1. INTRODUCTION

Accreting neutron stars (NSs) in low-mass X-ray binaries show bright Type I X-ray bursts. These begin with a rapid increase of the X-ray flux (the rise) followed by a slow decrease (the tail) to the pre-burst luminosity and last ∼10−100 s. These bursts are powered by thermonuclear runaways, which burn up a layer of accumulated light elements on the NS surface (for a review see Strohmayer & Bildsten 2006).

A significant fraction of bursts display quasi-periodic modulations, known as burst oscillations (BOs; Strohmayer et al. 1996). In the discovery paper, Strohmayer et al. suggested that BOs were related to the spin frequency of the NS. This has been confirmed in five accretion-powered millisecond X-ray pulsars (AMXPs), where it was found that BO frequencies are within a few percent of the spin frequencies (Strohmayer & Bildsten 2006). This implies that BOs are caused by a nearly stationary pressure or stress. This mechanism is particularly plausible for un-magnetized stars, where the existence of dynamically important magnetic fields is suggested by the presence of accretion-powered millisecond X-ray pulsars (AMXPs), where it was found that BO frequencies are within a few percent of the spin frequencies (Strohmayer & Bildsten 2006). This implies that BOs are caused by a nearly stationary pressure or stress.

The detailed phenomenology of BOs, however, is diverse. In the sources which have evidence for substantial magnetic fields (the persistent AMXPs), for example, BOs appear at a near constant frequency in the tail, with some fast chirps (the tail) to the pre-burst luminosity and last ∼10−100 s. These bursts are powered by thermonuclear runaways, which burn up a layer of accumulated light elements on the NS surface (for a review see Strohmayer & Bildsten 2006).

The origin of Type I BOs in IGR J17480−2446 (hereafter J17480) is the first secure case of a slowly rotating neutron star (NS) which shows Type I burst oscillations (BOs), all other sources featuring such oscillations spin at hundreds of Hertz. This means that we can test BO models in a completely different regime. We explore the origin of Type I BOs in IGR J17480−2446 and conclude that they are not caused by global modes in the NS ocean. We also show that the Coriolis force is not able to confine an oscillation-producing hot spot on the stellar surface. The most likely scenario is that the BOs are produced by a hot spot confined by hydromagnetic stresses.

2. OBSERVATIONS AND DATA ANALYSIS

J17480 was detected in the outburst on 2010 October 10 in a Galactic bulge scan with the International Gamma-Ray Astrophysics Laboratory (Bordas et al. 2010). The source is located in the globular cluster Terzan 5 and its outburst lasted for $\sim 55$ days (according to the Monitor of All-sky X-ray Image, MAXI, monitoring observations) before the source became undetectable due to solar constraints. Further monitoring observations by MAXI showed that the source had probably returned to quiescence by 2011 January. J17480 is an 11 Hz pulsar in a 21.3 hr orbit around a companion with $M > 0.4 M_\odot$ (Strohmayer & Markwardt 2010; Papitto et al. 2011). Follow-up observations with the RXTE/Proportional Counter Array (PCA) have collected approximately 294 ks of data to 2010 November 19. We used all RXTE/PCA (Jahoda et al. 2006) public observations of J17480 taken between MJD 55482.0 and 55519.2 (2010 October 13–November 19). For our coherent timing analysis we used Event and GoodXenon data modes, keeping only absolute channels 5–37 ($\sim 2$–16 keV), rebinned to 1/8192 s and barycentered with the FTOOLS fxbachary using the position of Pooley et al. (2010).

2.1. Light Curve and Accretion Rate

We estimate the flux during each observation from the background subtracted 2–16 keV Crab normalized intensity (estimated following van Straaten et al. 2003) and converted it to erg cm$^{-2}$ s$^{-1}$ assuming a Crab spectrum for the source. Flux is converted into luminosity using a distance of 5.5 kpc (Ortolani et al. 2007). Luminosity $L_x$ is converted into mass accretion rate $\dot{M}$ using $L_x = 20\% M \dot{c}^2$ (Frank et al. 2002). The value of $\dot{M}$ obtained is approximate, since the X-ray flux is not bolometric, and no correction has been applied for absorption, the unknown disc inclination, or gravitational redshift. Conversion of bolometric luminosity to mass accretion rate is further complicated by the uncertainty in the radiative efficiency. The overall uncertainty on $\dot{M}$ is within a factor of $\sim 3$, taking into account all these corrections (in’t Zand et al. 2007). The lowest luminosity observed gives $\dot{M} = 9 \times 10^{-10} M_\odot$ yr$^{-1}$ (in the first observation) while at the outburst peak $\dot{M} = 7 \times 10^{-9} M_\odot$ yr$^{-1}$, i.e., 5% and 37% of the Eddington rate $\dot{M}_{\text{Edd}} = 1.9 \times 10^{-8} M_\odot$ yr$^{-1}$ (assuming solar composition for the accreted gas).

2.2. Bursts

Bursts were identified visually in a 1 s light curve. The beginning and end of the bursts were defined as the points where the flux first and last exceeded the maximum pre-burst flux in the same observation. Typical burst length is $\sim 100$–200 s. Burst recurrence time and burst peak-to-persistent flux ratio decrease with increasing persistent flux until the outburst peak when the bursts disappear and millihertz quasi-periodic oscillations (Linares et al. 2010) appear. As the outburst flux decreases again, the bursts gradually reappear with recurrence time and the burst peak-to-persistent flux ratio increases with decreasing flux (Chakraborty & Bhattacharyya 2011). Between MJD 55486 and MJD 55492 the difference between bursts and persistent flux fluctuations becomes negligible and burst recurrence time is of the same order as the duration of the bursts themselves, therefore burst rise and tail become difficult to define. In this case we do not identify the bursts and for the purpose of measuring the oscillations treat all data as persistent flux.

Using this identification criterion, we found 231 bursts. As discussed by other authors, some which were observed when the persistent luminosity was $\lesssim 15\%$ Eddington, showed clear spectral evidence for cooling (Chakraborty & Bhattacharyya 2011; Motta et al. 2011; Linares et al. 2011), and, therefore, were identified conclusively as Type I (thermonuclear) bursts (Figure 1). The nature of the other bursts, observed when the persistent flux was $\sim 15\%$–$35\%$ Eddington, remains debated due to the lack of clear evidence for cooling (Galloway & in’t Zand 2010; Chakraborty & Bhattacharyya 2011).

2.3. Pulsation Analysis

The data were folded in non-overlapping intervals of $\sim 10$–20 s for the first observation (where APP and BO fractional amplitudes are $\sim 30\%$) and $\sim 100$–500 s for all others using the ephemeris of Papitto et al. (2011) to search for both APPs and BOs. This means that in some cases (when the signal is sufficiently strong) multiple BO profiles are constructed for each burst. Only pulse harmonics with signal-to-noise ratio (S/N) $> 3.5$ were retained (i.e., harmonics whose amplitude was larger than 3.5 times the amplitude standard deviation), giving less than one false pulse detection.

Each pulse profile was decomposed into the fundamental frequency and overtones to compute fractional amplitudes and

phases (we were able to identify up to five overtones in some intervals). The pulse phases of each profile were calculated for each harmonic and analyzed separately. The method applied is described in Patruno et al. (2010), along with the procedure to calculate pulse amplitudes and statistical errors. Phases were then fitted with a Keplerian orbit, a linear and a parabolic term representing the pulse frequency and its first time derivative.

3. DISCOVERY AND PROPERTIES OF BURST OSCILLATIONS

BOs were detected in all 231 bursts identified. Figure 1 shows the fractional amplitudes of the BOs compared to those of the APPs. The fractional amplitudes of BOs are always of the same order or larger than those of APPs and always significantly larger than expected if the modulations stem only from residual persistent emission. The detection of BOs can therefore be considered secure.

Note that the APP contribution has not been subtracted when calculating BO fractional amplitudes and phases. The measured BO fractional amplitudes are comparable to or higher than the APP ones; it can be seen from Equation (11) of Watts et al. (2005) and Equation (1) of Watts et al. (2008) that the correction is less than a few percent.

The presence of timing noise, as seen in other AMXPs (Patruno et al. 2009), complicates the timing analysis of APPs and BOs. The scatter observed in the oscillation phases has an amplitude of 0.1–0.2 cycles within each ObsId for both BOs and APPs. However, adjacent BOs and APPs are always phase coincident and phase locked to within ~0.05 cycles. In the first observation, for example, which has the highest S/N, the phase difference between the peak of the fundamental for APPs and BOs is 0.014 ± 0.005 cycles (5.1 ± 1.8 deg). This coincidence of results is remarkable given the strong timing noise, highlighting the fact that BOs do indeed closely track APPs.

To check whether BO phases have the same temporal dependence as the APPs, we fit a pulse frequency model plus its first derivative to the entire two data sets of BO and APP phases separately. The pulse frequency and derivative obtained are consistent with being the same to within two standard deviations for both the fundamental frequency and the first overtone (Table 1).

Inspecting the behavior of the pulse frequency locally (comparing BO and APP pulse frequencies in each individual ObsId), pulse frequency is again consistent with being the same for the two data sets within to two standard deviations. In the first observations, when the BO and APP amplitudes are around 30% (Figure 2), the frequencies of APPs (11.044881(2) Hz) and BOs (11.04493(7) Hz) are identical within the errors (~7 × 10^{-5} Hz).

Comparing the properties of J17480 to those of the other persistent pulsars with BOs (Chakrabarty et al. 2003; Strohmayer et al. 2003; Altamirano et al. 2010b; Riggio et al. 2011), J17480 shows BOs in every burst, just like SAX J1808.4-3658, XTE J1814-338, and IGR J17511-3057. J17480 is most similar to J1814: BOs are present throughout the bursts, BOs and APPs are phase locked very closely, BOs have strong harmonic content and no measurable frequency drifts. J1808 and J17511, by contrast, have BOs with weaker harmonic content, which do not persist throughout the bursts, and display fast drifts in the rise. In terms of BO amplitude, the persistent pulsars differ: J1808 has amplitudes of 3%–5% rms, J17511 of 5%–15%, and J1814 of 9%–15%. J17480 has BO amplitude of 30% rms in the first burst, dropping to ~2% thereafter. However, in all cases the BO amplitude is comparable to (within a few percent) the APP amplitude.

4. BURST OSCILLATION MODELS FOR J17480

We first show how we can exclude mode and Coriolis force confinement models based on the coincidence of BO and APP frequencies and on slow rotation.

4.1. Global Modes

Given a mode with azimuthal number m and frequency νₘ in the rotating frame of the star, the frequency ν₀ of an inertial observer would measure is

$$ν₀ = mνₘ + νᵣ,$$  (1)

where the sign of νᵣ is positive or negative, depending on whether the mode is prograde or retrograde.

In the first and best-constrained burst (Section 3), ν₀ and νᵣ were found to differ by no more than 10⁻⁴ Hz. Excluding modes with m > 2, which cannot explain the high fractional amplitudes (~30%) observed in the first burst (Heyl 2004), leaves us with two main possibilities.

The first is that we have modes with |νᵣ| ∼ νₘ and m = 0 (prograde) or m = 2 (retrograde). Even though modes with frequencies around 10 Hz, such as g-modes (Bildsten & Cumming 1998) do exist, it would require extreme fine tuning of parameters for νᵣ to match νₘ within ~10⁻⁴ Hz. We are not
aware of any mechanism that could tie the frequency of a mode so closely to the spin.

The second option would be to have prograde modes with \( m = 1 \) and \( v_\perp \sim 10^{-4} \) Hz. However, the process that excites a mode must have a timescale \( \tau \sim 1/v_\perp \). In this case \( \tau \sim 10^4 \) s, which is longer than the duration of the bursts. We therefore conclude that global modes cannot explain the presence of BOs in J17480.

### 4.2. Coriolis Force Confinement

For rapidly rotating stars, SLU02 showed that burning could be confined, due to the effect of the Coriolis force, over a length scale of the order of the Rossby adjustment radius (Pedlosky 1987):

\[
R_R = \sqrt{gH/4\pi v_\perp} = 34 \text{ km} \quad M_{1.4}^{1/2} R_{10}^{-1} H_{10}^{1/2} v_{s,10}, \tag{2}
\]

where \( M_{1.4} \) is the mass in units of 1.4 \( M_\odot \), \( R_{10} \) is the radius in units of 10 km, \( H_{10} \) is the scale height of the burning fluid in units of 10 m (SLU02), and \( v_{s,10} = v_s/(10 \text{ Hz}) \).

For J17480, \( R_R \) significantly exceeds the stellar radius; Coriolis force confinement is not effective. So although this mechanism might be important for faster NSs (for \( v_\perp \geq 200 \text{ Hz} \) and/or \( R_R \leq 1.7 \text{ km} \)), it cannot cause BOs in J17480.

### 5. MAGNETIC CONFINEMENT

Having ruled out these two models, we now explore the possibility that the magnetic field could confine the hot spot. We begin by placing limits on the strength of the magnetic field for this source, following the standard procedure outlined in Psaltis & Chakrabarty (1999). For the magnetic field to be strong enough to channel the accretion flow, and hence generate APPs, the magnetospheric radius (the point at which the magnetic field disrupts the disc) must exceed the stellar radius. This gives a lower limit on the magnetic field. In addition, to avoid propeller effects (which would inhibit accretion), the magnetospheric radius has to be lower than the corotation radius. This gives an upper limit on the magnetic field. Using the accretion rates derived in Section 2.1 we conclude that the magnetic field for J17480 is in the range \( 2 \times 10^8 \) to \( 3 \times 10^{10} \) G (see Psaltis & Chakrabarty 1999 and Andersson et al. 2005 for a detailed explanation of how to calculate the magnetic field).

We now need to estimate whether this field is strong enough to confine the burning material in order to generate BOs. We start by considering static fuel confinement. A mountain of accreted material induces a pressure gradient within the fuel. Brown & Bildsten (1998) computed the field that can statically compensate for such a gradient by magnetic tension. Confinement within an area of radius \( R_c \), at the ignition column depth \( \sim 10^8 \) g cm\(^{-2}\), requires a magnetic field

\[
B \gtrsim 3 \times 10^{10} \text{ G} \left( \frac{R_c}{1 \text{ km}} \right)^{-1/2}. \tag{3}
\]

Fuel confinement may however be ineffective due to MHD interchange or “ballooning” instabilities (Litwin et al. 2001), which allow accreted fluid to escape the polar cap region and spread over the NS surface. Nonetheless, confinement might still be achieved dynamically by the motion of the fluid itself. This is because such motion can induce a horizontal field component which can act to halt further spreading. This mechanism requires a weaker field (Heng & Spitkovsky 2009)

\[
B \gtrsim 4 \times 10^9 \text{ G} \left( \frac{R_c}{1 \text{ km}} \right)^{-1}. \tag{4}
\]

Both of these estimates are compatible with the magnetic field inferred for this source from its accretion properties. We conclude that magnetic confinement of the burning fluid is a viable mechanism to explain the BOs in J17480. Detailed theoretical studies will however be needed to verify this possibility, since it depends on poorly understood details of the interaction between the magnetic field and the hydrodynamics of the burning ocean. That said, confinement of burning material at the polar cap provides a natural explanation for the phase-locking and coincidence of the APPs and BOs (see also Lovelace et al. 2007) and would explain why the amplitudes of the two sets of pulsations track each other as the accretion footprint varies during the outburst (Figure 1).

### 6. CONCLUSIONS AND WIDER IMPLICATIONS

We have analyzed the bursts of the slowly rotating X-ray pulsar J17480 and found oscillations at the same frequency as the NS spin. We have shown that neither global modes nor a Coriolis force confined hot spot can explain the presence and frequency of these BOs. We suggest that the magnetic field could potentially provide the necessary confining force for a hot spot to persist. The field needs to be at least \( B \gtrsim 10^9 \) G and this requirement is compatible with the constraints set by the accretion process. This model would neatly explain the phase-locking of APPs and BOs, and the fact that the amplitudes of the two pulsations track each other.

Of the other persistent AMXPs, XTE J1814-338 is the most similar, showing almost constant frequency of the BOs, harmonic content, and remarkable phase-locking. Watts et al. (2008) excluded the possibility of magnetic confinement, since using the estimates of Brown & Bildsten (1998) (Equation (3)) the field was not strong enough to confine the fuel. However, they did not consider the case of dynamical confinement when spreading is allowed (Equation (4)). This operates at lower fields which are compatible with the magnetic field estimated for J1814.

This mechanism seems less likely for other AMXPs such as SAX J1808.4-3658 and IGR J17511-3057, where the fields are lower (Hartman et al. 2009) and there are frequency drifts in the rising phase of bursts (Chakrabarty et al. 2003; Altamirano et al. 2010b). That said, magnetic confinement would offer an explanation for the presence of higher harmonics in pulsar BOs, since the emitting area would be bounded (probably near the rotational poles, Muno et al. 2002b).

What about the non-pulsating sources and the intermittent pulsars with a weaker magnetic field? They do not show harmonic content and their BOs show drifts during the decay of the bursts. If magnetic confinement were responsible one would expect to see APPs from these sources as well. Unless the field can be boosted temporarily to detectable levels only during the burst (Boutloukos et al. 2010), a different mechanism may be required (Watts & Strohmayer 2006). If global modes or Coriolis confinement are responsible, then the wider emitting surface involved, or the involvement of higher colatitudes, would suppress the presence of harmonics, in line with the observations (Muno et al. 2002b; Strohmayer et al. 2003).
