Abstract

α–synuclein (α-syn) is a small lipid binding protein implicated in several neurodegenerative diseases, including Parkinson’s disease, whose pathobiology is conserved from yeast to man. There are no therapies targeting these underlying cellular pathologies, or indeed those of any major neurodegenerative disease. Using unbiased phenotypic screens as an alternative to target-based approaches, we discovered an N-aryl benzimidazole (NAB) that strongly and selectively protected diverse cell-types from α-syn toxicity. Three chemical genetic screens in wild-type yeast cells established that NAB promoted endosomal transport events dependent on the E3 ubiquitin ligase, Rsp5/Nedd4. These same steps were perturbed by α–syn itself. Thus, NAB identifies a druggable node in the biology of α-syn that can correct multiple aspects of its underlying pathology, including dysfunctional endosomal and ER-to-Golgi vesicle trafficking.

Phenotypic cell-based drug screens are a powerful yet underutilized approach to identify lead compounds and probe the underlying cellular pathologies that cause human disease (1). Such unbiased screens may be particularly helpful for neurodegenerative diseases (ND),...
such as Parkinson’s Disease (PD) and Alzheimer’s Disease (AD), where the molecular underpinnings of disease remain unclear. However, establishing robust neuronal phenotypes amenable to high-throughput screening and subsequent target identification remains a challenge. To bridge this gap, we exploit yeast cells that express ND-causing proteins to recapitulate salient cellular pathologies. α-synuclein, for example, causes derangements in vesicle trafficking, metal ion homeostasis and mitochondrial function that are associated with α–synucleinopathies, such as PD (2). The resulting growth inhibition greatly facilitates robust high throughput screening.

We recently screened ~190,000 compounds for their ability to restore the growth of cells expressing toxic levels of TDP-43 (3), a protein associated with diverse NDs. A weak hit from that screen, an N-Aryl Benzimidazole (NAB; Fig. 1A), proved more potent and effective against α-syn toxicity (Fig. 1B). NAB reversed diverse phenotypes caused by α-syn (4–7), including the accumulation of vesicular α-syn foci (Fig. 1C) (8, 9), the generation of reactive oxygen species (Fig. 1D), the block of ER-Golgi trafficking (Fig. 1E), and the nitration of proteins (6). The toxicity of α-syn is extremely dependent on expression levels (7, 10); however, NAB did not reduce α-syn accumulation (Fig. 1E).

We next asked if the protective activity of NAB was conserved in neurons. First, we tested a nematode model where PD-relevant dopaminergic neurons (DA) degenerate in an age-dependent manner in response to human α-syn expression (5). Second, we tested rat primary neuronal cultures where adenoviral expression of a familial α-syn mutation (A53T) causes selective loss of DA neurons: tyrosine-hydroxylase (TH) positive cells are lost and neuronal processes retract (4, 5). Third, we tested cortical neurons differentiated from PD-patient induced pluripotent stem cells (iPSCs) carrying either the A53T α-syn mutation or an α-syn triplication, both of which caused protein trafficking defects and nitrosative stress (6). In each case, NAB reversed α-syn toxicity or pathology, suggesting the compound’s target and mechanisms of action (MOA) were conserved from yeast to human cells (Fig. 1F, 1G, Fig. S1 (6)).

Yeast screens can reveal the target space for small molecules that suppress growth by identifying genetic alterations that restore it (11). At concentrations higher than those that rescued α-syn toxicity, NAB inhibited the growth of WT cells. To test if α-syn rescue and growth inhibition had related MOA, we synthesized twenty-nine NAB analogs (Fig. S2). Compounds inactive in rescuing α-syn did not reverse α-syn foci formation or rescue ER-to-Golgi trafficking (Fig. S3). Compounds that potently rescued α-syn, also more potently inhibited growth in WT cells (Fig. 2A, Fig. S2, supplementary online text). This empowered us to use genetic screens in WT cells to investigate NAB’s MOA. Importantly, though NAB inhibited growth, cells retained full viability (Fig. 2B).

Using our most potent analog – NAB2 – we selected for genetic alterations that allowed growth at high concentrations. We used three approaches: (1) a library of over-expression strains covering most genes in the yeast genome (~5,800 genes), (2) a library of ~ 300,000 random transposon-insertions (12), and (3) spontaneous genomic point mutations arising from ~2 million cells (fig. S4). A small number of hits were recovered and formed a highly connected network of functionally related genes (Fig. 2C). These were an E3 ubiquitin
ligase that promotes endosomal transport (RSP5), endocytic proteins (SLA1, VRP1), a multivesicular body sorting deubiquitinase (DOA4), an Rsp5 adaptor (BUL1), two proteins that can deubiquitinate Rsp5 substrates (UBP7, UBP11), known and potential Rsp5 substrates (BAP2, BAP3, MMP1) and VPS23, which directs Rsp5 substrates for degradation in the vacuole (Fig. 2C). Analogs ineffective against α–syn did not exhibit dosage sensitivity with NAB network genes (Fig. S5), thus supporting a related MOA between α–syn rescue and growth inhibition of WT cells.

The network topology of screen hits, and the nature of their altered dosage-sensitivity to NAB2 (Fig. S6–S8), suggested that NAB acts on Rsp5 to promote ubiquitin-mediated endosomal transport. With the exception of RSP5, which is essential, every other gene in our network could be deleted. But no deletion (including a double deletion of UBP7 and UBP11) conferred more than partial resistance to NAB2. Thus, while these other proteins are involved in NAB2 activity, they cannot themselves be its target. Indeed, the effects of altering RSP5 gene dosage indicate it is the central node: increased RSP5 dosage increased sensitivity to NAB2 and decreased RSP5 dosage decreased sensitivity to NAB2 (Fig. 2D). Furthermore, in otherwise isogenic cells, a single amino acid substitution in the ~1000 amino acid protein (rsp5G747E) conferred resistance to NAB2 (Fig. 2D, Fig. S7).

Rsp5 is the single yeast member of the highly conserved mammalian family of HECT domain Nedd4 E3 ligases. These proteins catalyze K63 linkages of ubiquitin to diverse membrane proteins and thereby regulate endosomal trafficking, not proteasomal degradation (13, 14). HECT domain ubiquitin ligases contain multiple protein-protein interaction domains that bind diverse adaptor proteins and substrates. Calcium, lipid binding, and autoinhibitory conformations regulate substrate specificity and endosomal transport from either the plasma membrane or Golgi to the vacuole/lysosome. Most aspects of these complex modes of Rsp5 regulation have not been recapitulated in vitro.

Therefore, to further investigate NAB2 activities, we monitored, in WT cells, its effects on three proteins whose trafficking depends on Rsp5: Mup1 (15), Sna3 (16) and Bap2 (17). NAB2 (1) promoted the Rsp5-dependent endocytosis and vacuolar delivery of the methionine permease, Mup1 (Fig. 2E, Fig. S9), (2) promoted the Rsp5-dependent Golgi-to-vacuole trafficking of the adaptor protein, Sna3 (Fig. 2F, Fig. S9), and (3) promoted the Rsp5-dependent degradation of the leucine permease, Bap2 (Fig. S10). (This affected leucine-dependent growth explaining its recovery in our overexpression screen.)

We further established the relevance of the NAB/Rsp5 network by genetically altering screen hits in the context of α–syn. Indeed, most but not all genetic manipulations that antagonized NAB2 activities in WT cells antagonized its activities against α–syn toxicity. For example, deleting Δsla1 and Δvps23, or overexpressing the deubiquitinases UBP7 and UBP11, all partially compromised the ability of NAB2 to rescue α–syn toxicity (Fig. 3A, Fig. S11). Deleting Δubp7 and Δubp11, either singly or in combination, had no effect NAB2’s rescue of α–syn toxicity (Fig. S11).

The spontaneous point mutation recovered in our screen, rsp5G747E, which compromised Rsp5 activity (Fig. 2E, 2F, Fig. S7) and conferred resistance to NAB2 in WT cells, shifted
the dose of NAB2 required for α-syn rescue in a complementary fashion (Fig. 3A).
Consistent with this, \( rsp5_{G747E} \) prevented NAB2 from fully reverting the formation of α-syn foci (Fig. 3B) and from restoring ER-to-Golgi trafficking (Fig. 3C) phenotypes. Together, these analyses established Rsp5 as the central node and only potential protein target within the NAB network.

Rsp5’s importance in modifying α-syn toxicity was highlighted by integrating the NAB/Rsp5 and α-syn genetic networks ((4, 18) and Table S3). These interactions connected our NAB network to nearly 30% of the previously established genetic modifiers of α-syn toxicity, including those that function in Golgi/vesicular transport, endosomal transport, lipid metabolism, protein catabolism, and tubulin assembly (Fig. 3D, Fig. S12).

Next we tested α-syn’s effect on Mup1-GFP and Sna3-GFP trafficking. Indeed, α-syn expression impeded both the methionine-induced transport of Mup1-GFP from the plasma membrane to the vacuole (Fig. 4A) and the constitutive trafficking of Sna3-GFP from the Golgi and the vacuole (Fig. 4B). Further, in the presence of α-syn, NAB2 restored trafficking of both substrates (Fig. 4A, 4B).

In addition to specific substrates, bulk endosomal transport from the plasma membrane to the vacuole was perturbed by α-syn (Fig.4C) (7–9, 19). When FM4-64 was used to pulse-label the endosomal pathway, after prolonged α-syn expression, the dye strongly co-localized with α-syn inclusions and failed to reach the vacuole (Fig. 4C). NAB2 fully restored endocytosis and concomitantly reduced α-syn inclusions (Fig. 4C, bottom panel). Thus, the ability of NAB to promote Rsp5-dependent processes directly restored diverse cellular pathologies caused by α-syn, including both ER-to-Golgi and endosomal trafficking (Fig. 4D, Fig. S8).

Rsp5/Nedd4 can ubiquitinate α-syn and Nedd4 localizes to Lewy Bodies in brain samples from PD patients (20). However, α-syn levels were not altered by NAB2 in vivo (Fig. 1E). And, when tested in vitro, NAB2 did not affect the ubiquitination of α-syn and Sna3 by Rsp5 (Fig. S13). As noted, however, most of the complexities of Rsp5 in vivo activities have yet to be recapitulated in vitro. Thus, NAB2 exemplifies the ability of unbiased in vivo phenotypic screens to uncover chemical probes that cannot be discovered through simple target-based in vitro approaches. Likewise, NAB2 chemical genetics identify a deeply rooted biological node, Rsp5 that had not been identified previous overexpression or deletion screens. Notably, despite their central role in protein homeostasis and several human diseases, to date E3 ubiquitin ligases are virtually untouched by biological probes, let alone therapeutics.

The vesicular trafficking processes perturbed by α-syn and promoted by NAB are fundamental to all eukaryotic cells, yet are particularly important to neurons that rely heavily on efficient synaptic vesicle dynamics and regulated neurotransmitter release. Indeed, dysfunctional endosomal transport is emerging as contributing factor in α-syn pathology in human neurons. Altered cell biology, post-mortem pathology, and human genetic risk factors all implicate altered vesicular trafficking (4, 7–9, 19, 21–25). The ability of NAB to promote endosomal trafficking through Rsp5/Nedd4 and thus ‘reset’ vesicle
trafficking homeostasis, in turn, rescued several other, seemingly disparate, \( \alpha \)-syn phenotypes. Identifying such deeply rooted pathways that ramify to affect multiple aspects of protein folding pathology may be critical for developing disease-modifying therapies.
