Abstract

\textbf{PURPOSE}—Isocitrate dehydrogenase (\textit{IDH}) gene mutations occur in low-grade and high-grade gliomas. We sought to identify the genetic basis of malignant phenotype heterogeneity in \textit{IDH}-mutant gliomas.

\textbf{METHODS}—We prospectively implanted tumor specimens from 20 consecutive \textit{IDH1}-mutant glioma resections into mouse brains and genotyped all resection specimens using a CLIA-certified molecular panel. Gliomas with cancer driver mutations were tested for sensitivity to targeted inhibitors in vitro. Associations between genomic alterations and outcomes were analyzed in patients.

RESULTS—By 10 months, 8 of 20 IDH1-mutant gliomas developed intracerebral xenografts. All xenografts maintained mutant IDH1 and high levels of 2-hydroxyglutarate on serial transplantation. All xenograft-producing gliomas harbored “lineage-defining” mutations in CIC (oligodendroglioma) or TP53 (astrocytoma), and 6 of 8 additionally had activating mutations in PIK3CA or amplification of PDGFRA, MET or N-MYC. Only IDH1 and CIC/TP53 mutations were detected in non-xenograft-forming gliomas (P=.0007). Targeted inhibition of the additional alterations decreased proliferation in vitro. Moreover, we detected alterations in known cancer driver genes in 13.4% of IDH-mutant glioma patients, including PIK3CA, KRAS, AKT or PTEN mutation or PDGFRA, MET or N-MYC amplification. IDH/CIC mutant tumors were associated with PIK3CA/KRAS mutations while IDH/TP53 tumors correlated with PDGFRA/MET amplification. Presence of driver alterations at progression was associated with shorter subsequent progression-free survival (median 9.0 vs. 36.1 months, P=.0011).

CONCLUSION—A subset of IDH-mutant gliomas with mutations in driver oncogenes has a more malignant phenotype in patients. Identification of these alterations may provide an opportunity for use of targeted therapies in these patients.

IDH mutation; glioma; progression; orthotopic xenograft; driver mutation

INTRODUCTION

Shortly after the discovery of recurrent mutations in the isocitrate dehydrogenase (IDH1) and IDH2 genes it was recognized that IDH-mutant diffuse gliomas have a clinical phenotype distinct from IDH-wildtype gliomas (1-4). More recently, two major genetic subtypes of IDH-mutant glioma have been identified: one genetic lineage is defined by TP53 and alpha thalasemia/mental retardation syndrome x-linked (ATRX) mutations and strong correlation with astrocytic histology (1, 2, 5, 6), and a second lineage is characterized by concurrent mutations in homolog of Drosophila capicua (CIC), Far Upstream Element Binding Protein (FUBP1) and the telomerase reverse transcriptase (TERT) promoter as well as tight association with 1p/19q codeletion and oligodendroglioma histopathology (2, 5, 7-12). Notably, the genomic alterations that frequently occur in the more common IDH-wildtype primary glioblastoma (GBM, WHO Grade IV), including EGFR gene amplification and rearrangement, PTEN mutation and CDKN2A-CDKN2B deletion, are rare in IDH-mutant gliomas (2, 5, 12, 13). Thus, IDH-mutant gliomas are thought to arise via a molecular pathway that is distinct from primary GBM (5, 6).

Although IDH-mutant diffuse gliomas carry a relatively better prognosis (1-4), most ultimately transform to a more malignant phenotype and become lethal. A fundamental paradigm in cancer progression imparts that morphologic changes during the process of malignant transformation reflect the sequential acquisition of genetic alterations (14). IDH1/2 mutation and widespread hypermethylation of CpG islands (CpG island hypermethylator phenotype or CIMP) are the earliest known events in glioma development, preceding the “lineage-defining” acquisition of TP53 mutation in astrocytomas or 1p/19q co-deletion in oligodendrogliomas (5, 10, 15-18). Mutant IDH1/2 represents a “trunk”
mutation (19) in the molecular evolutionary tree of gliomas since it is ubiquitously present throughout the tumor cell mass (15, 20) and retained on progression from low- to high-grade with few exceptions (2, 10, 15, 20, 21). The lineage-defining or “secondary” genetic alterations in IDH-mutant gliomas (TP53/ATRX mutations or 1p/19q codeletion/CIC mutations) are also early events in tumor development, as they are present in the vast majority of low-grade (WHO grade II) diffuse gliomas (2, 12). Therefore, “primary” IDH1/2 mutation and “secondary” genetic alterations are unlikely to be the triggers of more malignant behavior. A few genetic alterations have been reported to be associated with higher grade or progressive IDH-mutant gliomas, however the alterations that drive transformation to a more malignant phenotype remain largely unknown (2, 5, 13, 15).

One limitation in the study of IDH-mutant glioma has been the scarcity of experimental models harboring endogenous IDH1/2 mutation. Successful propagation of tumor initiating cells (TICs), cancer cells that display stem cell properties, and generation of intracerebral glioma xenografts from IDH-mutant patient gliomas are rare (22-25). The reasons for the difficulty in establishing models from patient IDH-mutant gliomas are unknown.

Herein, we hypothesized that additional “tertiary” genetic alterations, which have been noted to occur in IDH-mutant gliomas (7, 15, 26, 27), could be the drivers of the progressive malignant phenotype of IDH-mutant gliomas. We therefore tested 20 consecutive IDH-mutant glioma specimens from patients undergoing surgery at our institution for the ability to establish intracerebral xenografts in mice. We performed a comparative genetic analysis of all primary tumor specimens using a CLIA-certified molecular panel and discovered that the IDH-mutant gliomas that successfully established orthotopic xenografts (8 tumors) were enriched with additional tertiary oncogenic genetic alterations, including PIK3CA mutation and amplification of the PDGFRA, MET, and N-MYC genes. IDH-mutant glioma TICs generated from xenograft-forming tumors exhibit oncogenic addiction to tertiary mutations. In IDH-mutant glioma patients, tertiary alterations appear to be acquired at the time of tumor progression and also associated with higher pathological grade and shorter progression-free survival. These data indicate acquisition of tertiary alteration is associated with more aggressive tumor behavior and may predict the ability to establish intracerebral xenografts in mice.

**METHODS**

**Biologic Samples and Clinical Data**

From September 2011 to October 2012, we prospectively accrued 20 consecutive untreated (9 patients) and previously treated (11 patients) IDH-mutant glioma patients undergoing resection at the Massachusetts General Hospital (MGH). Patients either had previously confirmed IDH mutation or were accrued if clinical suspicion of IDH-mutant glioma was high based on characteristic features such as young age, frontal location, and lesser degree of contrast enhancement and necrosis on neuroimaging (5). Progression of disease was confirmed by either tissue diagnosis or standard response criteria (28). All tumor samples and clinical information were collected under MGH institutional review board-approved protocols, and informed consent was obtained from all patients. All mouse procedures were approved by the Subcommittee on Research Animal Care at MGH.
Glioma Neurospheres and Orthotopic Xenografts

Fresh surgical specimens were enzymatically dissociated, and 2-5 \times 10^4 cells were stereotactically implanted into the right striatum of the brains of 7-10-week-old female SCID mice as described (29). In some cases when an excess of tumor tissue was available, cells were briefly cultured in neurosphere medium as described (30) to enrich for TIC neurospheres, and a similar number of cells were implanted within 48 hours of \textit{in vitro} culture. There was no notable difference in xenograft formation with either method. Mice were monitored for status twice per week and sacrificed when neurological deficits became significant. A minimum 10-month observation period after implantation was required to determine whether orthotopic xenografts developed, although all animals were sacrificed after 1 year to assess for tumor formation. Brains were removed for pathological studies and tumors were excised to re-establish TIC neurosphere cultures. TICs were then either implanted into the brains of new mice or used for \textit{in vitro} assays as described (29, 31).

Histology and Immunostaining

Hematoxylin and eosin staining and immunohistochemistry (IHC) were performed on formalin-fixed paraffin-embedded (FFPE) sections as described (29, 31). Primary antibodies used for IHC were anti-IDH1 R132H (Dianova, 1: 100), Ki-67 (MIB-1, Dako, 1: 150), anti-CD31 (BD Pharmingen, 1: 150) and anti-nestin (Santa Cruz, 1: 400).

Genotyping and Fluorescent in Situ Hybridization Data

Clinical molecular profiling was performed as described (32, 33). Briefly, the MGH SNaPshot assay is a multiplexed, PCR-based, single-base extension assay that interrogates 73 commonly mutated loci from 23 genes (\textit{AKT1, APC, BRAF, CTNNB1, EGFR, EML4-ALK, HER2, FGFR3, GNA11, GNAQ, GNAS, HRAS, IDH1, IDH2, KIT, KRAS, MEK1, MEK2, NOTCH1, NRAS, PIK3CA, PTEN, RET, TP53}). Genomic PCR-based sequencing was used to sequence all coding exons of the \textit{IDH1, CIC, TP53, PIK3CA} and \textit{PIK3R1} genes. PCR products were amplified from genomic DNA templates with Platinum Taq polymerase per manufacturer’s protocol using intron-based primers spanning the expressed coding sequences (Supplementary Table S2) then Sanger sequenced (Beckman Coulter Genomics). Fluorescence in situ hybridization (FISH) assays for the \textit{EGFR, MET} and \textit{PDGFR\alpha} genes were performed using BAC probes CTD-2113A18 (7p \textit{EGFR} locus), CTB-13N12 (7q \textit{MET} locus), CEP7 (centromere 7 control), RP11-58C6 (4q \textit{PDGFR\alpha} locus) and CEP4 (centromere 4 control) (Abbott) as described (32). BAC clone RP11-480N14 (chr2: 15991148-16158895) was used to make the \textit{N-MYC} probe and ALK (2p23) Proximal Probe (Kreatech) was used for centromere 2 control. Gene/control probe copy number ratios of > 2.0 were considered amplified. 1p and 19q status was determined using the Vysis 1p36/1q25 and 19q13/19p13 FISH Probe Kit (Abbott). 1p/1q and 19q/19p ratios of < 0.75 were considered loss and > 0.75 as maintained.

Gas chromatography-mass spectroscopy (GC-MS) Data

Ten to 20 mg of frozen tumor tissue was homogenized and extracted with methanol/chloroform. Metabolites were derivatized with N-(tert-butyldimethylsilyl)-N-methyl-trifluoroacetamide, with 1% tert-Butyldimethylchlorosilane (Sigma) and analyzed on a
6890N GC system (Agilent Technologies) combined with a 5975B Inert XL MS system (Agilent Technologies). 2HG fragment 433m/z and the glutamate fragment 432m/z were used for further analysis (34). 2HG and glutamate concentrations were normalized to the internal standard norvaline and tissue weight as described (35).

**In vitro Drug and shRNA Inhibition Studies**

Dissociated TICs were seeded to 96-well plates at 7000 - 8000 cells per well. Serially diluted inhibitor was added to wells, and cells were further cultured for 5 days. Viability of cells was measured by CellTiter-Glo assay (Promega) and the EC50 values were determined. All *in vitro* inhibitor assays were performed on TICs within 5 passages from dissociation from tumor. JQ1 and BYL719 were gifts from James E. Bradner and Jeffrey A. Engelman, respectively. Crizotinib and sunitinib were obtained from Selleck Chemicals.

To knock down N-myc expression, lentivirus vectors carrying shRNA for *N-MYC* (Sigma, pLKO.1) were packaged using ScreenFect (Wako)-mediated co-transfection of vector and packaging plasmid DNAs to 293T cells. MGG152 cells were infected with lentivirus in the presence of polybrene (6 μg/ml), selected with puromycin (0.5 μg/ml) for 3 days, and silencing confirmed with Western blot. Cell viability and sphere formation were assessed 7 days later.

**Statistical Analyses**

Statistical analysis was performed with JMP software. For parametric analyses, two-tailed t-tests were employed and for analysis of frequencies of nominal data, two-tailed Fisher's Exact test was employed. Data are expressed as mean + SD. Survival was analyzed by the Kaplan-Meier method with two-sided log-rank statistics.

**RESULTS**

**Establishment of Intracerebral Xenografts with Endogenous IDH Mutation**

We studied the potential of 20 serially collected patient *IDH1*-mutant glioma specimens to form xenograft after stereotactic implantation in immunocompromised mouse brains. Two tumors were low-grade (WHO grade II), 10 were anaplastic (WHO grade III), and 8 were GBMs, of which 3 were “secondary” GBMs that had transformed from a known lower-grade glioma (Table 1). All 20 gliomas in our study had *IDH1* mutations, which occur far more frequently than *IDH2* mutations in gliomas (2, 36). In parallel, we cultured TIC-enriched cells using the neurosphere system. Notably, 8 of 20 *IDH*-mutant glioma tumors generated intracerebral xenografts, with the time to lethal xenograft ranging between 1-7 months (**Fig. 1, Table 1, Supplementary Fig. S1**). All xenografts closely recapitulated parent human tumor phenotypes histologically (**Fig. 1, Supplementary Figs. S1, S2, S3, Table 1**). *In vitro* proliferation of the different lines varied, with doubling times ranging from 2.5 days (MGG152) to 10 days (MGG79, MGG108, MGG132). All lines could be passaged for at least 5 passages, however 2 lines (MGG119, MGG152) could be stably cultured for at least 4 months. All xenografts harbored endogenous *IDH1 R132H* mutation and retained the mutant allele upon serial passage *in vitro* or serial transplantation in orthotopic xenograft (**Supplementary Figs. S4, S5**). Orthotopic xenografts were confirmed
by GC-MS to have high-level production of the mutant-specific metabolite, 2-hydroxyglutarate (2HG) (Supplementary Table S1).

Genetic Alterations Associated With Ability to Generate Intracerebral Xenograft

We sought to identify the mechanisms accounting for the ability to generate orthotopic xenograft in our set of IDH-mutant gliomas. There was no clear distinction in host factors such as patient age, sex, or prior treatment (radiation or various combinations of radiation and different chemotherapies; Table 1) between gliomas that formed orthotopic xenograft versus those that did not. Generally, tumors that were able to form xenografts had GBM (WHO grade IV) histology (6 of 8 xenografts vs. 2 of 12 in the non-xenograft-forming subset) and lacked 1p/19q codeletion (7 of 8 xenografts).

We conducted a comparative genetic analysis on the primary tumor specimens to assess whether additional oncogenic alterations might account for differences in the ability to generate xenograft. All 8 xenograft-forming tumors and 10 of 12 non-xenograft-forming tumors harbored the IDH1 R132H variant, which accounts for ~90% of the IDH1 mutations in gliomas (2, 12, 36), and the remaining two non-xenograft-forming gliomas harbored IDH1 R132C. Interestingly, one glioma xenograft (MGG79) was homozygous for IDH1 R132H mutation and the corresponding orthotopic xenograft produced high-levels of 2HG (Supplementary Fig. S4, Supplementary Table S1). This finding is in contrast with a previous report suggesting a wild-type IDH1 allele is necessary for 2HG production (37).

Focused genotyping analysis of all implanted primary tumors was conducted with our CLIA-certified clinical molecular profiling platform (32), which surveys 25 commonly-mutated cancer-associated genes. We specifically assessed for “tertiary” genetic alterations, which we defined as non-lineage mutations, since lineage-associated mutations (astrocytic ATRX/TP53 mutations or oligodendroglial CIC/TERT mutations and 1p/19q codeletion) occur in virtually all low-grade IDH-mutant gliomas. Strikingly, 6 of 8 xenograft-forming tumors harbored tertiary mutations whereas none were detected in non-xenograft-forming patient gliomas (P = .0007) (Table 1).

The detected tertiary alterations included hotspot activating mutations in PIK3CA (2/6) and high-level focal amplifications in the PDGFRA (2/6) and MET (1/6) genes (Table 1). In addition, we sequenced the entire coding regions of PIK3CA, which encodes p110alpha, and PIK3R1, which encodes the PI3K regulatory subunit p85alpha, in all xenograft-forming tumors and detected no other mutations. Notably, one GBM had focal primitive neuroectodermal tumor (PNET) histopathology (MGG152, Fig. 1A) and was unusually malignant in both the patient (5 month overall survival) and in orthotopic xenograft (lethal within 1 month, Table 1). A previous study detected C-MYC or N-MYC amplification in a significant proportion of malignant gliomas harboring PNET-like components (38), therefore we interrogated these genes in MGG152 and identified high-level N-MYC amplification (Fig. 2A). We confirmed that all the tertiary genetic alterations detected in the primary tumors were maintained in the respective orthotopic xenografts (Fig. 2A), suggesting these mutations play a role in the tumor initiating capability of IDH1-mutant gliomas.

Clin Cancer Res. Author manuscript; available in PMC 2014 December 01.
Tertiary Genetic Alterations are Drivers in IDH-Mutant Glioma Xenografts

We then tested the effect of small molecule inhibitors targeted at the identified tertiary mutations on in vitro proliferation. We examined the impact of BYL719, a highly selective inhibitor of p110alpha (39), on the viability of MGG108 (PIK3CA R93Q) and MGG152 (PIK3CA/PIK3R1 wildtype) TICs. We observed more potent inhibition of MGG108 than MGG152 cells (IC$_{50}$ = 7.5 μM for MGG108 vs. 20.1 μM for MGG152), indicating PIK3CA mutation functions as a driver of proliferation in MGG108 cells (Fig. 2B). We then examined the effect of the Myc pathway small molecule inhibitor JQ1 (40) in MGG108 and MGG152 (N-MYC amplified). As expected, MGG152 was significantly more sensitive to JQ1 in cell viability assays relative to MGG108, which lacks N-MYC or C-MYC amplification (IC$_{50}$ = 0.04 μM for MGG152 vs. 2.08 μM for MGG108) (Fig. 2B). Furthermore, shRNA knockdown of N-myc expression in MGG152 suppressed cell proliferation and nearly eliminated sphere formation ability (Fig. 2C, Supplementary Fig. S6). We also tested sunitinib and crizotinib, small molecule inhibitors of PDGFR and c-Met, respectively, in several lines with known PDGFRA and MET copy number status. We found that sunitinib was more potent against a line with high-level PDGFRA amplification (MGG117) than those without (MGG108 and MGG119), while crizotinib was most effective in a line harboring MET amplification (MGG132) (Supplementary Fig. S7). These data suggest that tertiary alterations are oncogenic drivers in IDH-mutant glioma xenografts.

Acquisition of Tertiary Mutations During Malignant Transformation

We then asked whether tertiary alterations are acquired when lower-grade IDH-mutant gliomas progress or transform to higher grade tumors in patients. We examined our dataset of 149 IDH-mutant glioma patients who had clinical molecular profiling at our center and identified 20 tumors with tertiary alterations (13.4%). Tertiary alterations were nearly exclusively present in progressive low-grade (WHO grade II) or high-grade (WHO grade III or IV) tumors (Table 2); specifically 6 grade II (4 progressive), 6 grade III and 8 grade IV tumors. Presence of a tertiary mutation was associated with grade IV (GBM) vs. lower grade (grade II or III) histology ($P$ = .027).

We then analyzed a subset of 56 patients who underwent biopsy and genotyping at the time of radiographically defined disease progression. Presence of tertiary alteration in the progressive tumor (14 patients, 25%) was associated with significantly shorter subsequent PFS (median 9.0 months, 95% CI 4.4 - 49.3, with tertiary alteration versus 36.1 months, 95% CI 18.7 - 52.8, without ($P$ = .0011) (Figs. 3A, 3B). Notably, there was no difference in PFS from the time of initial diagnosis (median 55.6 months, 95% CI 24.6- 93.1, with tertiary alteration versus 54.1 months, 95% CI 35.7 - 73.0, without, $P$ = .76) (Fig. 3A), implicating the tertiary alteration detected at progression as the driver of malignant degeneration in these patients. There was no detectable difference in overall survival, however there were few deaths in either group (13 of 56 total patients) therefore longer follow-up time is needed to assess this endpoint.

Several tertiary genetic events were recurrently identified (Table 2), including activating mutations in PIK3CA (9 tumors) and KRAS (4 tumors) and PDGFRA amplification (4
tumors). \textit{PIK3CA} and \textit{KRAS} mutations were most often detected in tumors with at least a component of oligodendroglioma histology (7 of 9 \textit{PIK3CA} mutant and 3 of 4 \textit{KRAS} mutant tumors). Interestingly, all 4 \textit{PDGFRA}-amplified tumors were purely astrocytic (\(P = .026\)). When specific oncogenes were compared by \textit{IDH} genetic lineage rather than histopathology (within the set of tumors with tertiary mutations and confirmed lineage mutations), we identified significant associations between 1p/19q codeleted tumors and intracellular signaling pathway gene mutations (\textit{KRAS} or \textit{PIK3CA}, \(P = .002\)) and between receptor tyrosine kinase amplification (\textit{PDGFRA} or \textit{MET}) and non-1p/19q codeleted (\textit{TP53} mutant) tumors (\(P = .029\)).

To assess whether tertiary alterations are acquired at tumor progression, we examined paired tumor specimens from newly diagnosed and progressive tumors from 6 patients in whom we detected tertiary mutations. For two patients with \textit{PDGFRA} amplification and one patient with focal \textit{MET} amplification, we confirmed these alterations were present in the progressive but not in the initial tumor specimens (\textbf{Fig. 3C}). In 2 of 3 \textit{PIK3CA} mutant patients, the \textit{PIK3CA} mutations were present only in the progressive tumor (\textbf{Fig. 3C}). The third patient (Patient 6 in Table 2) had \textit{PIK3CA E545G} mutation in both the diagnostic and progressive tumor specimens. This patient was treated with 12 cycles of temozolomide and progressed just 24.6 months after diagnosis, a relatively rapid time to progression for low-grade oligodendrogliomas with 1p/19q codeletion.

\section*{DISCUSSION}

\textit{IDH}-mutant diffuse gliomas nearly always progress after radiation therapy and chemotherapy and eventually transform to more malignant tumors. Effective therapeutic options at that stage are lacking. Herein we demonstrate that the subset of \textit{IDH}-mutant gliomas that acquire an aggressive phenotype late in the disease are driven by specific tertiary oncogenic alterations. These tertiary alterations are associated with more malignant tumors in patients and increased tumor-forming ability in mice. Importantly, these tertiary alterations represent potential therapeutic targets for patients with \textit{IDH}-mutant gliomas who are most in need of treatment.

Our data suggest that after acquisition of lineage-defining mutations, \textit{IDH}-mutant gliomas may follow multiple pathways to transformation (\textbf{Fig. 4}). 1p/19q codeleted tumors tend to activate the PI3K/mTOR or Ras intracellular signaling pathways and \textit{TP53}-mutant tumors tend to amplify growth factor receptor tyrosine kinases. Our findings are consistent with prior reports; recurrent \textit{PIK3CA} mutations have been detected in a subset of \textit{IDH}-mutant, 1p/19q codeleted anaplastic oligodendrogliomas (7, 26) and two recent reports observed enrichment of \textit{PDGFRA} amplification in \textit{IDH}-mutant versus \textit{IDH}-wildtype primary GBM (27, 41). In addition, we find that activation of N-myc may be a particularly malignant transformation pathway in \textit{IDH}-mutant glioma. A recent study similarly observed a correlation between \textit{c-Myc} expression and shorter time to transformation within \textit{IDH}-mutant gliomas (42). Together with these reports, our data suggests \textit{IDH}-mutant gliomas may undergo a sequenced genetic evolution analogous to \textit{IDH2}-mutant acute myeloid leukemia, where stepwise acquisition of distinct classes of mutations results in more aggressive disease (43).
The mechanisms by which IDH-mutant gliomas acquire tertiary mutations are largely unknown. A recent study observed that a subset of IDH-mutant low-grade gliomas developed a hypermutation phenotype (15, 44) after treatment with temozolomide. All of the hypermutated gliomas in their dataset harbored driver mutations, many in the PI3K/mTOR signaling pathway (15). In our dataset, 10 of 20 patients with tertiary mutation were previously treated with alkylating chemotherapy (Table 2). Five of our 10 chemotherapy-treated patients had PI3K/mTOR pathway mutations in their tumors, and interestingly one tumor had activating mutations in 3 oncogenes (PIK3CA, AKT and KRAS), suggesting it may be hypermutated. However, 9 patients as well as two xenograft-forming tumors from our implantation study harbored tertiary alterations and had no prior treatment, indicating that genomic instability resulting from DNA-damaging therapy is not the sole evolutionary path to malignant progression in IDH-mutant gliomas. The drivers of tertiary mutation in untreated IDH-mutant tumors remain to be determined.

The overall frequency of tertiary mutations in our dataset was 13.4%, which may be reflective of the focused nature of our genotyping panel. Our data suggests re-sampling of tumor specimens at the time of progression may increase detection frequencies. We also provide rationale for sampling tumor specimens throughout the course of disease as the acquired tertiary mutation may present an opportunity for therapeutic targeting. Future genomic profiling studies that also include paired tumor samples will address important remaining questions including the scope and frequency of recurrent tertiary mutations, the timing of their appearance and the mechanisms that drive their development. Of note, our genotyping panel did not interrogate many genes commonly mutated in gliomas, such as CDK4/6, MDM2, CCND2, AKT3, RB, PARK2 and NF1 (1, 45). However, these mutations were detected in datasets consisting mostly of IDH-wildtype gliomas that evolve along a distinct molecular pathway.

By identifying recurrent, functionally significant tertiary genetic alterations, we set the stage for targeted therapy in IDH-mutant gliomas. Pharmacologic inhibitors for all of the tertiary alterations identified in our work are in development. Notably, our data suggests PDGFRA amplification warrants investigation in TP53-mutant, IDH-mutant gliomas. Outcomes for this subgroup are poor relative to the 1p/19q codeleted subtype (6) possibly due to the uncertain efficacy of chemotherapy in these tumors given their lack of 1p/19q codeletion (46, 47). We detected recurrent mutations in KRAS, which have been reported to be rare in glial tumors (45, 48, 49). Recent clinical data suggest that cancers driven by KRAS mutation may be sensitive to MEK inhibitors (50). Additionally, our data suggests investigation of Myc pathway inhibitors (40) may be justified for particularly aggressive IDH-mutant gliomas, since these may harbor C-MYC or N-MYC amplification or inappropriate c-Myc expression. Analogously, a recent study reported that Myc pathway inhibition potently reduces viability of acute myeloid leukemia cells driven by mutant IDH2 (43).

Finally, development of anticancer agents in IDH-mutant gliomas has been limited by the scarcity of biologically accurate preclinical models that are serviceable for testing therapeutics. We have established a panel of endogenous IDH-mutant intracerebral glioma xenografts that represent a powerful platform for studying IDH-mutant tumor biology and for answering fundamental questions regarding treatment of IDH-mutant gliomas. Future
work utilizing these orthotopic xenografts may help determine the optimal therapeutic strategy for IDH-mutant gliomas, which may involve inhibition of mutant IDH1, inhibition of tertiary genetic alterations, alteration of metabolic or epigenetic pathways, or a combination thereof.

REFERENCES

Recurrent mutations in the isocitrate dehydrogenase 1 (IDH1) and IDH2 genes identify gliomas with a better prognosis. However, most IDH-mutant gliomas eventually transform to more aggressive tumors and become fatal. The genetic events that drive this later malignant behavior are largely unknown. Here, we find that a subset of IDH-mutant gliomas acquire mutations in cancer driver genes when they recur. Presence of these mutations is associated with more rapid subsequent progression. We also find that genetic subtypes of IDH-mutant gliomas utilize distinct oncogenic pathways during transformation to more malignant tumors. Moreover, IDH-mutant gliomas with driver mutations preferentially establish orthotopic xenograft tumors in mouse brain and are sensitive to targeted inhibition of the mutant gene product. Identification of targetable recurrent driver mutations provides novel therapeutic possibilities for the IDH-mutant glioma patients who are most in need of new treatments.
Figure 1. Mouse orthotopic xenografts generated from patient IDH1 R132H-mutant gliomas
(A) Rows: Individual IDH1-mutant glioma orthotopic (intracerebral) xenografts. Columns left to right: xenograft line and patient tumor histology; representative patient MRI (yellow arrows highlight areas of tumor); gross xenograft histological hematoxylin and eosin (HE) section; microscopic xenograft HE section; gross xenograft immunohistochemical (IHC) section stained with IDH1 R132H mutant-specific antibody (brown); microscopic xenograft anti-IDH1 R132H (brown) IHC. Predominantly nodular (MGG60, 152) and infiltrative (MGG79, 117) growth patterns of xenografts are in accordance with the respective human tumors as demonstrated by MRI. (B and C) Microscopic section of MGG117 primary tumor (B) and orthotopic xenograft (C) showing marked cellular heterogeneity and nuclear pleomorphism in both sections. (D and E) MGG60 xenograft demonstrating tumor angiogenesis by (D) HE and (E) endothelium-specific anti-CD31 antibody IHC. GBM-O, GBM with oligodendrogial component; Rec AOA, recurrent anaplastic oligoastrocytoma; Sec GBM, secondary GBM; GBM-PNET, GBM with primitive neuroectodermal tumor component.

Clin Cancer Res. Author manuscript; available in PMC 2014 December 01.
Figure 2. Recurrent tertiary genetic alterations in IDH-mutant gliomas drive tumor cell growth

(A) Fluorescent in situ hybridization (FISH) images of primary tumors (left column) and corresponding orthotopic xenografts (right column). Top row: MGG117 probed with PDGFRα (red) and CEN4 control (green). 2nd row: MGG132 primary tumor (left) probed with MET (green) and CEN7 control (red) and xenograft (right) probed with MET (red) and CEN7 (green). 3rd row: MGG152 probed with N-MYC (orange) and 2p23 control (green). Bottom row: Sequencing traces of the PIK3CA R93 locus with wildtype (black trace) and mutant (green trace, red arrow) alleles. Left: PIK3CA wildtype primary tumor (control). Middle: MGG108 primary tumor. Right: MGG108 TICs. (B) Effect of BYL719 and JQ1 on MGG108 and MGG152 TICs. Asterisk: MGG108 (PIK3CA mutant) and MGG152 (N-MYC amplified) at 10 μM of BYL719 (P = .004, t-test). (C) N-Myc knockdown in MGG152 TICs. MGG152 was infected with lentivirus carrying N-MYC shRNA or empty vector. Upper left panel: Western blot of TICs using antibodies against N-myc and vinculin (loading control). Lower left panel: Cell viability assays of TICs expressing N-MYC shRNA or empty vector. Right panels: TIC neurospheres infected with lentivirus carrying empty (upper) or N-MYC shRNA (lower). TIC, tumor initiating cell.
Figure 3. Tertiary alterations are acquired at progression and reduce subsequent progression-free survival

(A and B) Kaplan-Meier estimates of progression-free survival (PFS) in patients who had biopsy at initial diagnosis and at progression by presence of tertiary alteration. (A) PFS from the time of initial diagnosis and (B) from the time of progression. (C) SNaPshot and FISH images of matched patient tumors. Top left: SNaPshot images of patient 8 reveal wildtype PIK3CA E545 genotype in the initial tumor and PIK3CA E545K mutant allele (red arrow) in the progressive tumor (8-P). Bottom left: FISH images of patient SA initial and progressive (SA-P) tumor with PDGFRA probe (red) and CEN4 control probe (green). Top right: FISH images of patient 19 initial and progressive tumor (19-P) probed for PDGFRA (red) and CEN4 (green). Bottom right: Patient 14 initial and progressive (14-P) tumor probed with MET (green) and CEN7 control (red).
We propose that IDH-mutant gliomas develop and progress through an ordered sequence of oncogenic alterations. IDH-mutant gliomas are initiated by the occurrence of IDH1 or IDH2 mutation and widespread hypermethylation of CpG islands (CpG island methylator phenotype, CIMP) in a glial progenitor cell population. The subsequent acquisition of TP53 and ATRX mutations results in development along an astrocytoma pathway whereas the codeletion of 1p and 19q (t1;19) along with CIC, FUBP1 and TERT mutations result in the formation of oligodendrogliomas. After acquisition of these “lineage-defining” mutations, IDH-mutant astrocytomas and oligodendrogliomas may follow several “tertiary” genetic pathways during the transformation to malignant or high-grade tumors. Astrocytomas tend to amplify growth receptor genes such as PDGFRA and MET, whereas oligodendrogliomas tend to develop activating mutations in intracellular signaling genes such as PIK3CA and KRAS. Alternative tertiary pathways include Myc activation and other undescribed mutations. Acquisition of tertiary genetic alterations may result in more malignant behavior.

RTK, receptor tyrosine kinase; PI3K, Phosphoinositide 3-kinase; MAPK, mitogen-activated protein kinase.

Figure 4. Molecular taxonomy of IDH-mutant glioma progression

We propose that IDH-mutant gliomas develop and progress through an ordered sequence of oncogenic alterations. IDH-mutant gliomas are initiated by the occurrence of IDH1 or IDH2 mutation and widespread hypermethylation of CpG islands (CpG island methylator phenotype, CIMP) in a glial progenitor cell population. The subsequent acquisition of TP53 and ATRX mutations results in development along an astrocytoma pathway whereas the codeletion of 1p and 19q (t1;19) along with CIC, FUBP1 and TERT mutations result in the formation of oligodendrogliomas. After acquisition of these “lineage-defining” mutations, IDH-mutant astrocytomas and oligodendrogliomas may follow several “tertiary” genetic pathways during the transformation to malignant or high-grade tumors. Astrocytomas tend to amplify growth receptor genes such as PDGFRA and MET, whereas oligodendrogliomas tend to develop activating mutations in intracellular signaling genes such as PIK3CA and KRAS. Alternative tertiary pathways include Myc activation and other undescribed mutations. Acquisition of tertiary genetic alterations may result in more malignant behavior.
