $Z$-problems as well as many others (see, e.g., [1, 3, 7, 9–11, 13, 20, 28, 29, 31, 32, 49, 55, 56]), which all give rise to nonlinear moment conditions with respect to the nuisance functions.

We assume that the nuisance functions $h_0$ arise as conditional expectations of some variables that can be modeled and estimated in the approximately sparse framework, as formally described below. For instance, in the example mentioned above, the function $h_0$ is indeed a conditional expectation of the endogenous variable given the instrumental variable. We let $\hat{h} = (\hat{h}_m)_{m=1}^M$ denote the estimator of $h_0$, which obeys conditions stated below. The estimator $\hat{\theta}$ of $\theta_0$ is constructed as any approximate $\varepsilon_n$-solution in $\Theta$ to a sample analog of the moment condition above:

$$\|E_n[\psi(w, \hat{\theta}, \hat{h}(z))]| | \leq \varepsilon_n \quad \text{where} \quad \varepsilon_n = o(n^{-1/2}).$$
The key condition needed for regular estimation of $\theta_0$ is the orthogonality condition:

\begin{equation}
E[\partial_i \psi(w_i, \theta_0, h_0(z_i))|z_i] = 0, \quad i = 1, \ldots, n,
\end{equation}

where here and below we use the symbol $\partial_i$ to abbreviate $\frac{\partial}{\partial w_i}$. For instance, in the IV example this condition holds, since $\partial_i \psi(w_i, \theta_0, h_0(z_i)) = (u_i - \theta_0 d_i)$ and $E[(u_i - \theta_0 d_i)|z_i] = 0$ by assumption. In other examples, it is important to construct the scores that have this orthogonality property. Generally, if we have a score, which identifies the target parameter but does not have the orthogonality property, we can construct the score that has the required property by projecting the original score onto the orthocomplement of the tangent space for the nuisance parameter; see, for example, [36, 50, 51] for detailed discussions. This often results in a semiparametrically efficient score function.

The orthogonality condition reduces sensitivity to “crude” estimation of the nuisance function $h_0$. Indeed, under appropriate sparsity assumptions stated below, the estimation errors for $h_0$, arising as sampling, approximation, and model selection errors, will be of order $o_P(n^{-1/4})$. The orthogonality condition together with other conditions will guarantee that these estimation errors do not impact the first-order asymptotic behavior of the estimating equations, so that

\begin{equation}
\sqrt{n} E_n[\psi(w, \hat{\theta}, \hat{h}(z))] = \sqrt{n} E_n[\psi(w, \hat{\theta}, h_0(z))] + o_P(1).
\end{equation}

This leads us to a regular estimation problem, despite $\hat{h}$ being highly nonregular.

In what follows, we shall denote by $c$ and $C$ some positive constants, and by $L_n$ a sequence of positive constants that may grow to infinity as $n \to \infty$.

**CONDITION SP.** For each $n$, we observe the independent data vectors $(w_i)_{i=1}^n$ with law determined by the probability measure $P = P_n$. Uniformly, for all $n$ the following conditions hold. (i) The true parameter values $\theta_0$ obeys (5.1) and is interior relative to $\Theta$, namely there is a ball of fixed positive radius centered at $\theta_0$ contained in $\Theta$, where $\Theta$ is a fixed compact subset of $\mathbb{R}^d$. (ii) The map $\nu \mapsto \psi(w, \nu)$ is twice continuously differentiable with respect to $\nu = (\nu_k)_{k=1}^K = (\theta, t)$ for all $\nu \in \Theta \times T$, where $T$ is convex, with $\sup_{\nu \in \Theta \times T} |\partial_{\nu_k} \partial_{\nu_j} \psi_j(w_i, \nu)| \leq L_n$ a.s., for all $k, r \leq K, j \leq d$, and $i \leq n$. The conditional second moments of the first derivatives are bounded as follows: P-a.s. $E(\sup_{\nu \in \Theta \times T} |\partial_{\nu_k} \psi_j(w_i, \nu)|^2|z_i) \leq C$ for each $k, j$ and $i$. (iii) The orthogonality condition (5.3) holds. (iv) The following identifiability condition holds: for all $\theta \in \Theta$, $\|E[\psi(w, \theta, h_0(z))]\| \geq 2^{-1}\|J_n(\theta - \theta_0)\| c)$, where $J_n := E[\partial_\theta \psi(w, \theta_0, h_0(z))]$ has singular values bounded away from zero and above. (v) $E[\|\psi(w, \theta_0, h_0(z))\|^3]$ is bounded from above.
In addition to the previous conditions, Condition SP imposes standard identifiability and certain smoothness on the problem, requiring second derivatives to be bounded by $L_n$, which is allowed to grow with $n$ subject to restrictions specified below. It is possible to allow for nondifferentiable $\psi$ at the cost of a more complicated argument; see [11]. In what follows, let $\delta_n \searrow 0$ be a sequence of constants approaching zero from above.

**Condition AS.** The following conditions hold for each $n$. (i) The function $h_0 = (h_{0m})_{m=1}^M : \mathcal{Z} \mapsto T$ is approximately sparse, namely, for each $m$, $h_{0m}(\cdot) = \sum_{i=1}^p P_{mi}(\cdot) \hat{\beta}_{0mi} + r_m(\cdot)$, where $P_{mi} : \mathcal{Z} \mapsto \mathbb{R}$ are approximating functions, $\hat{\beta}_{0mi} = (\hat{\beta}_{0mi})_{i=1}^p$ obeys $|\text{supp}(\hat{\beta}_{0mi})| \leq s$, $s \geq 1$, and the approximation errors $(r_m)_{m=1}^M : \mathcal{Z} \mapsto \mathbb{R}$ obey $\mathbb{E}[r_m^2(z)] \leq C \log(p \vee n)/n$. There is an estimator $\hat{h}_m(\cdot) = \sum_{i=1}^p P_{mi}(\cdot) \hat{\beta}_{mi}$ of $h_{0m}$ such that, with probability at least $1 - \delta_n$, $\hat{h}_m = (\hat{h}_m)_{m=1}^M$ maps $\mathcal{Z}$ into $T$, $\hat{\beta}_m = (\hat{\beta}_m)_{i=1}^p$ satisfies $\|\hat{\beta}_m - \beta_{0m}\|_1 \leq C \sqrt{s^2 \log(p \vee n)/n}$ and $\mathbb{E}[(\hat{h}_m(z) - h_{0m}(z))^2] \leq C \log(p \vee n)/n$ for all $m$. (ii) The scalar random variables $\psi_{mjl}(w_l) := \partial_{w_l} \psi_{j}(w_l, \theta_0, h_{0}(z)) P_{ml}(z_l)$ obey $\max_{m,j,l} \mathbb{E}[(\psi_{mjl}(w_l))^2] \leq L_n^2$ with probability at least $1 - \delta_n$ and $\max_{m,j,l} (\mathbb{E}[\psi_{mjl}(w_l)^3]/(\mathbb{E}[\psi_{mjl}(w_l)^2])^{1/2} \leq M_n$. (iii) Finally, the following growth restrictions hold as $n \to \infty$:

$$L_n^2 s^2 \log^2(p \vee n)/n \to 0 \quad \text{and} \quad \log(p \vee n)n^{-1/3} M_n^2 \to 0.$$  

The assumption records a formal sense in which approximate sparsity is used, as well as requires reasonable behavior of the estimator $\hat{h}$. In the previous sections, we established primitive conditions under which this behavior occurs in problems where $h_0$ arise as conditional expectation functions. By virtue of (5.5) the assumption implies that $\{\mathbb{E}_n(\hat{h}_m(z) - h_{0}(m(z))^2\}^{1/2} = o_P(n^{-1/4})$. It is standard that the square of this term multiplied by $\sqrt{n}$ shows up as a linearization error for $\sqrt{n}(\hat{\theta} - \theta_0)$ and, therefore, this term does not affect its first-order behavior. Moreover, the assumption implies by virtue of (5.5) that $\|\hat{\beta}_m - \beta_{0m}\|_1 = o_P(L_n^{-1}(\log(p \vee n))^{-1})$, which is used to control another key term in the linearization as follows:

$$\sqrt{n} \max_{j,m,l} \mathbb{E}_n[\psi_{mjl}(w)]\|\hat{\beta}_m - \beta_{0m}\|_1 \leq P L_n \sqrt{\log(p \vee n)} \|\hat{\beta}_m - \beta_{0m}\|_1 = o_P(1),$$

where the bound follows from an application of the moderate deviation inequalities for self-normalized sums (Lemma 4). The idea for this type of control is borrowed from [3], who used it in the IV model above.

**Theorem 8.** Under Conditions SP and AS, the estimator $\hat{\theta}$ that obeys equation (5.2) and $\hat{\theta} \in \Theta$ with probability approaching 1, satisfies $\sqrt{n}(\hat{\theta} - \theta_0) = -J_n^{-1} \sum_{i=1}^n \psi(w_i, \theta_0, h_0(z_i)) + o_P(1)$. Furthermore, provided $\Omega_n = \mathbb{E}[\psi(w, \theta_0, h_0(z))\psi(w, \theta_0, h_0(z))']$ has eigenvalues bounded away from zero, $\Omega_n^{-1/2} J_n \sqrt{n}(\hat{\theta} - \theta_0) \Rightarrow N(0, I)$. 

This theorem extends the analogous result in [3, 8] for a specific linear problem to a generic nonlinear setting, and could be of independent interest in many problems cited above. The theorem allows for the probability measure $P = P_n$ to change with $n$, which implies that the confidence bands based on the result have certain uniform validity (“honesty”) with respect to $P$, as formalized in [10], thereby constructively addressing [37]’s critique. See [11] for a generalization of the result above to the case $\dim(\theta_0) \gg n$.

**Example PL.** It is instructive to conclude this section by inspecting the example of approximately sparse partially linear regression [9, 10], which also nests the sparse linear regression model [55]. The partially linear model of [41] is

$$y_i = d_i \theta_0 + g(z_i) + \varepsilon_i,$$

$$E[\varepsilon_i | z_i, d_i] = 0,$$

$$d_i = m(z_i) + v_i,$$

$$E[v_i | z_i] = 0.$$

The target is the real parameter $\theta_0$, and an orthogonal score function $\psi$ for this parameter is $\psi(w_i, \theta, t) = (y_i - \theta(d_i - t_2) - t_1)(d_i - t_2)$, where $t = (t_1, t_2)'$ and $w_i = (y_i, d_i, z_i)'$. Let $\ell(z_i) := \theta_0 m(z_i) + g(z_i)$, and $h_0(z_i) := (\ell(z_i), m(z_i))' = (E[y_i | z_i], E[d_i | z_i])'$. Note that

$$E[\psi(w_i, \theta_0, h_0(z_i)) | z_i] = 0$$

and

$$E[\partial_t \psi(w_i, \theta, h_0(z_i)) | z_i] = 0,$$

so the orthogonality condition holds. If the regression functions $\ell(z_i)$ and $m(z_i)$ are approximately sparse with respect to $x_i = P(z_i)$, we can estimate them by $\sqrt{\text{Lasso}}$ or ols post $\sqrt{\text{Lasso}}$ regression of $y_i$ on $x_i$ and $d_i$ on $x_i$, respectively. The resulting estimator $\hat{\theta}$ of $\theta_0$, defined as a solution to (5.2), is a $\sqrt{\text{Lasso}}$ analog of Robinson’s [41] estimator. If assumptions of Theorem 8 hold, $\hat{\theta}$ obeys

$$\Omega_n^{-1/2} J_n \sqrt{\Omega_n} (\hat{\theta} - \theta_0) \Rightarrow N(0, 1)$$

for $J_n = E[v^2]$ and $\Omega_n = E[\varepsilon^2 v^2]$. In a homoscedastic model, $\hat{\theta}$ is semiparametrically efficient, since its asymptotic variance $\Omega_n / J_n^2$ reduces to the efficiency bound $E[\varepsilon^2] / E[\varepsilon^2]$ of Robinson [41]; as pointed out in [9, 10]. In the linear regression model, this estimator is first-order equivalent to, but different in finite samples from, a one-step correction from the scaled Lasso proposed in [55]; in the partially linear model, it is equivalent to the post-double selection method of [9, 10].

**APPENDIX A: PROOFS OF SECTION 3**

**Proof of Lemma 1.** The first result holds by the inequalities given in the main text.
To show the next statement, note that $T$ does not change by including repeated regressors (indeed, since $T$ is selected by the oracle (2.2), $T$ will not contain repeated regressors). Let $R$ denote the set of repeated regressors and $\tilde{x}_i = (x'_i, z'_i)$ where $x_i \in \mathbb{R}^p$ is the vector of original regressors and $z_i \in \mathbb{R}^{|R|}$ the vector of repeated regressors. We denote by $\hat{\Gamma}$ and $\| \cdot \|_{2,\hat{\alpha}}$ the penalty loadings and the prediction norm associated with $(\tilde{x}_i)^T$. Let $\delta = (\delta_1', \delta_2')'$, where $\delta_1 \in \mathbb{R}^p$ and $\delta_2 \in \mathbb{R}^{|R|}$, define $\hat{\delta} \in \mathbb{R}^p$ so that $\hat{\delta}_j^{\hat{\alpha}} = \delta_j^2$ if $j \in R$, and $\hat{\delta}_j = 0$ if $j \notin R$, and denote $\hat{\delta} = \delta^1 + \delta^2$. It follows that

$$L \geq \frac{\|\delta\|_{2,\hat{\alpha}}}{\|\hat{\Gamma}\delta_T\|_1 - \|\hat{\Gamma}\delta_T^c\|_1} = \frac{\|\delta\|_{2,n}}{\|\hat{\Gamma}\delta_T\|_1 - \|\hat{\Gamma}\delta_T^c\|_1 - \|\hat{\Gamma}\delta_T^c\|_1},$$

which is minimized in the case that $\delta_1 = \delta$ and $\delta_2 = 0$. Thus, the worst case for $\hat{\kappa}$ correspond to $\hat{\delta}_2 = 0$ which corresponds to ignoring the repeated regressors. $\square$

**Proof of Lemma 2.** The first part is shown in the main text. The second part is proven in supplementary material [2]. $\square$

**Proof of Lemma 3.** By definition of $\hat{\beta}$, $\sqrt{\hat{Q}(\hat{\beta})} - \sqrt{\hat{Q}(\beta_0)} \leq \frac{\lambda}{n} \|\Gamma\beta_0\|_1 - \frac{\Delta}{n} \|\Gamma\hat{\beta}\|_1$. By convexity of $\sqrt{\hat{Q}}$, by $-\tilde{S} \in \partial \sqrt{\hat{Q}(\beta_0)}$, and by $\lambda/n \geq c||\Gamma^{-1}\tilde{S}||_{\infty}$, we have $\sqrt{\hat{Q}(\hat{\beta})} - \sqrt{\hat{Q}(\beta_0)} \geq -\tilde{S}'\hat{\delta} \geq -\|\Gamma^{-1}\tilde{S}\|_{\infty} \|\hat{\delta}\|_1 \geq -\frac{\Delta}{cn} \|\Gamma\hat{\delta}\|_1$ where $\hat{\delta} = \hat{\beta} - \beta_0$. Combining the lower and upper bounds yields $\|\Gamma\hat{\delta}\|_1 \geq c(||\Gamma(\beta_0 + \hat{\delta})||_1 - ||\Gamma\beta_0||_1)$. Thus, $\hat{\delta} \in R_c$; that $\hat{\delta} \in \Delta_\varepsilon$ follows by a standard argument based on elementary inequalities. $\square$

**Proof of Theorem 1.** First, note that by Lemma 3 we have $\hat{\delta} := \hat{\beta} - \beta_0 \in R_c$. By optimality of $\hat{\beta}$ and definition of $\hat{\kappa}$, $\hat{\zeta} = \lambda \sqrt{s}/[\hat{n}\hat{\kappa}]$, we have

(A.1) \hspace{1cm} \sqrt{\hat{Q}(\hat{\beta})} - \sqrt{\hat{Q}(\beta_0)} \leq \frac{\lambda}{n} \|\Gamma\beta_0\|_1 - \frac{\lambda}{n} \|\Gamma\hat{\beta}\|_1 \leq \hat{\zeta} \|\hat{\delta}\|_{2,n}.$$

Multiplying both sides by $\sqrt{\hat{Q}(\hat{\beta})} + \sqrt{\hat{Q}(\beta_0)}$ and since $(a+b)(a-b) = a^2 - b^2$

(A.2) \hspace{1cm} \|\hat{\delta}\|_{2,n}^2 \leq 2E_n[(\sigma \varepsilon + r)x'\hat{\delta}] + (\sqrt{\hat{Q}(\hat{\beta})} + \sqrt{\hat{Q}(\beta_0)})\hat{\zeta} \|\hat{\delta}\|_{2,n}.$$

From (A.1), we have $\sqrt{\hat{Q}(\hat{\beta})} \leq \sqrt{\hat{Q}(\beta_0)} + \hat{\zeta} \|\hat{\delta}\|_{2,n}$ so that

$$\|\hat{\delta}\|_{2,n}^2 \leq 2E_n[(\sigma \varepsilon + r)x'\hat{\delta}] + 2\sqrt{\hat{Q}(\beta_0)}\hat{\zeta} \|\hat{\delta}\|_{2,n} + \hat{\zeta}^2 \|\hat{\delta}\|_{2,n}^2.$$
Since \(|\mathbb{E}[(\sigma_r + r)\cdot x]\| = \sqrt{\hat{Q}(\beta_0)}||S\| \leq \sqrt{\hat{Q}(\beta_0)}\hat{\sigma}_{\text{c}}||\delta||_{2,n}\), we obtain
\[
\|\hat{\delta}\|_{2,n}^2 \leq 2\sqrt{\hat{Q}(\beta_0)}\hat{\sigma}_{\text{c}}||\delta||_{2,n} + 2\sqrt{\hat{Q}(\beta_0)}\hat{\sigma}_{\text{c}}||\delta||_{2,n} + \hat{\zeta}^2||\delta||_{2,n}^2,
\]
and the result follows provided \(\hat{\zeta} < 1\). □

**Proof of Theorem 2.** We have \(\hat{\delta} := \hat{\beta} - \beta_0 \in R_{\hat{c}}\) under the condition that \(\lambda/n \geq c||\Gamma^{-1}\tilde{S}||_{\infty}\) by Lemma 3. We also have \(\hat{\zeta} = \lambda\sqrt{s}/[n\tilde{\kappa}] < 1\) by assumption.

First, we establish the upper bound. By the previous proof, we have inequality (A.1). The bound follows from Theorem 1 to bound \(||\hat{\delta}||_{2,n}\). To establish the lower bound, by convexity of \(\sqrt{Q}\) and the definition of \(\hat{\sigma}_{\text{c}}\) we have \(\sqrt{\hat{Q}(\hat{\beta})} - \sqrt{\hat{Q}(\beta_0)} \geq -\|\hat{S}\|\hat{\delta} - \hat{\sigma}_{\text{c}}||\delta||_{2,n}\). Thus, by Theorem 1 we obtain
\[
\sqrt{\hat{Q}(\hat{\beta})} - \sqrt{\hat{Q}(\beta_0)} \geq -2\sqrt{\hat{Q}(\beta_0)}\hat{\sigma}_{\text{c}}B_n.
\]
Moreover, by the triangle inequality
\[
|\sqrt{\hat{Q}(\hat{\beta})} - \sigma| \leq |\sqrt{\hat{Q}(\hat{\beta})} - \sigma\{\mathbb{E}n[\varepsilon^2]\}^{1/2}| + |\sigma\{\mathbb{E}n[\varepsilon^2]\}^{1/2} - 1|
\]
and the right-hand side is bounded by \(||\hat{\beta} - \beta_0||_{2,n} + c_s + \sigma||\mathbb{E}n[\varepsilon^2] - 1||\). □

**Proof of Theorem 3.** For notational convenience, we denote \(\phi_n(m) = \phi_{\max}(m, \Gamma^{-1}\mathbb{E}n[xx']\Gamma^{-1})\). We shall rely on the following lemma, whose proof is given after the proof of this theorem.

**Lemma 5 (Relating sparsity and prediction norm).** Under Condition ASM, let \(G \subseteq \text{supp}(\hat{\beta})\). For any \(\lambda > 0\), we have
\[
\frac{\lambda}{n}\sqrt{\hat{Q}(\hat{\beta})}\sqrt{|G|} \leq \sqrt{|G||\Gamma^{-1}\tilde{S}||_{\infty}}\sqrt{\hat{Q}(\beta_0)} + \sqrt{\phi_{\max}(|G\setminus T|, \Gamma^{-1}\mathbb{E}n[xx']\Gamma^{-1})||\hat{\beta} - \beta_0||_{2,n}}.
\]

Define \(\hat{m} := |\text{supp}(\hat{\beta}) \setminus T|\). In the event \(\lambda/n \geq c||\Gamma^{-1}\tilde{S}||_{\infty}\), by Lemma 5
\[
(A.3) \left(\sqrt{\frac{\hat{Q}(\hat{\beta})}{\hat{Q}(\beta_0)}} - \frac{1}{c}\right)\frac{\lambda}{n}\sqrt{\hat{Q}(\beta_0)}\sqrt{|\text{supp}(\hat{\beta})|} \leq \sqrt{\phi_n(\hat{m})||\hat{\beta} - \beta_0||_{2,n}}.
\]
Under the condition \(\hat{\zeta} = \lambda\sqrt{s}/[n\tilde{\kappa}] < 1\), we have by Theorems 1 and 2 that
\[
\left(1 - 2\hat{\sigma}_{\text{c}}B_n - \frac{1}{c}\right)\frac{\lambda}{n}\sqrt{\hat{Q}(\beta_0)}\sqrt{|\text{supp}(\hat{\beta})|} \leq \sqrt{\phi_n(\hat{m})2\sqrt{\hat{Q}(\beta_0)}B_n},
\]
where \( B_n = \frac{\varphi_n + \zeta}{1 - \varphi^2} \). Since we assume \( 2\varphi_n B_n \leq 1/(c\varphi) \), we have

\[
\sqrt{|\text{supp}(\hat{\beta})|} \leq 2\varphi \sqrt{\phi_n(m)\hat{m}} B_n = \sqrt{s} \sqrt{\phi_n(m) 2\varphi B_n / (c\kappa)},
\]

where the last equality follows from \( \hat{\zeta} = \lambda \sqrt{s}/[n\kappa] \).

Let \( L := 2\varphi B_n / (c\kappa) \). Consider any \( m \in \mathcal{M} \), and suppose \( \hat{m} > m \). Therefore, by the sublinearity of maximum sparse eigenvalues (see Lemma 3 in [6]), \( \phi_n(\ell m) \leq [\ell]\phi_n(m) \) for \( \ell \geq 1 \), and \( \hat{m} \leq |\text{supp}(\hat{\beta})| \) we have \( \hat{m} \leq s \cdot \max \frac{m}{m} |\phi_n(m)L^2 | \). Thus, since \( |k| < 2k \) for any \( k \geq 1 \) we have \( m < s \cdot 2\varphi_n(m)L^2 \) which violates the condition of \( m \in \mathcal{M} \) and \( s \). Therefore, we must have \( \hat{m} \leq m \). Repeating the argument once more with \( \hat{m} \leq m \) we obtain \( \hat{m} \leq s \cdot \phi_n(m)L^2 \). The result follows by minimizing the bound over \( m \in \mathcal{M} \).

To show the second part, by Lemma 2 and \( \lambda/n \geq c\|\Gamma^{-1}S\|_\infty \), we have \( \varphi \leq \frac{\lambda \sqrt{s}}{n\kappa} \). Lemma 1 yields \( \hat{\kappa} \geq \kappa \) and recall \( \hat{\zeta} = \lambda \sqrt{s}/[n\kappa] \). Therefore,

\[
B_n/(\hat{\zeta}) \leq \frac{1 + \{(\lambda \sqrt{s}/(n\kappa))((1 + \hat{\zeta})/c)\}\{n\kappa / (\lambda \sqrt{s})\}}{\lambda \sqrt{s} / (n\kappa)} \leq \frac{1 + (1 + \hat{\zeta})/c}{\kappa \hat{\zeta} / (1 - \hat{\zeta}^2)} = \frac{\hat{\zeta}}{\kappa \hat{\zeta} / (1 - \hat{\zeta}^2)} \leq \frac{\hat{\zeta}}{\kappa \hat{\zeta} / (1 - \hat{\zeta}^2)} \leq \frac{\hat{\zeta}}{\kappa \hat{\zeta} / (1 - \hat{\zeta}^2)} \leq \frac{2\varphi}{\kappa \varphi},
\]

where the last inequality follows from the condition \( \hat{\zeta} \leq 1/\sqrt{2} \). Thus, it follows that \( 4\varphi^2 (B_n)/(\hat{\zeta})^2 \leq (4\varphi^2 / \kappa \varphi)^2 \) which implies \( \mathcal{M}^* \subseteq \mathcal{M} \). □

**Proof of Lemma 5.** Recall that \( \Gamma = \text{diag}(\gamma_1, \ldots, \gamma_p) \). \( \hat{\beta} \) is the solution of a conic optimization problem (see Section H.1 of supplementary material [2]). Let \( \hat{a} \) denote the solution to its dual problem: \( \max_{a \in \mathbb{R}^n} \mathbb{E}_n[ya] : \|\Gamma^{-1}\mathbb{E}_n[x_ja]\|_\infty \leq \lambda/n, \|a\| \leq \sqrt{n} \). By strong duality \( \mathbb{E}_n[ya] = \|Y - \hat{X}\hat{\beta}\| / \sqrt{n} + \lambda \sum_{j=1}^p \gamma_j |\hat{\beta}_j| \). Moreover, by the first-order optimality conditions, \( \mathbb{E}_n[x_j\hat{a}] |\hat{\beta}_j| / n \) holds for every \( j = 1, \ldots, p \). Thus, we have

\[
\mathbb{E}_n[ya] = \|Y - \hat{X}\hat{\beta}\| / \sqrt{n} + \sum_{j=1}^p \mathbb{E}_n[x_j\hat{a}] |\hat{\beta}_j| = \|Y - \hat{X}\hat{\beta}\| / \sqrt{n} + \mathbb{E}_n \left[ \hat{a} \sum_{j=1}^p x_j |\hat{\beta}_j| \right] .
\]

Rearranging the terms, we have \( \mathbb{E}_n[(y - x\hat{\beta})\hat{a}] = \|Y - \hat{X}\hat{\beta}\| / \sqrt{n} \).

If \( \|Y - \hat{X}\hat{\beta}\| = 0 \), we have \( \sqrt{Q(\hat{\beta})} = 0 \) and the statement of the lemma trivially holds. If \( \|Y - \hat{X}\hat{\beta}\| > 0 \), since \( \|\hat{a}\| \leq \sqrt{n} \) the equality can only hold for \( \hat{a} = \sqrt{n} (Y - \hat{X}\hat{\beta}) / \|Y - \hat{X}\hat{\beta}\| = (Y - X\hat{\beta}) / \sqrt{Q(\hat{\beta})} \).
Next, note that for any $j \in \text{supp}(\hat{\beta})$ we have $E_n[x_j \hat{\alpha}] = \text{sign}(\hat{\beta}_j)\lambda \gamma_j/n$. Therefore, for any subset $G \subseteq \text{supp}(\hat{\beta})$ we have

$$\sqrt{Q(\hat{\beta})} \sqrt{|G|} \lambda$$

$$\leq \|\Gamma^{-1}(X'Y - \hat{X}\hat{\beta})_G\| + \|\Gamma^{-1}(X'X(\hat{\beta}_0 - \hat{\beta}))_G\|$$

$$\leq \sqrt{|G|n\|\Gamma^{-1}E_n[x(\sigma \varepsilon + r)]\|_\infty}$$

$$+ n \sqrt{\phi_{\max}([G \backslash T], \Gamma^{-1}E_n[xx']\Gamma^{-1})\|\hat{\beta} - \beta_0\|_2}$$

$$= \sqrt{|G|n\|Q(\hat{\beta})\|\|\Gamma^{-1}S\|_\infty}$$

$$+ n \sqrt{\phi_{\max}([G \backslash T], \Gamma^{-1}E_n[xx']\Gamma^{-1})\|\hat{\beta} - \beta_0\|_2},$$

where we used

$$\|\Gamma^{-1}(X'X(\hat{\beta} - \beta_0))_G\| \leq \sup_{\|\alpha\| \leq 1 \in \{G \backslash T\}, \|\alpha\|} \|\alpha\|^{1/2} X'X(\hat{\beta} - \beta_0)$$

Proof of Theorem 4. In this proof, let $f = (f_1, \ldots, f_n)'$, $R = (r_1, \ldots, r_n)'$, $\varepsilon = (\varepsilon_1, \ldots, \varepsilon_n)'$ ($n$-vectors) and $X = [x_1; \ldots; x_n]'$ (an $n \times p$ matrix). For a set of indices $S \subseteq \{1, \ldots, p\}$, define $P_S = X[S](X[S]'X[S])^{-1}X[S]'$, where we interpret $P_S$ as a null operator if $S$ is empty. We have that $f - X\hat{\beta} = (I - P_{\hat{T}})f - \sigma P_{\hat{T}}\varepsilon$, where $I$ is the identity operator. Therefore,

$$\sqrt{n}\|\beta_0 - \hat{\beta}\|_2 \leq \|X\beta_0 - X\hat{\beta}\|$$

$$= \|f - X\hat{\beta} - R\|$$

$$= \|(I - P_{\hat{T}})f - \sigma P_{\hat{T}}\varepsilon - R\|$$

$$\leq \|(I - P_{\hat{T}})f\| + \sigma\|P_{\hat{T}}\varepsilon\| + \|R\|$$

where \(\|R\| \leq \sqrt{n}c_s\). Since for $\hat{m} = [\hat{T}\backslash T]$, we have

$$\|X[\hat{T}](X[\hat{T}]'X[\hat{T}])^{-1}\|_{op} \leq \sqrt{1/\phi_{\min}(\hat{m}, E_n[xx'])} = \sqrt{1/\phi_{\min}(\hat{m})},$$

[where the bound is interpreted as $+\infty$ if $\phi_{\min}(\hat{m}) = 0$], the term $\|P_{\hat{T}}\varepsilon\|$ in (A.4) satisfies

$$\|P_{\hat{T}}\varepsilon\| \leq \sqrt{1/\phi_{\min}(\hat{m})}\|X[\hat{T}]'\varepsilon/\sqrt{n}\| \leq \sqrt{\hat{T}/\phi_{\min}(\hat{m})}\|X'\varepsilon/\sqrt{n}\|_\infty.$$
Therefore, we have $\|\hat{\beta} - \beta_0\|_{2,n} \leq \frac{\sigma \sqrt{s + m} \|E_n[xe]\|_{\infty}}{\sqrt{\phi_{\mu}(m)}} + c_s + c_{\hat{T}}$, where $c_{\hat{T}} = \min_{\beta \in \mathbb{R}^p} \sqrt{E_n[(f - x'\beta_{\hat{T}})^2]}$. Since supp($\hat{\beta}$) $\subseteq \hat{T}$ and (3.4) holds,

$$c_{\hat{T}} = \min_{\beta \in \mathbb{R}^p} \{E_n[(f - x'\beta)^2]\}^{1/2} \leq \{E_n[(f - x'\hat{\beta})^2]\}^{1/2} \leq c_s + \|\beta_0 - \hat{\beta}\|_{2,n} \leq c_s + 2\sqrt{\hat{Q}(\beta_0)}B_n,$$

where we have used Theorem 1. □

**Proof of Theorem 5.** Note that because $\sigma = 0$ and $c_s = 0$, we have $\sqrt{\hat{Q}(\beta_0)} = 0$ and $\sqrt{\hat{Q}(\hat{\beta})} = \|\hat{\beta} - \beta_0\|_{2,n}$. Thus, by optimality of $\hat{\beta}$ we have $\|\hat{\beta} - \beta_0\|_{2,n} + \frac{1}{\sqrt{n}} \|\Gamma\hat{\beta}\|_1 \leq \frac{1}{\sqrt{n}} \|\Gamma\beta_0\|_1$ which implies $\|\Gamma\hat{\beta}\|_1 \leq \|\Gamma\beta_0\|_1$. Moreover, $\delta = \hat{\beta} - \beta_0$ satisfies $\|\delta\|_{2,n} \leq \frac{1}{\sqrt{n}} \|\Gamma\beta_0\|_1 - \|\Gamma\hat{\beta}\|_1 \leq \zeta \|\delta\|_{2,n}$, where $\zeta = \frac{n^2}{\kappa^2} < 1$. Hence, $\|\delta\|_{2,n} = 0$.

Since $\|\Gamma\hat{\beta}\|_1 \leq \|\Gamma\beta_0\|_1$ implies $\delta \in \Delta_1$, it follows that $0 = \sqrt{s} \|\delta\|_{2,n} \geq \|\Gamma\delta\|_{1/\kappa_1 \geq \zeta \|\delta\|_1/\kappa_1}$, which implies that $\delta = 0$ if $\kappa_1 > 0$. □

**Proof of Theorem 6.** If $\lambda/n \geq c\|\Gamma^{-1}\tilde{S}\|_{\infty}$ and $\tilde{\zeta} = \lambda \sqrt{n}/[n\kappa] < 1$, by Theorem 1 we have $\|\hat{\beta} - \beta_0\|_{2,n} \leq 2\sqrt{\hat{Q}(\beta_0)}B_n$, and the bound on the prediction norm follows by $\sqrt{\hat{Q}(\beta_0)} \leq c_s + n\sqrt{E_n[\epsilon^2]}$.

Thus, we need to show that the choice of $\lambda$ and $\Gamma$ ensures the event $\lambda/n \geq c\|\Gamma^{-1}\tilde{S}\|_{\infty}$ with probability no less than $1 - \alpha - \eta_1 - \eta_2$. Since $\gamma_j = \max_{1 \leq i \leq n} |x_{ij}| \geq \epsilon_n^{-2}$ with probability $1$, the choice of $u_n$ we have

$$P\left(c\|\Gamma^{-1}\tilde{S}\|_{\infty} > \frac{\lambda}{n}\right) \leq P\left(\max_{1 \leq j \leq p} \frac{c[E_n|\sigma \epsilon + r_{xj}|]}{\gamma_j \sqrt{E_n[\epsilon^2]}} > \frac{\lambda}{n(1 + u_n)^{1/2}}\right) + \eta_1$$

$$
\leq I + II + \eta_1,
$$

$I := P\left(\max_{1 \leq j \leq p} \frac{|E_n[\epsilon x_j]|}{\gamma_j \sqrt{E_n[\epsilon^2]}} > \sqrt{2 \log(2p/\alpha)}\right)$,

$II := P\left(\frac{\|E_n[r x]\|_{\infty}}{\sqrt{E_n[\sigma^2]}} > (1 + u_n)^{1/2}\right)$.

We invoke the following lemma, which is proven in [6]—see step 2 of the proof of [6]'s Theorem 2; for completeness, supplementary material [2] also provides the proof.

**Lemma 6.** Under Condition ASM, we have $\|E_n[xr]\|_{\infty} \leq \min\{\frac{\epsilon_n}{\sqrt{n}}, c_s\}$. 

By Lemma 6, $\|E_n[x]\|_\infty \leq \sigma/\sqrt{n}$ and $P(E_n[\varepsilon^2] \leq \{1 + u_n\}^{-1}) \leq \eta_2$, we have $I \leq \ln P(\sqrt{E_n[\varepsilon^2]} \leq \{1 + u_n\}^{-1/2}) \leq \eta_2$. Also,

$$I \leq p \max_{1 \leq j \leq p} P\left(\frac{\sqrt{n E_n[\varepsilon x_j]}}{\sqrt{E_n[x_j^2 \varepsilon^2]}} > \sqrt{2 \log(2p/\alpha)}\right) \leq \alpha$$

where we used that $\gamma_j \sqrt{E_n[\varepsilon^2]} \geq \sqrt{E_n[x_j^2 \varepsilon^2]}$, the union bound, and the sub-Gaussian inequality for self-normalized sums stated in Theorem 2.15 of [25], since $\varepsilon_i$’s are independent and symmetric by assumption. □

**Proof of Corollary 1.** See supplementary material [2]. □

**APPENDIX B: PROOFS OF SECTION 4**

**Proof of Theorem 7.** The proof is given in supplementary material [2] and follows from Theorems 1–3 with the help of Lemma 7 in supplementary material [2]. □

**Proof of Corollary 2.** See supplementary material [2]. □

**APPENDIX C: PROOFS FOR SECTION 5**

**Proof of Theorem 8.** Throughout the proof, we use the notation

$$B(w) := \max_{j,k} \sup_{\nu \in \Theta \times T} |\partial_{\nu_k} \psi_j(w, \nu)|, \quad \tau_n := \sqrt{s \log(p \vee n)/n}.$$ 

Step 1. (A preliminary rate result.) In this step, we claim that $\|\hat{\theta} - \theta_0\| \leq \alpha\tau_n$. By definition, $\|E_n[\psi(w, \hat{\theta}, h_0(z))]\| \leq \varepsilon_n$ and $\hat{\theta} \in \Theta$ with probability $1 - o(1)$, which implies via triangle inequality that with the same probability:

$$\|E[\psi(w, \theta, h_0(z))]_{\theta = \hat{\theta}}\| \leq \varepsilon_n + I_1 + I_2 \leq \alpha\tau_n,$$

where $I_1$ and $I_2$ are defined in step 2 below, and the last bound also follows from step 2 below and from the numerical tolerance obeying $\varepsilon_n = o(n^{-1/2})$ by assumption. Since by Condition SP(iv), $2^{-1}(\|J_n(\hat{\theta} - \theta_0)\| \wedge c)$ is weakly smaller than the left-hand side of the display, we conclude that $\|\hat{\theta} - \theta_0\| \leq \alpha\tau_n$, using that singular values of $J_n$ are bounded away from zero uniformly in $n$ by Condition SP(v).

Step 2. (Define and bound $I_1$ and $I_2$.) We claim that:

$$I_1 := \sup_{\theta \in \Theta}\|E_n[\psi(w, \theta, h_0(z)) - E_n[\psi(w, \theta, h_0(z))]|_{\theta = \hat{\theta}}\| \leq \alpha\tau_n,$$

$$I_2 := \sup_{\theta \in \Theta}\|E_n[\psi(w, \theta, h_0(z)) - E[\psi(w, \theta, h_0(z))]|_{\theta = \hat{\theta}}\| \leq \alpha\tau_n.$$
Using Taylor’s expansion, for \( \hat{h}(z; \theta, j) \) denoting a point on a line connecting vectors \( h_0(z) \) and \( h(z) \), which can depend on \( \theta \) and \( j \),

\[
I_1 \leq \sum_{j=1}^{d} \sum_{m=1}^{M} \sup_{\theta \in \Theta} \| E_n[\partial_m \psi_j(w, \theta, \hat{h}(z; \theta, j))(\hat{h}_m(z) - h_{0m}(z))]/
\leq dM \{ E_n B^2(w) \}^{1/2} \max \{ E_n (\hat{h}_m(z) - h_{0m}(z))^2 \}^{1/2},
\]

where the last inequality holds by definition of \( B(w) \) given earlier and Hölder’s inequality. Since \( E B^2(w) \leq C \) by Condition SP(ii), \( E_n B^2(w) \lesssim_P 1 \) by Markov’s inequality. By this, by Condition AS(i), by \( d \) and \( M \) fixed, conclude that \( I_1 \lesssim_P \tau_n \).

Using Jain–Marcus’ theorem, as stated in Example 2.11.13 in [51], we conclude that \( \sqrt{n} I_2 \lesssim_P 1 \). Indeed the hypotheses of that example follow from the assumption that \( \Theta \) is a fixed compact subset of \( \mathbb{R}^d \), and from the Lipschitz property, \( \| \psi(w, \theta, h_0(z)) - \psi(w, \theta, h_0(z)) \| \leq \sqrt{d} B(w) \| \theta - \theta \| \) holding uniformly for all \( \theta \) and \( \mu \) in \( \Theta \), with \( E B^2(w) \leq C \).

**Step 3.** (Main step.) We have that \( \sqrt{n} \| E_n \psi(w, \theta, \hat{h}(z)) \| \leq \epsilon_n \sqrt{n} \). Application of Taylor’s theorem and the triangle inequality gives

\[
\| \sqrt{n} E_n \psi(w, \theta_0, h_0(z)) + J_n \sqrt{n} (\hat{h}(z) - \theta_0) \| \leq \epsilon_n + \| I_1 \| + \| I_2 \| + \| I_3 \| = o_P(1),
\]

where \( J_n = E \partial_\psi \psi(w, \theta_0, h_0(z)) \), the terms \( I_1 \), \( I_2 \) and \( I_3 \) are defined and bounded below in step 4; the \( o_P(1) \) bound follows from step 4 and from \( \epsilon_n \sqrt{n} = o(1) \) holding by assumption. Conclude using Condition SP(iv) that

\[
\| J_n^{-1} \sqrt{n} E_n \psi(w, \theta_0, h_0(z)) + \sqrt{n}(\hat{h}(z) - \theta_0) \| = o_P(1),
\]

which verifies the first claim of the theorem. Application of Liapunov’s central limit theorem in conjunction with Condition SP(v) and the conditions on \( \Omega_n \) imposed by the theorem imply the second claim.

**Step 4.** (Define and bound \( I_1, I_2 \) and \( I_3 \).) Let \( I_1 := (I_{1j})_{j=1}^d \) and \( I_2 := (I_{2j})_{j=1}^d \), where

\[
I_{1j} := \sum_{m=1}^{M} \sqrt{n} E_n[\partial_m \psi_j(w, \theta_0, h_0(z))(\hat{h}_m(z) - h_{0m}(z))],
\]

\[
I_{2j} := \sum_{r,k=1}^{K} \sqrt{n} E_n[\partial_{\theta_r} \partial_{\nu_r} \psi_j(w, \bar{\nu}(w); j) \{ \bar{\nu}_r(w) - \nu_0_r(w) \} \{ \nu_0_k(w) - \nu_0_k(w) \}],
\]

\[
I_{3j} := \sqrt{n} E_n \partial_{\theta_0} \psi(w, \theta_0, h_0(z)) - J_n(\hat{h}(z) - \theta_0),
\]

where \( \nu_0(w) := (\nu_0_k(w))_{k=1}^{K} := (\theta_0, h_0(z)'; j); \ K = d + M; \ \bar{\nu}(w) := (\bar{\nu}_k(w))_{k=1}^{K} := (\hat{\theta}', \tilde{h}(z)'; j), \) and \( \bar{\nu}(w; j) \) is a vector on the line connecting \( \nu_0(w) \)
and \( \hat{\nu}(w) \) that may depend on \( j \). We show in this step that \( \| II_1 \| + \| II_2 \| + \| II_3 \| \lesssim_P o(1) \).

The key portion of the proof is bounding \( II_1 \), which is very similar to the argument given in [3] (pages 2421–2423). We repeat it here for completeness. We split \( II_1 = III_1 + III_2 = (III_{1j})_{j=1}^d + (III_{2j})_{j=1}^d \), where

\[
III_{1j} := \sum_{m=1}^M \sqrt{n} \mathbb{E}_n \left[ \partial_{\nu_m} \psi_j(w, \theta_0, h_0(z)) \sum_{l=1}^p P_m(z) (\hat{\beta}_{ml} - \beta_{0ml}) \right],
\]

\[
III_{2j} := \sum_{m=1}^M \sqrt{n} \mathbb{E}_n [\partial_{\nu_m} \psi_j(w, \theta_0, h_0(z)) r_m(z)].
\]

Using Hölder inequality, \( \max_j |III_{1j}| \leq M \max_{j,m,l} |\sqrt{n} \mathbb{E}_n \hat{\psi}_{mj}(w)||\hat{\beta}_m - \beta_{0ml}|. \) By Condition AS(i) \( \max_m \| \hat{\beta}_m - \beta_{0ml} \|_1 \leq C \sqrt{s} r_n \) with probability at least \( 1 - \delta_n \). Moreover, using \( \mathbb{E} \hat{\psi}_{mj}(w_i) = 0 \) for all \( i \), which holds by the orthogonality property (5.3), and that \( \max_{j,m,l} \mathbb{E}_n |\hat{\psi}_{mj}(w)|^2 \leq L_n^2 \) with probability at least \( 1 - \delta_n \) by Condition AS(ii), we can apply Lemma 4 on the moderate deviations for self-normalized sums, following the idea in [3], to conclude that \( \max_{j,m,l} |\sqrt{n} \mathbb{E}_n \hat{\psi}_{mj}(w)| \leq \sqrt{2 \log(pn)} L_n \) with probability \( 1 - o(1) \). Note that this application requires the side condition \( \sqrt{2 \log(pn)} M_n n^{-1/6} = o(1) \) be satisfied for \( M_n \) defined in Condition AS(ii), which indeed holds by Condition AS(iii).

We now recall the details of this calculation:

\[
P \left( \max_{j,m,l} |\sqrt{n} \mathbb{E}_n \hat{\psi}_{mj}(w)| > \sqrt{2 \log(pn)} L_n \right)
\]

\[
\leq P \left( \max_{j,m,l} |\sqrt{n} \mathbb{E}_n \hat{\psi}_{mj}(w)| / \sqrt{\mathbb{E}_n |\hat{\psi}_{mj}(w)|^2} > \sqrt{2 \log(pn)} \right) + \delta_n
\]

\[
\leq dM p \max_{j,m,l} P \left( |\sqrt{n} \mathbb{E}_n \hat{\psi}_{mj}(w)| / \sqrt{\mathbb{E}_n |\hat{\psi}_{mj}(w)|^2} > \sqrt{2 \log(pn)} \right) + \delta_n
\]

\[
= dM p (1 - \Phi(\sqrt{2 \log(pn)}))(1 + o(1)) + \delta_n \leq dM p \frac{2}{pn} (1 + o(1)) + \delta_n = o(1),
\]

where the penultimate inequality occurs due to the application of Lemma 4 on moderate deviations for self-normalized sums. Putting bounds together we conclude that \( \| III_1 \| \leq \sqrt{d} \max_j |III_{1j}| \lesssim_P L_n \sqrt{\log(p \vee n)/n} \sqrt{s} r_n = o(1), \) where \( o(1) \) holds by the growth restrictions imposed in Condition AS(iii).

The bound on \( III_2 \) also follows similarly to [3]. \( III_2 \) is a sum of \( M \) terms, each having mean zero and variance of order \( s \log(p \vee n)/n = o(1) \). Indeed, the mean zero occurs because

\[
n^{-1/2} \sum_{i=1}^n \mathbb{E}[\partial_{\nu_m} \psi_j(w_i, \theta_0, h_0(z_i)) r_m(z_i)] = n^{-1/2} \sum_{i=1}^n \mathbb{E}[0 \cdot r_m(z_i)] = 0
\]
for each $m$th term, which holds by $E[\partial_{m} \psi_{j}(w_{i}, \theta_{0}, h_{0}(z_{i}))]|z_{i} = 0$, that is, the orthogonality property (5.3), and the law of iterated expectations. To derive the variance bound, note that for each $m$th term the variance is

$$n^{-1} \sum_{i=1}^{n} E[\{\partial_{m} \psi_{j}(w_{i}, \theta_{0}, h_{0}(z_{i}))\}^{2} r_{m}^{2}(z_{i})] \leq C E[r_{m}^{2}(z)] \leq C^{2} s \log(p \lor n)/n,$$

which holds by $E[\{\partial_{m} \psi_{j}(w_{i}, \theta_{0}, h_{0}(z_{i}))\}^{2}|z_{i}] \leq E[B^{2}(w)|z_{i}] \leq C$ a.s. by virtue of Condition \textbf{SP}(iii), and the law iterated expectations; the last bound in the display holds by \textbf{AS}(i). Hence, $\var(III_{2j}) \leq M^{2}C^{2} s \log(p \lor n)/n \lesssim s \log(p \lor n)/n = o(1)$. Therefore, $\|III_{2}\| \lesssim P \sqrt{s \log(p \lor n)/n} = o(1)$ by Chebyshev’s inequality.

To deduce that $\|II_{2}\| = o_{P}(1)$, we use Condition \textbf{AS}(i)–(iii), the claim of step 1, and Hölder inequalities, concluding that

$$\max_{j} \|II_{2j}\| \leq \sqrt{n} K^{2} L n \max_{k} \mathbb{E}_{n}\{\hat{v}_{k}(w) - \nu_{0k}(w)\}^{2} \lesssim P \sqrt{n} L n \tau_{n}^{2} = o(1).$$

Finally, since $\|III_{3}\| \leq \sqrt{n} \|J_{n} \mathbb{E}_{n} \partial_{\theta} \psi(w, \theta_{0}, h_{0}(z)) - J_{n}\|_{op} \|\hat{\theta} - \theta_{0}\|$ and since $\|\mathbb{E}_{n} \partial_{\theta} \psi(w, \theta_{0}, h_{0}(z)) - J_{n}\|_{op} \lesssim P n^{-1/2}$ by Chebyshev’s inequality, using that $\mathbb{E}B^{2}(w) \leq C$ by Condition \textbf{AS}(ii), and $\|\hat{\theta} - \theta_{0}\| \lesssim P \tau_{n}$ by step 1, conclude that $\|II_{3}\| \lesssim P \tau_{n} = o(1)$. \hfill \square

Acknowledgements. We are grateful to the Editors and two referees for thoughtful comments and suggestions, which helped improve the paper substantially. We also thank seminar participants at the 2011 Joint Statistical Meetings, 2011 INFORMS, Duke and MIT for many useful suggestions. We gratefully acknowledge research support from the NSF.

SUPPLEMENTARY MATERIAL

Supplementary material (DOI: 10.1214/14-AOS1204SUPP; .pdf). The material contains deferred proofs, additional theoretical results on convergence rates in $\ell_{2}, \ell_{1}$ and $\ell_{\infty}$, lower bound on the prediction rate, and Monte-Carlo simulations.
