Topologically protected excitons in porphyrin thin films

Joel Yuen-Zhou1*, Semion K. Saikin1,2, Norman Y. Yao3 and Alán Aspuru-Guzik1,2

The control of exciton transport in organic materials is of fundamental importance for the development of efficient light-harvesting systems. This transport is easily deteriorated by traps in the disordered energy landscape. Here, we propose and analyse a system that supports topological Frenkel exciton edge states. Backscattering of these chiral Frenkel excitons is prohibited by symmetry, ensuring that the transport properties of such a system are robust against disorder. To implement our idea, we propose a two-dimensional periodic array of tilted porphyrins interacting with a homogeneous magnetic field. This field serves to break time-reversal symmetry and results in lattice fluxes that mimic the Aharonov-Bohm phase acquired by electrons. Our proposal is the first blueprint for realizing topological phases of matter in molecular aggregates and suggests a paradigm for engineering novel excitonic materials.

Our approach to this challenge draws on ideas from the field of disordered electronic systems—in particular, from the phenomenology broadly termed as ‘quantum Hall effects’ (QHEs; ref. 10). A hallmark of such quantum Hall systems is that they exhibit delocalized current-carrying chiral edge modes. Specifically, the breaking of time-reversal symmetry (TRS) in these systems ensures that there are no counter-propagating modes to backscatter into1. Elegant extensions of these ideas include photonic set-ups12–15 and topological insulators (TI)—materials that preserve TRS but whose edge modes are related to strong spin–orbit coupling16,17. We note that organometallic TIs have recently been suggested by Liu and co-workers18–21, paving the way towards a wider and possibly cheaper group of materials that may exhibit these exotic phenomena. As QHEs have been posed in the context of electrons and photons, it is natural to inquire whether their excitonic analogue exists. The present Article answers this question positively, by explicitly constructing a minimal model of a Frenkel exciton porphyrin lattice which supports topologically protected edge states when it interacts with a magnetic field. As this effort is already challenging by itself, we limit ourselves to cryogenic temperatures and, therefore, disregard effects of vibrational dephasing of excitons, which we shall study elsewhere. As far as we are aware, this is curiously the first work that addresses the joint effects of both magnetic fields and coherence in molecular exciton transport. Furthermore, this Article is also the first example of topological phases in molecular excitons and, therefore, offers a novel approach to the design of a new generation of materials for more efficient energy harvesting and transport.

The model
Our set-up consists of a two-dimensional periodic array of unsubstituted metalloporphyrins (hereafter referred to just as porphyrins), molecules with D∞h symmetry that maintain their planarity owing to their metal centres22, and which are well-known compounds in photovoltaic applications23. These porphyrins are arranged in a square lattice in the xy plane with a unit cell of area \(s \times s\) (Fig. 1a), where \(s \approx 1/2–2\) nm. The lattice consists of two sublattices, \(a\) and \(b\), where the porphyrins are tilted out of the xy plane in ways that depend on two angles per sublattice, \(\theta\), and \(\phi\), \((i = a, b)\), respectively. This two-dimensional lattice can in principle be realized by self-assembly techniques exploiting an already crystalline substrate24–29, which in our case shall be chosen to avoid exciton quenching processes (an insulating material fulfils this condition30,31).

Using a Cartesian vector notation in the ‘lab’ or array frame throughout the Article, the \(a\) sites are located at positions \(n_s \equiv (n_s, n_s, 0)s\) for \(n_s, n_s\) integers, whereas the \(b\) sites are at \((n_s + 1/2, n_s + 1/2, 0)s\). We shall be concerned with the three lowest electronic states in each molecule—namely, its ground state \(|g\rangle\) and its degenerate Q-band absorbing in the visible spectrum \((\omega_0 \approx 17,350\text{ cm}^{-1};\text{ ref. 32})\), consisting of the orthogonal states \(|Q^x\rangle\) and \(|Q^y\rangle\) (we use capital labels for Cartesian coordinates for the molecular frame of each sublattice).

Owing to the degeneracy of the Q-band, the states \(|Q^x\rangle\) and \(|Q^y\rangle\) can be arbitrarily defined as long as their transition dipole

Porphyrin lattice under a uniform magnetic field. We consider a three-porphyrin loop. Each porphyrin consists of two orthogonal to it: $\mu_{i,\alpha} = +\mu_{i,\alpha}$ and $\mu_{i,\beta} = -\mu_{i,\beta}$ are chosen such that $\mu_{i,\alpha}$ has zero projection along the $y$ axis, and $\mu_{i,\beta}$ is orthogonal to it:

$$\mu_{i,\alpha} = d(\cos \theta_i, 0, \sin \theta_i)$$

$$\mu_{i,\beta} = d(-\sin \phi_i, \cos \theta_i, \cos \phi_i, \sin \phi_i, \cos \theta_i)$$

where $d \sim 2-8$ D depending on the chemical environment of the porphyrins. These vectors define molecular frames for each sublattice, with Cartesian unit vectors $X_i = \mu_{i,\alpha} / \mu$ and $Z_i = \mu_{i,\beta}$, and $Z = X \times Y$. Also, in general $(\theta_i, \phi_i) \neq (\theta_j, \phi_j)$, so the tilting angles distinguish the sublattices.

Before dealing with the dipolar interactions between the different porphyrins, we consider their Zeeman interaction with a perpendicular and homogeneous magnetic field $B = (0, 0, B)$ (see ref. 34; Fig. 2):

$$H_0 = \mu_i \cdot B \cdot (L^{(0)} + 2S^{(0)})$$

Here, $H_0 = \omega_0 (|Q_{x,\alpha}^0 \rangle \langle Q_{x,\alpha}^0| + |Q_{y,\beta}^0 \rangle \langle Q_{y,\beta}^0|)$ is the bare Hamiltonian of each porphyrin, $\mu_0 = 0.47$ cm$^{-1}$ T$^{-1}$ is the Bohr magneton, and $L^0$ and $S^0$ are the electronic orbital angular momentum and spin of the ith porphyrin. Each of the three states per molecule is a singlet state with $S^0 = 0$. It is valid to regard the porphyrins as approximate rings in the $XY$ plane occupied by 18 electrons.

This implies that the solutions to equation (1) are states with approximately good angular momentum quantum number $L_y = \pm m$ perpendicular to the plane of the molecules at $Z$, for integer $m$ (here $h = 1$). In particular, we have $L_y^2 (|Q_{x,\beta}^0 \rangle \langle Q_{x,\beta}^0| + |Q_{y,\beta}^0 \rangle \langle Q_{y,\beta}^0|)$, and $H_0^2 (|Q_{x,\alpha}^0 \rangle \langle Q_{x,\alpha}^0| + |Q_{y,\beta}^0 \rangle \langle Q_{y,\beta}^0|)$, where half of the Zeeman splitting is given by $\Delta = \mu_i B \cdot \kappa$, and we have used $\kappa = Z = \cos \theta_i \cos \phi_i$. That is, under a magnetic field, the degenerate $Q$-band in each porphyrin splits into two Zeeman levels $Q_{x,\alpha}$ with different energies. Notice that as a result of TRS breaking, their coefficients in terms of the ‘bare’ states $|Q_{x,\alpha}^0 \rangle$ and $|Q_{y,\beta}^0 \rangle$ are in general complex. Although not essential, we simplify the model by fixing the projection of the magnetic field on both sublattices to be a constant $|\kappa| = \kappa \neq 0$, yielding a constant Zeeman splitting throughout $|\Delta| = \Delta$. There is, however, a possibly different ordering of the $Q_{x,\alpha}^0$ states, depending on the sign of $B \cdot \kappa$. With this in mind, each porphyrin has states of energy $\omega_{iL} \equiv \omega_{iL} - \Delta$ and $\omega_{iU} \equiv \omega_{iU} + \Delta$, which we call the lower and upper energy states $|Q_{x,\alpha}^0 \rangle$ and $|Q_{y,\beta}^0 \rangle$, and $(L, U) = (+, -)$, if $B \cdot \kappa > 0$ and $(L, U) = (-, +)$ otherwise. Working under a magnetic field of $|B| = 10$ T, this splitting attains a value of $2.4 \sim 84$ cm$^{-1}$, which is confirmed by magnetic dichroism experiments (the reference reports half of the actual splitting due to isotropic averaging). It is clear from this model that other chromophores with similar electronic structure, such as metallophthalocyanines, can be used instead of metalloporphyrins.

We now turn our attention to interactions between Zeeman levels across the lattice, which we characterize with the energy scale $J$, and electronic structure, such as metallophthalocyanines, can be used instead of metalloporphyrins.
such that $J \ll 2\Delta$. We are interested only in ‘single-excitation’ effects, which can be described by the following Hamiltonian:

$$\mathcal{H}_t = \sum_n (\epsilon_n a_n^\dagger a_n + b_n^\dagger b_n) + \sum_n \left( J_{0,NE} (a_n^\dagger n b_n + a_{n-NE} b_n^\dagger) + J_{0,SW} (a_n^\dagger n b_n + a_{n-NW} b_n^\dagger) + J_{0,E} (a_n^\dagger n b_n + a_{n-N} b_n^\dagger) + J_{0,B} (a_n^\dagger n b_n + J_{0,B} b_n^\dagger n a_n) + \text{c.c.} \right) \tag{2}$$

Here, $a_n^\dagger$ and $b_n^\dagger$ are creation operators for excitations $|Q_0\rangle$ located at $n$ for $i = a$ and at $(n_x + 1/2, n_y + 1/2, 0)$ for $i = b$. We have considered only nearest-neighbour $(\text{NN}, J_{0,NE}, J_{0,SW})$ and next-nearest-neighbour $(\text{NNN}, J_{0,E}, J_{0,B}, J_{0,N}, J_{0,S})$ dipolar couplings, labelled by the vector $\mathbf{V}$ connecting the two interacting dipoles, $\mathbf{N} = (0, 0)$ (north), $\mathbf{E} = (1, 0)$ (east), $\mathbf{NE} = 1/2(1,1,0)$ (northeast) and $\mathbf{NW} = 1/2(-1,1,0)$ (northwest). The analogous Hamiltonian $\mathcal{H}_e$ can be similarly constructed using the states $|Q_2\rangle$. It can be checked that NNN couplings $J_{0,N}$ are real-valued, whereas NN couplings $J_{0,E}$ and $J_{0,B}$ are complex-valued in general owing to TRS breaking. Furthermore, the spinors $|n\rangle$ and $|\bar{n}\rangle$ are defined such that the real parts of $\langle n| J_{0,N} |\bar{n}\rangle$, $\langle n| J_{0,E} |\bar{n}\rangle$, $\langle n| J_{0,B} |\bar{n}\rangle$ are real-valued, whereas NNN couplings $J_{0,N}$ are complex-valued in general owing to TRS breaking.

This picture contrasts radically with that of the integer QHE in a two-dimensional electron gas in the absence of a lattice, where the direction of the magnetic field imposes a fixed direction of cyclotron motion of the electrons and, therefore, also the chirality of all the edge currents. As an illustration of these ideas, Fig. 3 shows the topological phase diagram for the $\kappa = 1/2$, $B_c > 0$ case. Given $\kappa$ and the fact that $\cos \phi_0\cos \phi_1 = -1$, we must restrict $\theta_{0,1} \in [-\pi, \pi]$. The remainder of the angles violate the condition of fixed $|\kappa| = \kappa$, but a fraction of them still contains topologically non-trivial phases. The characteristic of this precise fraction is beyond the scope of this Article, but will be explored in the extension of this work.

Let us be more explicit by considering a particular point $(\theta_0, \phi_0) = (-\pi/3, 0)$ and $(\theta_0, \phi_0) = (0, \pi/3)$ of this phase diagram, where $-\pi/2 < \kappa < \kappa = \kappa = 1/2$. We refer the reader to Fig. 4, which is organized in panels a and b, each of them containing three parts. We show results for $\mathcal{H}_t$, with the conclusions for $\mathcal{H}_e$ being analogous except for opposite chirality of edge currents (energies and dips are plotted in units of $J$ and $d$). In Fig. 4a, we show the ideal case where the tilting angles of the porphyrins are placed exactly at the mentioned values. In Fig. 4b, we show a specific realization of disorder where each of the site angles has been randomized with Gaussian noise $0.15\pi$ standard deviation about the ideal values. The left panels show the current density for a particular eigenstate of $\mathcal{H}_l$ under OBC. These currents are concentrated along the edges of the material, so they correspond to exciton edge states and they flow clockwise, consistent with $\kappa = -1$. Interestingly, in the disordered lattice, regardless of the tilting randomization, the edge current and its chirality are still preserved. To accentuate this effect, we add a potential barrier at the left corner of the lattice, simulating an obstacle. The exciton current simply circumvents the obstacle, keeping its delocalization throughout, exemplifying the properties of topological protection. We have shown lattices with approximately 200 porphyrins, corresponding to a reasonable number of molecules that remain coherently coupled at cryogenic temperatures; this number might even be a lower bound, as coherence size is limited by coupling to vibrations and disorder, but the latter is somehow circumvented in these topological systems. The centre panels offer the energy diagrams of the respective lattices under OBC along y and periodic boundary conditions (PBC) along x. For the ideal lattice, this corresponds to two bulk bands as a function of quasimomentum $k_x$ together with edge states that span the gap between the latter from $E \approx -2J$ to $2J$. The dispersion of the edge states is positive and negative, corresponding to currents at the bottom and top edges of the lattice. Note that these states of opposite dispersion merge at $k_x = 0$ with the bulk bands. The analogous band diagram is unavailable for the disordered lattice owing to lack of translational symmetry, so we simply collapse all the eigenenergies in the same line. A study of the eigenstates reveals that the eigenstates between $E \approx -0.8J$ and $0.4J$ exhibit mostly edge character. We comment...
that, in fact, edge states seem to survive up to a large amount of disorder—namely, with noise distributed at \( \pi/6 \) standard deviation. Finally, the right panels show the linear absorption spectra of the lattice with OBCs along both directions \( x \) and \( y \). In analogy with \( J \)- and \( H \)-aggregates, most of their oscillator strength is concentrated in relatively few bulk eigenstates in the ideal lattice, although neither at top or bottom of the bands, as opposed to the simple quasi-one-dimensional scenario\(^4\). This renders the edge states in the top panel mostly dark, with the brightest edge state absorbing only 2.7% of the highest absorption peak in the spectrum. This fact is consistent with the observation that, in the dipole approximation, only states with \( k_x = 0 \) are bright, but there are no such states located at the edge in our particular model. Counterintuitively, moderate amounts of disorder provide a solution to this problem, as the edge states in this lattice borrow enough oscillator strength from the original bulk states to yield peaks in the absorption spectrum that are more experimentally accessible\(^6\), with some edge absorption peaks attaining intensities of about 26% of that of the highest bulk bands. Hence, linear absorption spectra provide a coarse signature of the edge states, although no actual confirmation of their topological character. To experimentally probe the latter, we forsee the use of near-field microscopy, where a metal tip locally creates excitons at optical microscopy, where a metal tip locally creates excitons at appropriate chemical functionalization\(^4\). Hence, if \( 2\Delta \) can be enhanced otherwise (for instance, via optical dressing), the domain validity of the model can be pushed to much higher temperatures. For arbitrary exciton–vibrational couplings, the current model needs to be adapted and, at present, it is not clear under which general conditions topologically non-trivial phases will survive, as vibrations might suppress them if they serve as a thermal dephasing bath, but may also sustain them non-trivially if they act as a non-Markovian bath.

**Summary and conclusions**

This Article introduces the concepts of topological phases to the field of molecular excitonics. It does so by explicitly constructing a topologically non-trivial model for Frenkel excitons in a two-dimensional lattice of porphyrins. Important ingredients of the model are the presence of two orbitally polarized excitons per porphyrin, the interaction of the lattice with a perpendicular magnetic field, the anisotropy of dipolar interactions between excitons, and the two-sublattice configuration of tilted porphyrins, yielding two pairs of exciton energy bands. The proposed system is a variant of the Haldane model, yielding one-way exciton edge states that are robust against disorder, as we have shown by calculations of topological invariants of the resulting energy bands as well as by explicit simulations of finite lattices. An experimental signature of these edge states is given by linear absorption spectra, although the experimental confirmation of their topological character requires more careful experiments, which will be proposed elsewhere.

We believe that our work is just one of many examples yet to be studied of a new pool of strategies to engineer robust ‘exciton wires’ that can efficiently transport light-harvested energy. Among some specific future directions, we plan to explore whether the...
These parameters yield a $\theta_2 = -\frac{47}{2} \approx u$ for a phase, which exhibits anticlockwise edge exciton currents. To the eigenstates of the lower energy Hamiltonian $\theta_n + 1$ is the position vector pointing from the $i$th porphyrin, $| \theta \rangle = \langle \theta | = \frac{1}{\sqrt{45}}$ for porphyrin tilting angles ($C_\theta H H H$), and $| \eta \rangle = \langle \eta | = 0.13$ for $J$ and $g$ which are a new class of materials where orbital degrees of freedom together with spatial symmetries of the lattice render pseudospin–orbit coupling, yielding excitonic TI analogues or, more precisely, analogues of topological crystalline insulators, which are a new class of materials where orbital degrees of freedom together with spatial symmetries of the lattice render topologically non-trivial band structures. $\eta$ is the position vector pointing from the sublattice $i$ to the $m$th porphyrin of sublattice $j$, and $\epsilon_{nm}^{ij} = \mathbf{R}_{nm}^{ij} / |\mathbf{R}_{nm}^{ij}|$. To establish an energy scale associated with these interactions, we define $J = \frac{d^2}{s^3}$, which for $d = 3 \text{D}$ and $s = 2 \text{nm}$ gives $J = 5.7 \text{cm}^{-1}$—thus, $J \ll 2 \Delta$ and the Zeeman splitting is much larger than the dipolar couplings, consistent with our assumptions. Couplings between Zeeman levels follow from equation (3) and the appropriate change of basis

$$
(n_i^a | \mathcal{J} | m_j^b) = \sum_{q=+x,y} (Q_i^q | \mathcal{J} | m_j^q)$$

where $a, b = L, U$. The various coupling terms in equation (2) are given by $J_{kx} = (n+V)^a_i | \mathcal{J} | n_j^a = (n-V)^a_i | \mathcal{J} | n_j^a$ for the different direction vectors $V$. From the energetic considerations above, we need to include couplings within each band of $Q_i^q$, or $Q_i^q$, states, but not between them. Therefore, we may write a Frenkel exciton Hamiltonian for the total lattice that reads as $\mathcal{J} = \mathcal{J}_L + \mathcal{J}_U$. In particular, $\mathcal{J}_L$, which is explicitly given by equation (2), is constructed using the lower energy states $|Q_i^q\rangle$, or alternatively $|n_i^a\rangle$, by coupling of excitons with various spatially shaped electromagnetic fields, such as plasmons and optical cavities, renders topologically non-trivial motion of excitons. Furthermore, connections between this work and theories of TRS breaking in quantum transport remain to be explored. Another intriguing extension of this work is the TRS version of the model, where no magnetic field is present. Regarding the Q-band of each porphyrin as a pseudospin, the anisotropy of the dipolar couplings may be regarded as a pseudospin–orbit coupling, yielding excitonic TI analogues or, more precisely, analogues of topological crystalline insulators, which are a new class of materials where orbital degrees of freedom together with spatial symmetries of the lattice render topologically non-trivial band structures. Topological excitonics is an exciting frontier of soft condensed matter and materials physics research.

**Methods**

**Dipolar interactions between Zeeman levels.** Let us elaborate on the derivation of equation (2). We are interested only in weak, single-excitation effects, so it is convenient to introduce the global ground state $|G\rangle = |g\rangle \cdots |g\rangle$ as well as the single-site excited states $|n_i^a\rangle = |g\rangle \cdots |Q_i^q\rangle \cdots |g\rangle$, with $q = X, Y, L, U$, where every porphyrin in the lattice is in the ground state except for the porphyrin in sublattice $i$, located at $n_s$ or $(n_t + 1/2, n_g + 1/2, 0) \nu$ (depending on whether $i = a$ or $b$, respectively), which is in the $|Q_i^q\rangle$ excited state. Couplings between the bare porphyrin sites in the lattice are well approximated by the classical real-valued dipole–dipole interaction

$$
(n_i^a | \mathcal{J} | m_j^b) = \frac{\eta}{|\mathbf{R}_{nm}^{ij}|} \left[ \frac{(Q_i^m \cdot \mathbf{R}_{nm}^{ij} - 3(n_i^a \cdot \epsilon_{nm}^{ij})(n_j^b \cdot \epsilon_{nm}^{ij}))}{|\mathbf{R}_{nm}^{ij}|} \right]
$$

Here, $\eta = 5.04 \text{cm}^{-1} (\text{nm}^3 \text{D}^{-3})$ (we have set the index of refractive to 1), $q, r = X, Y$, and $\mathbf{R}_{nm}^{ij}$ is the position vector pointing from the $m$th porphyrin of sublattice $i$ to the $n$th porphyrin of sublattice $j$, and $\epsilon_{nm}^{ij} = \mathbf{R}_{nm}^{ij} / |\mathbf{R}_{nm}^{ij}|$. To establish an energy scale associated with these interactions, we define $J = \frac{d^2}{s^3}$, which for $d = 3 \text{D}$ and $s = 2 \text{nm}$ gives $J = 5.7 \text{cm}^{-1}$—thus, $J \ll 2 \Delta$ and the Zeeman splitting is much larger than the dipolar couplings, consistent with our assumptions.
introducing the second quantized notation for each sublattice $a_\alpha^\dagger(G) = |n_\alpha^\alpha\rangle$ and $b_\alpha^\dagger(G) = |n_\alpha^\beta\rangle$.

Topological characterization of the lattice Hamiltonian $\mathcal{H}_L$. By imposing periodic boundary conditions (PBC) along $x$ and $y$, $\mathcal{H}_L$ can be rewritten in quasimomentum $k$-space using the operators $a_\alpha^\dagger = 1/\sqrt{N_x N_y} \sum_{k_x,k_y} a_{\alpha,k_x,k_y}^\dagger$ and $b_\alpha^\dagger = 1/\sqrt{N_x N_y} \sum_{k_x,k_y} b_{\alpha,k_x,k_y}^\dagger$, where $N_x$ and $N_y$ are the number of unit cells along the $x$ and $y$ directions, and $k = (k_x, k_y)$ can take values in the Brillouin zone $-\pi \leq k_x, k_y < \pi$ in discrete steps of $\Delta k_x = 2\pi/N_x$ and $\Delta k_y = 2\pi/N_y$, respectively. In terms of these operators, equation (2) becomes $\mathcal{H}_L = \sum_{k_x,k_y} \text{e}^{i(k_x a_{\alpha,k_x,k_y} b_{\alpha,k_x,k_y}^\dagger - \text{h.c.})}$, where $\text{h.c.}$ indicates real and imaginary parts; see main text for the definitions of these coupling terms.

Using this parameterization, one can readily compute the Chern number $\chi_L$, a topological invariant that, due to the bulk-edge correspondence, yields the (integer) number of edge states per quasimomentum under open boundary conditions (OBC) lying in the gap of the spectrum of $\mathcal{H}_L$, or alternatively $H(k)$, whose energy bands are given by

$$\epsilon = \langle f(k) | \pm | d(k) \rangle$$

(5)

Defining the unit vector $\hat{d}(k) = \langle d(k) | d(k) \rangle$, $\chi_L$ can be calculated as an integral in $k$-space:

$$\chi_L = \frac{\text{Numerator}}{\text{Denominator}}$$

(6)

where $\text{Numerator} = (A, B) - A, B) | C_i \cos(2k_x) + (C_i - C_j)(-3 + 2 \cos(k_x) \cos(k_y)) - C_j \cos(2k_y)|$

and $\text{Denominator} = \frac{32N_x N_y}{2} \left[ (C_i \cos(k_x) + C_j \cos(k_y))^2 + \frac{1}{2} (A_i^2 + B_i^2) + C_i \cos(k_x) + C_j \cos(k_y) + (A_i + B_i) (1 + \cos(k_x + k_y)) \right]^{1/2}$

(7)

The sign of $\chi_L$ indicates the chirality of the edge state and topologically non-trivial phases are characterized by a nonvanishing $\chi_L$.

A word of caution follows about the correct interpretation of $\chi_L$ in the context of this exciton problem, besides the one already given. First, were $\mathcal{H}_L$ to describe an electronic rather than an exciton problem, not every band structure obtained by imposing $\chi_L$ represents a Chern insulator which exhibits a quantized transverse conductance $e^2/\hbar \chi_L$, i.e. charge of an electron and $\hbar$ is Planck's constant) under a weak voltage bias, giving an experimental interpretation to the meaning of $\chi_L$ (ref. 40). Our case is different, as we are limiting ourselves to single-excitation effects, rather than considering a macroscopic occupation of the states, as in an actual electronic insulator, and the occupation of the bands occurs through light and not through a difference in electrochemical potential. Yet, it is an intriguing problem to find an excitonic observable that directly corresponds to $\chi_L$. One could imagine designing a protocol that occupies the edge states and not the bulk bands, and which applies a bias potential to the excitons via, say, mechanical strain. The measurement of an exciton current in this situation would be related to $\chi_L$. As noted in the main text, a more careful description of such an experimental protocol involving near-field spectroscopic techniques will be defined in the extension of this work; for now, we will content ourselves with the first interpretation of $\chi_L$ in terms of the number of edge states. Even though everything in this section referred to $\mathcal{H}_L$, the analogous conclusions apply to $\mathcal{H}_L$.

In fact, one can easily show that equation (7) is also valid for $\chi_L$, provided the corresponding dipolar couplings are used.

Finally, we shall discuss some symmetries of $\chi_L$. In the text, we argued that $\chi_L = -\chi_L$, i.e., flipping the $+$ and $-$ labels, $(|Q_1^\alpha\rangle, |Q_2^\alpha\rangle) \leftrightarrow (|Q_1^\beta\rangle, |Q_2^\beta\rangle)$. By keeping track of the various matrix elements, we see that $\chi_L$ also reverses sign on the transformation $k \mapsto -k$, across both sublattices. However, inverting the projection of the magnetic field on the phorphyrins, $k \mapsto -k$, also reasigns the upper and lower energy states ($Q_1^\alpha$) and $Q_2^\alpha$ between $Q_1^\beta$ and $Q_2^\beta$, switching $+$ and $-$ labels. Hence, the value of $\chi_L$ (and consequently, of $\chi_L$) is fixed across tilting configurations, and by computation seen to correspond to $\chi_L = -1$ for $B_x > 0$. Because $B_x$ also switches $+$ and $-$, $\chi_L = 1$ for $B_x < 0$.
