Leptonic \( \tau \) decays are generally well suited to investigate the Lorentz structure of electroweak interactions in a model-independent way [1]. In particular, leptonic radiative decays \( \tau \rightarrow l\gamma\nu \), where the charged lepton \( (l) \) is either an electron \((e)\) or a muon \((\mu)\), have been studied for a long time because they are sensitive to the anomalous magnetic moment of the \( \tau \) lepton [2]. At tree level, these decays can proceed through three Feynman diagrams depending on whether the photon is emitted by the incoming \( \tau \), the outgoing charged lepton, or the intermediate \( W \) boson, as shown in Fig. 1. The amplitude for the emission of the photon by the intermediate boson is suppressed by a factor \((m_c/M_W)^2\) with respect to a photon from the incoming/outgoing fermions and is thus negligible with respect to next-to-leading-order QED radiative corrections [3]. Both branching fractions have been measured by the CLEO collaboration. CLEO obtained \( B(\tau \rightarrow \mu\nu\gamma) = (3.61 \pm 0.16 \pm 0.35) \times 10^{-3} \) and \( B(\tau \rightarrow e\nu\gamma) = (1.75 \pm 0.06 \pm 0.17) \times 10^{-2} \) for a minimum photon energy of 10 MeV in the \( \tau \) rest frame [4]. In addition, the OPAL collaboration finds \( B(\tau \rightarrow \mu\nu\gamma) = (3.0 \pm 0.4 \pm 0.5) \times 10^{-3} \) for a minimum photon energy of 20 MeV in the \( \tau \) rest frame [5].

In the present work, we perform a measurement of \( \tau \rightarrow l\gamma\nu \) branching fractions for a minimum photon energy of 10 MeV in the \( \tau \) rest frame, using 431 fb\(^{-1}\) of \( e^+e^- \) collisions collected at the center-of-mass energy of the \( \Upsilon(4S) \) resonance with the \( \text{BABAR} \) detector at the PEP-II storage rings. We find \( B(\tau \rightarrow \mu\nu\gamma) = (3.69 \pm 0.03 \pm 0.10) \times 10^{-3} \) and \( B(\tau \rightarrow e\nu\gamma) = (1.847 \pm 0.015 \pm 0.052) \times 10^{-2} \), where the first quoted error is statistical and the second is systematic. These results are substantially more precise than previous measurements.

muon identification. About half of the data were taken with the IFR embedded with resistive plate chambers, later partially replaced by limited streamer tubes.

For this analysis, a Monte Carlo (MC) simulation is used to estimate the signal efficiency and to optimize the selection algorithm. Simulated $\tau$-pair events are generated using KK2f [10], and $\tau$ decays are simulated with TAUOLA [11]. Final-state radiative effects for $\tau$ decays in TAUOLA are simulated using PHOTOS [12]. A signal $\tau$-pair MC sample is generated where one of the $\tau$ leptons decays to $\tau \rightarrow l\nu\bar{\nu}$, and the other decays according to known decay modes [13]. For the signal sample, we require the minimum photon energy in the $\tau$ rest frame to be $E_{\gamma,\text{min}} > 10$ MeV. The $\tau \rightarrow l\nu\bar{\nu}$ decays with $E_{\gamma,\text{min}} < 10$ MeV are treated as background. A separate $\tau$-pair MC sample is generated requiring each $\tau$ lepton to decay in a mode based on current experimental knowledge; we exclude signal events in the former sample to obtain a $\tau$-pair background sample. Other MC simulated background samples include $\mu^+\mu^-$, $q\bar{q}$ ($u\bar{u}$, $d\bar{d}$, $s\bar{s}$, $c\bar{c}$), and $BB$ ($B = B^+, B^0$) events. The $\mu^+\mu^-$ events are generated by KK2f, $q\bar{q}$ events are generated using the JETSET generator [14], while $BB$ events are simulated with EVTGEN [15]. The detector response is simulated with GEANT4 [16]. Background from two-photon and Bhabha events is estimated from data.

The signature for $\tau \rightarrow l\nu\bar{\nu}$ decays is a charged particle (track), identified either as an electron or a muon, and an energy deposit (cluster) in the EMC not associated with any track, photon, or undetected neutral cluster, measured on the inner wall of the EMC. Since muons with momenta less than 20 GeV/c do not penetrate into the IFR, the BDT also uses as input the energy loss $dE/dx$ in the tracking system to maintain a very low $\mu$ misidentification probability and a high selection efficiency. The electron and muon identification efficiencies are 91% and 62%, respectively. The probability for a $\tau$ to be misidentified as an $e$ is below 0.1%, while the probability to be misidentified as a $\mu$ is around 1% depending on momentum.

After the preselection, both samples are dominated by background events. For the $\tau \rightarrow \mu\nu\bar{\nu}$ sample, the main background sources are initial-state radiation, $\tau \rightarrow \pi\nu\bar{\nu}$
decays, $e^+e^- \to \mu^+\mu^-$ events, and $\tau \to \pi \nu$ decays. For the $\tau \to e\nu\bar{\nu}$ sample, almost all background contribution is from $\tau \to e\nu\bar{\nu}$ decays in which the electron radiates a photon in the magnetic field of the detector (bremsstrahlung). Further background suppression is obtained by placing requirements on the angle between the lepton and photon in the CM frame ($\cos \theta_{\gamma\nu}$). For $\tau \to \mu\nu\bar{\nu}$ we require $\cos \theta_{\gamma\nu} > 0.99$, while for $\tau \to e\nu\bar{\nu}$ we require $\cos \theta_{\gamma\nu} > 0.97$ (see Figs. 2 and 3). To reject background from $\tau \to e\nu\bar{\nu}$ decays in the $\tau \to e\gamma\nu\bar{\nu}$ sample, we further impose a minimum value for the invariant mass of the lepton-photon pair $M_{l\gamma} \geq 0.14 \text{ GeV}/c^2$ for this channel. In addition to the aforementioned quantities, the selection criteria use the energy of the photon and $d_{l\gamma}$. The selection criteria are optimized in order to give the smallest statistical and systematic uncertainty on the branching fractions.

After optimization, for $\tau \to \mu\nu\bar{\nu}$, we require $\cos \theta_{\gamma\nu} \geq 0.99$, $0.10 \leq E_{\gamma} \leq 2.5 \text{ GeV}$, $6 \leq d_{l\gamma} \leq 30 \text{ cm}$, and $M_{l\gamma} \leq 0.25 \text{ GeV}/c^2$. The requirement on $M_{l\gamma}$ rejects backgrounds from nonsignal $\tau$ decays. For the $\tau \to e\gamma\nu\bar{\nu}$ channel, we require $\cos \theta_{\gamma\nu} \geq 0.97$, $0.22 \leq E_{\gamma} \leq 2.0 \text{ GeV}$, $8 \leq d_{l\gamma} \leq 65 \text{ cm}$ in addition to $M_{l\gamma} \geq 0.14 \text{ GeV}/c^2$.

The signal efficiencies, the fraction of background events, and the number of events selected in the data are given in Table I.

The branching fraction is determined using

$$B = \frac{N_{\text{obs}}(1 - f_{\text{bkg}})}{2\sigma_{\tau \tau} L \epsilon},$$

where $N_{\text{obs}}$ is the number of observed events, $\sigma_{\tau \tau}$ is the cross section for $\tau$ pair production, $L$ is the total integrated luminosity, and the signal efficiency $\epsilon$ is determined from the MC sample.

After applying all selection criteria, we find

$$B(\tau \to \mu\nu\bar{\nu}) = (3.69 \pm 0.03 \pm 0.10) \times 10^{-3},$$

$$B(\tau \to e\gamma\nu\bar{\nu}) = (1.847 \pm 0.015 \pm 0.052) \times 10^{-2},$$

where the first error is statistical and the second is systematic.

The systematic uncertainties on signal efficiency and on the number of the expected background events affect the final result and are summarized in Table II. The most

FIG. 2 (color online). Selection of the $\tau \to \mu\nu\bar{\nu}$: (a) distance between lepton and photon candidates on the inner EMC wall, (b) cosine of the angle between momenta of the lepton and photon candidates in the CM frame, (c) invariant mass of the lepton photon pair, and (d) photon candidate energy in the CM frame for radiative $\tau$ decay into a muon after applying all selection criteria except the one on the plotted quantities. The selection criteria on the plotted quantities are highlighted by the vertical lines; we retain the regions indicated by the horizontal arrows.
important contributions to the total uncertainty are from the uncertainties on particle identification and photon detection efficiency.

To estimate the uncertainty on photon detection efficiency, we rely on $e^+ e^- \rightarrow \mu^+ \mu^- \gamma$ events for the high energy region ($E_{\gamma} > 1$ GeV) and photons from $\pi^0$ decays for the low energy region ($E_{\gamma} < 1$ GeV). Using fully reconstructed $e^+ e^- \rightarrow \mu^+ \mu^- \gamma$ events, we find that the photon detection efficiency for data and MC samples are consistent within 1% for $E_{\gamma} > 1$ GeV. For photon energies $E_{\gamma} < 1$ GeV, we measure the ratio of the branching fractions for $\tau \rightarrow \pi \nu$ and $\tau \rightarrow \rho \nu$ decays. The resulting uncertainty on the $\pi^0$ reconstruction efficiency is found to be below 3%. Taking into account the 1.1% uncertainty on the branching fractions, the resulting energy-averaged

uncertainty on the single photon detection efficiency is 1.8%. We use this value as the systematic uncertainty in the efficiency for $\tau \rightarrow \ell \nu \bar{\nu}$.

The uncertainties on particle identification efficiency are estimated using control samples, by measuring the deviation of the data and MC efficiencies for tracks with the same kinematic properties. The uncertainty on the efficiency of the electron identification is evaluated using a control sample consisting of radiative and nonradiative Bhabha events, while the uncertainty for muons is an $e^+e^- \rightarrow \mu^+\mu^-\gamma$ control sample. The uncertainty on the probability of misidentifying the pion as a muon or electron is evaluated using samples of $\tau \rightarrow \pi\pi\nu\bar{\nu}$ decays. The corresponding systematic uncertainty on the efficiency for $\tau \rightarrow \ell \nu \bar{\nu}$ is 1.5% for both channels.

For the background estimation, we define control regions that are enhanced with background events. For $\tau \rightarrow \mu\nu\bar{\nu}$, where the major background contribution is not peaking in $\cos \theta_{\mu\gamma}$, we invert the cut on $\cos \theta_{\mu\gamma}$. For $\cos \theta_{\mu\gamma} < 0.8$, the maximum expected signal rate is 3% of the corresponding background rate. The maximum discrepancy between the MC sample prediction and the number of observed events is 8%, with an excess of events in the MC sample. We take this discrepancy as an estimate of the uncertainty on the background prediction. For $\tau \rightarrow e\nu\bar{\nu}$, the maximum contamination of signal events in this region is 10%, and the maximum discrepancy between the prediction and the number of observed events is 4% with an excess of data events. We take this value as an estimate of the uncertainty on the background rate. The errors on the branching fractions due to the uncertainty on background estimates are 0.9% for $\tau \rightarrow \mu\nu\bar{\nu}$ and 0.7% for $\tau \rightarrow e\nu\bar{\nu}$, respectively (Table II).

Cross-checks of the background estimation are performed by considering the number of events expected and observed in different sideband regions immediately neighboring the signal region for each decay mode and found to be compatible with the aforementioned systematic uncertainties.

The asymmetric configuration of the BABAR experiment may lead to a dependence of the result on the charge of the final state lepton. We studied this possible bias source by comparing the efficiencies and the branching fractions, as found separately for the two charge conjugated states, for the two signal channels. In both cases we find the yields to be in agreement within statistical uncertainties, and we conclude that this contribution is negligible.

All other sources of uncertainty, including current knowledge of the $\tau$ branching fractions [13], total number of $\tau$ pairs, limited MC statistics, dependence on selection criteria, and track momentum resolution are found to be smaller than 1.0%.

In conclusion, we have made a measurement of the branching fractions of the radiative leptonic $\tau$ decays $\tau \rightarrow e\nu\bar{\nu}$ and $\tau \rightarrow \mu\nu\bar{\nu}$, for a minimum photon energy of 10 MeV in the $\tau$ rest frame, using the full data set of $e^+e^-$ collisions collected by BABAR at the center-of-mass energy of the $\Upsilon(4S)$ resonance. We find $\mathcal{B}(\tau \rightarrow e\nu\bar{\nu}) = (3.69 \pm 0.03 \pm 0.10) \times 10^{-3}$ and $\mathcal{B}(\tau \rightarrow \mu\nu\bar{\nu}) = (1.847 \pm 0.015 \pm 0.052) \times 10^{-2}$, where the first error is statistical and the second is systematic. These results are more precise by a factor of 3 compared to previous experimental measurements. Our results are in agreement with the Standard Model values at tree level, $\mathcal{B}(\tau \rightarrow e\nu\bar{\nu}) = 3.67 \times 10^{-3}$ and $\mathcal{B}(\tau \rightarrow \mu\nu\bar{\nu}) = 1.84 \times 10^{-2}$ [3], and with current experimental bounds.

We are grateful for the extraordinary contributions of our PEP-II colleagues in achieving the excellent luminosity and machine conditions that have made this work possible. The success of this project also relies critically on the expertise and dedication of the computing organizations that support BABAR. The collaborating institutions wish to thank SLAC for its support and the kind hospitality extended to them.
