Running title: Uptake of H₂ during the life cycle of soil actinobacteria

Summary
Microbe-mediated soil uptake is the largest and most uncertain variable in the budget of atmospheric hydrogen (H₂). The diversity and ecophysiological role of soil microorganisms that can consume low atmospheric abundances of H₂ with high-affinity [NiFe]-hydrogenases is

Author current addresses: (4) Stanford University, Environmental Earth System Science, Palo Alto, CA, 94305, USA. (5) Georgetown University, Communication, Culture and Technology, Washington, DC, 20057.
unknown. We expanded the library of atmospheric H$_2$-consuming strains to include four soil Harvard Forest Isolate (HFI) *Streptomyces* spp., *Streptomyces cattleya*, and *Rhodococcus equi* by assaying for high-affinity hydrogenase (*hhyL*) genes and quantifying H$_2$ uptake rates. We find that aerial structures (hyphae and spores) are important for *Streptomyces* H$_2$ consumption; uptake was not observed in *Streptomyces griseoflavus* Tu4000 (deficient in aerial structures) and was reduced by physical disruption of *Streptomyces* sp. HFI8 aerial structures. H$_2$ consumption depended on the life cycle stage in developmentally distinct actinobacteria: *Streptomyces* sp. HFI8 (sporulating) and *R. equi* (non-sporulating, non-filamentous). Strain HFI8 took up H$_2$ only after forming aerial hyphae and sporulating, while *R. equi* only consumed H$_2$ in the late exponential and stationary phase. These observations suggest that conditions favoring H$_2$ uptake by actinobacteria are associated with energy and nutrient limitation. Thus, H$_2$ may be an important energy source for soil microorganisms inhabiting systems in which nutrients are frequently limited.

**Main Text**

**Introduction**

Microbe-mediated soil uptake is the leading driver of variability in atmospheric H$_2$ and accounts for 60% to 90% of the total H$_2$ sink; however, the dependence of this sink on environmental parameters is poorly constrained by field and lab measurements (Xiao et al., 2007; recently reviewed by Ehhalt and Rohrer, 2009). Atmospheric H$_2$ is an abundant reduced trace gas (global average of 530 ppb) that influences the atmospheric chemistry of the troposphere and the protective stratospheric ozone layer (Novelli et al., 1999). Most notably, the reaction of H$_2$ with the hydroxyl radical (•OH) attenuates the amount of •OH available to scavenge potent greenhouse gases, like methane (CH$_4$), from the atmosphere. The H$_2$ soil sink may play a
considerable role in buffering anthropogenic H$_2$ emissions, which constitute approximately 50% of atmospheric H$_2$ sources (Ehhalt and Rohrer, 2009). A process-level understanding of the H$_2$ soil sink is required to understand the natural variability of atmospheric H$_2$ and its sensitivity to changes in climate and anthropogenic activities.

Early studies established the H$_2$ soil sink as a biological process because of the enzymatic nature of H$_2$ consumption (Conrad and Seiler, 1981; Schuler and Conrad, 1990; Häring and Conrad, 1994). Initially, free soil hydrogenases were thought to be the primary drivers of the H$_2$ soil sink because chemical fumigation of soils had little effect on soil H$_2$ uptake rates but significantly reduced the active microbial consumption or production of other trace gases, e.g., the active microbial uptake of CO (Conrad and Seiler, 1981; Conrad et al., 1983b; Conrad, 1996). Only indirect evidence existed to support the notion that the soil sink was an active microbial process (Conrad and Seiler, 1981; Conrad et al. 1983a; King, 2003b) until the isolation of *Streptomyces* sp. PCB7, the first microorganism to exhibit significant consumption of atmospheric H$_2$ (Constant et al., 2008). This organism demonstrated high-affinity (K$_m$ ~10-50 ppm), low-threshold (< 0.1 ppm) H$_2$ uptake kinetics characteristic of uptake by environmental soil samples (Conrad, 1996). Previously, only low-affinity (K$_m$ ~1000 ppm), high-threshold (> 0.5 ppm) H$_2$-oxidizing microorganisms were characterized, which were unable to consume H$_2$ at atmospheric concentrations (Conrad et al., 1983b; Conrad, 1996; Guo and Conrad, 2008; summarized by Constant et al., 2009).

*Streptomyces* spp. are ubiquitous soil microorganisms that degrade recalcitrant materials in soils (Kieser et al., 2000). Theoretically, the observed rates of atmospheric H$_2$ soil consumption can sustain the maintenance energy requirements for typical numbers of *Streptomyces* spp. cells in soils (Conrad, 1999; Constant et al., 2010; Constant et al., 2011a).
However, the importance of atmospheric H₂ as a source of energy to soil microorganisms remains unknown. Atmospheric H₂ uptake was specifically linked to a group 5 [NiFe]-hydrogenase gene cluster containing genes that encode for the small and large hydrogenase subunits, \( hhyS \) and \( hhyL \), respectively (Constant et al., 2010). The \( hhyL \) gene is distributed unevenly amongst the Actinobacteria, Proteobacteria, Chloroflexi, and Acidobacteria phyla (\textit{e.g.}, many, but not all \textit{Streptomyces} spp. possess the gene) (Constant et al., 2010; Constant et al., 2011b). The link between high-affinity H₂ uptake and \( hhyL \) has been reported in nine \textit{Streptomyces} spp. and in \textit{Mycobacterium smegmatis} (Constant et al., 2011b; King, 2003b), but it remains untested in many soil microorganisms. Additional research adding to the library of atmospheric H₂-oxidizing bacteria is needed to identify the key microorganisms involved in H₂ biogeochemical cycling. Information about the genes and ecophysiology of these organisms can improve the process-level understanding of the H₂ soil sink (Conrad, 1996; Madsen, 2005).

The life cycle of \textit{Streptomyces} is complex and controls the timing of many physiological activities, which may include H₂ uptake (Kieser et al., 2000; Schrempf, 2008; Flärdh and Buttner, 2009). In soils, \textit{Streptomyces} exist predominantly as inactive spores, which germinate in response to environmental triggers such as moisture and nutrient availability (Kieser et al., 2000) and grow vegetatively, producing a network of mycelia that grow into the substrate (Flärdh and Buttner, 2009). Over time, and in response to environmental triggers such as nutrient depletion or physiological stresses, the colony differentiates to form hydrophobic aerial hyphae that break the substrate surface tension and grow into the air, forming a millimeter-scale canopy in immediate contact with the atmosphere (Kieser et al., 2000; Schrempf, 2008). Finally, aerial hyphae differentiate and septate to form chains of resistant spores (Flärd and Buttner, 2009). In cultures of \textit{Streptomyces} sp. PCB7 growing on soil particles, H₂ uptake coincided with the
presence of aerial hyphae and spores (Constant et al., 2008). It is unknown if H₂ uptake occurs at
the same life cycle stage in other Streptomyces strains and how long uptake persists in the spore
stage. Furthermore, the timing of atmospheric H₂ uptake in microbes that possess hhyL, but do
not sporulate has not been measured.

The goal of this paper is to address two questions. First, our study asks whether
environmental isolates and culture collection strains with the genetic potential for atmospheric
H₂ uptake, i.e., the hhyL gene, actually exhibit atmospheric H₂ uptake. To expand the library of
atmospheric H₂-oxidizing bacteria, we quantify H₂ uptake rates by novel Streptomyces soil
isolates that contain the hhyL and by three previously isolated and sequenced strains of
actinobacteria whose hhyL sequences span the known hhyL diversity. Second, we investigate
how H₂ uptake varies over organismal life cycle in one sporulating and one non-sporulating
microorganism, Streptomyces sp. HFI8 and Rhodococcus equi, respectively. These experiments
probe the advantage of atmospheric H₂ consumption to microbes and relationship between
environmental conditions, physiology of soil microbes, and H₂.

Results

H₂ uptake by microbial soil isolates and culture collection strains possessing hhyL.

Candidate Streptomyces strains, referred to henceforth as Harvard Forest Isolate (HFI)
strains, were isolated from Harvard Forest soils. PCR amplification revealed that hhyL encoding
the high-affinity [NiFe]-hydrogenase was present in six out of nine tested strains. Four of these
strains (HFI6, HFI7, HFI8, and HFI9) were successfully retained in culture and were used to test
the link between hhyL and H₂ uptake activity. These strains exhibited distinctive Streptomyces
traits such as pigmentation, a fuzzy appearance indicating the production of aerial hyphae
(Figures S1 and S2), and the distinctive earthy scent of geosmin (Schrempf, 2008). The 16S
rRNA gene sequences of the new isolates fell within the *Streptomyces* genus and were 100% identical to several different strains of *Streptomyces* spp. (Table S1). Of two clusters that were defined by Constant et al. (2011b) based on a deeply rooted split (99% of bootstrap replicates) in the phylogenetic tree of *hhyL* amino acid sequences (Figure S3), the HFI6 - HFI9 *hhyL* sequences group with *hhyL* Cluster 1. In addition to our *Streptomyces* isolates, we examined three culture collection strains in this study to broaden representation across the *hhyL* clusters and genera (Bergey et al., 1957): *Streptomyces griseoflavus* Tu4000 (Cluster 1), *Rhodococcus equi* (Actinobacterium, Cluster 1), and *Streptomyces cattleya* (Cluster 2).

(Insert Table 1 here)

To test whether organisms with *hhyL* gene sequences consume H$_2$, we measured the uptake of atmospheric H$_2$ in sporulated *Streptomyces* cultures and in stationary stage of *R. equi*. The presence of *hhyL* predicted atmospheric H$_2$ uptake activity in HFI strains 6-9, *S. cattleya*, and *R. equi*, but not in *S. griseoflavus* Tu4000 (Table 1). We find that atmospheric H$_2$ uptake observed in strains with *hhyL* from Cluster 1 (*Streptomyces* strains HFI6 - HFI9 and *R. equi*) and Cluster 2 (*S. cattleya*). The biomass-weighted H$_2$ uptake rates of these isolates spanned nearly two orders of magnitude (from 10 to 780 nmol min$^{-1}$ g$^{-1}$), and the *Streptomyces* strains that took up H$_2$ did so at rates more than 10-fold greater than dense stationary phase cultures of *R. equi* (Table 1). *R. equi* consumed atmospheric H$_2$, both when grown on solid R2A medium and in liquid TSB medium (data not shown). Uptake rates of *Streptomyces* cultures were measured on solid medium because *Streptomyces* cultures typically do not progress through their full developmental cycle in liquid medium (Flårdh and Buttner, 2009). The Michaelis-Menten substrate affinity was determined from the x-intercept of Lineweaver-Burk plots of the inverse relationship between the first-order H$_2$ uptake rate and initial headspace H$_2$ concentrations.
between 0 and 35 ppm. This method can be more error prone than the non-inverse approach performed over a greater range of initial H₂ mole fractions, but it better restricts H₂ uptake by low-affinity hydrogenases, and has enough sensitivity to distinguish high- and low-affinity uptake kinetics. Kₘ values of HFI strains were typically low (40-80 ppm for HFI strains), which indicated that enzymatic processing of H₂ is tuned to operate efficiently at atmospheric levels of H₂ (high-affinity uptake). *S. cattleya* and *R. equi* appeared have high- or intermediate-affinity Kₘ values (<1000 ppm), but did not pass the quality control measures (Experimental Procedures) to be included in Table 1. The minimum H₂ concentration, or threshold, consumed by each HFI strain ranged from 0.12 to 0.15 ppm, which is well below typical atmospheric mole fractions of around 0.53 ppm (Table 1). *S. cattleya* and *R. equi* thresholds were also below atmospheric levels at least below 0.45 and 0.30 ppm, respectively (Table 1). This study augments the library of organisms that contain *hhyL* sequences and take up atmospheric H₂ with high-affinity and a low-threshold from 10 to 16 strains.

**H₂ uptake correlates with lifecycle stage in *Streptomyces* sp. HFI8**

We randomly selected *Streptomyces* sp. HFI8 from our HFI strains as a representative organism to determine whether high-affinity H₂ consumption depended on the stage of the life cycle and how long uptake lasted in the sporulation stage. Microscopy revealed the progression of strain HFI8 through developmental stages over 44 days on solid agar (Figure S4). Following germination, the colonies of strain HFI8 grew as substrate mycelia (Figure S4-A). By day 1.8 the lawn reached its maximal aerial coverage and grew upward as aerial hyphae formed and then sporulated (Figure S4-B). The co-occurrence of partially septated aerial hyphae and spores indicated that the events were not simultaneous throughout the colony (Figure S4-B). Measurements of H₂ uptake revealed that H₂ consumption began only after the formation of
aerial hyphae and sporulation around day 2 (Figure 1). Aerial hyphae formation and sporulation are stages of the life cycle often associated with nutrient limitation in *Streptomyces* spp. H2 uptake reached a maximum rate (9.4±2.3 nmol h\(^{-1}\)) on day 3.8, two days after sporulation had begun, and then slowly decreased over the next 40 days, dropping below the detection limit of ±0.24 nmol h\(^{-1}\). Most cells between days 2.9 and 44 were a lawn of “dormant” spores that had completed the full life cycle (Figures S4-C-H). H2 oxidation rates by dormant spores declined slowly over the 44-day experiment to negligible rates (Figure 1). All three replicates displayed similar timing, but the H2 uptake rates were systematically lower in the third replicate, although the area coverage of the lawn and biomass was not demonstrably different among the replicates. A cursory set of measurements (data not shown) indicated similar trends in H2 uptake over the life cycle of *Streptomyces* sp. HFI6, *Streptomyces* sp. HFI7, *Streptomyces* sp. HFI9, and *S. cattleya*.

Because the formation of aerial biomass (hyphae and spores) occurred at the same time as the onset of H2 consumption in *Streptomyces*, we asked whether H2 uptake activity was physically located in the aerial biomass. We isolated the aerial fraction (spores and aerial hyphae) of strain HFI8 cultures by gently rolling glass beads over the entire surface of the colony and transferring the beads and aerial biomass to an empty, sterile glass vial (Figure S5). H2 uptake rates were measured in whole cultures before the transfer, in the vials with the transferred aerial fraction, and in the original vial with the substrate fraction that remained after the glass bead procedure (Table 2, Samples 1-6; Figure S5). The experiment lasted 2-4 hours following the aerial biomass transfer. H2 uptake in the transferred aerial biomass fraction was consistently low, typically near or below the limit of detection of ±0.24 nmol h\(^{-1}\), and was thus often
statistically indistinguishable from zero. Low uptake rates in the aerial fraction were not the
result of poor biomass transfer efficiency by the glass bead procedure; glass beads transferred a
significant proportion (Table 2, 0.7±0.6 mg) of the aerial biomass from the replicate cultures of
that could be collected using a metal spatula (1.2±0.5 mg). The drop in uptake also cannot be
explained by aging over this period, because this occurs over the course of days or weeks and not
hours (Figure 1). No reduction in H₂ uptake stemming from reduced spore viability was expected
because the biomass transfer procedure by glass beads is based on established methods for
harvesting viable spores (e.g., Hirsch and Ensign, 1976; Hardisson et al., 1978). Furthermore, the
number of viable spores in bead-treated cultures was indistinguishable from the number of viable
spores obtained by transferring aerial biomass by a metal spatula from replicate vials incubated
at the same time. This test was done by harvesting spores by the two methods, plating spore
suspension dilutions, and counting the number of colony forming units as a function of the initial
amount of biomass (protein mass) in the spore suspensions.

We found that the net H₂ uptake diminished after the separation of the aerial biomass
from the substrate biomass (Table 2). Even in replicates where glass beads were gently rolled
over strain HFI8 lawns and all biomass was left in the original vial, net H₂ uptake was
significantly reduced (Table 2, Samples 7-12). The larger the initial H₂ oxidation rate, the larger
percentage reduction by the glass beads (Figure S6, linear fit, R²=0.93), regardless of culture age
or the amount of glass beads used for transfer (Samples 1-12). These experiments suggested that
the colony structure and the presence of intact aerial hyphae were important for H₂ uptake.

**H₂ uptake correlates with the growth stage of Rhodococcus equi**

(Insert Figure 2 here)
Only some microbes containing hyl are sporulating Streptomyces (Figure S3). To test whether H$_2$ uptake by non-sporulating Actinobacterium R. equi is related to its lifecycle, we measured the uptake of H$_2$ by this organism at various stages of growth in liquid cultures (Figure 2). The growth phases were determined from optical density measurements of the cultures. R. equi did not consume measurable quantities of H$_2$ during the exponential growth phase (day 1 to 4), but started taking up H$_2$ in the late exponential growth phase (day 4 to 7) and in the stationary phase (day 7 to 17) until the end of the experiment (Figure 2). The late exponential phase and stationary phase growth stages are associated with nutrient limitation.

The low H$_2$ uptake rates by R. equi were much closer to the experimental detection limit than Streptomyces sp. HFI8. This suggested that the lack of uptake could be related to low R. equi cell densities in late exponential and early stationary phase rather than the altered cell physiology. To test this, we concentrated cells from a culture in exponential growth phase (day 1.9) into either fresh medium or sterile water to match the cell densities (Figure 2b) of H$_2$-oxidizing cultures in the late exponential and early stationary phases (comparable to those on days 4-6). In spite of the comparable cell densities, cells concentrated in this manner did not consume H$_2$ (-0.075±0.15 nmol h$^{-1}$, Figure 2a). In addition, we diluted cells in stationary phase (day 7.8) into fresh medium or water to obtain suspensions whose cell densities matched those during days 2-3 of the exponential phase (Figure 2). Although H$_2$ oxidation rates of the exponentially growing cultures on days 2 and 3 were below the limit of detection (±0.12 nmol h$^{-1}$), comparably dense cells derived from the diluted stationary phase cultures took up H$_2$ (0.43±0.047 nmol h$^{-1}$). All cultures were shaken vigorously to ensure the delivery of H$_2$ into the medium. Some extracellular factors of relevance to H$_2$ uptake, such as extracellular hydrogenases, may have been carried over into the diluted suspensions. The decrease in the
uptake of H₂ by stationary phase cells (74% of undiluted uptake) did not scale with the dilution 
(22% of the undiluted cell biomass), which corresponds to a relative mismatch factor of 3.5 in H₂ 
uptake versus dilution. The reason is unclear, and could result from H₂ substrate diffusion 
limitation in very dense cultures, which was partially alleviated upon dilution. If the cultures 
were diffusion limited for H₂ substrate, the observed H₂ oxidation rate (Table 1) and H₂ uptake 
rates during late exponential and stationary phases (Figure 2) may underestimate the potential H₂ 
uptake by cultures of R. equi. The uptake of H₂ only by stationary phase cells, either in the old 
culture medium or when resuspended in fresh medium or water, related the uptake of H₂ to the 
late exponential and stationary phases. Overall, these tests linked R. equi H₂ consumption with 
growth phase.

Discussion

Link between hhyL and H₂ uptake

Our results confirm links between hhyL and H₂ uptake to include R. equi, four

Streptomyces HFI soil isolates from Cluster 1, and S. cattleya from Cluster 2, thereby providing 
additional support for the use of the high-affinity hydrogenase gene hhyL as a predictor for the 
capability to consume atmospheric hydrogen. H₂ uptake by hhyL by strains from Clusters 1 and 2 
indicate that the phylogenetic divergence between the two groups does not compromise 
atmospheric H₂ uptake activity by hhyL, or its prediction. Strains HFI6 - HFI9 exhibit high H₂ 
uptake affinities and low uptake thresholds. Culture collection strains exhibit more variable H₂ 
uptake kinetics, in keeping with a recent suggestion that H₂ consuming microorganisms exhibit a 
continuum of affinities rather than a discrete grouping of high and low affinities (Constant et al., 
2010). Current observations of high-affinity H₂ uptake are limited to the Actinobacteria, and 
future studies are required to determine whether H₂ uptake occurs in the other phyla containing
the \textit{hhyL} gene, such as Chloroflexi, Planctomycetes, Verrucomicrobia, and Proteobacteria (Figure S3). A genome data-mining investigation revealed the ubiquity of \textit{hhyL} in DNA extracted from forest, desert, agricultural, and peat soils samples, and although some evidence suggests a correlation between soil \textit{H}_2 uptake rates and the number of \textit{H}_2-oxidizing bacteria, no correlation was found between \textit{hhyL} DNA copies and soil \textit{H}_2 uptake rates (Constant et al., 2011a; Constant et al., 2011b). Future work should be aimed both at understanding the diversity and ecophysiology of these \textit{hhyL}-containing microorganisms and at developing methods to predict \textit{H}_2 uptake activity across ecosystems.

\textbf{H}_2 \textit{uptake and the developmental cycle of actinobacteria}

Our results support a correlation between the developmental stage of \textit{Streptomyces} spp. and high-affinity \textit{H}_2 uptake in two ways. First, we did not observe any \textit{H}_2 uptake in the substrate mycelium developmental phase of \textit{Streptomyces} sp. HFI8. \textit{H}_2 uptake began only after the formation of aerial hyphae and sporulation. Second, we found that \textit{S. griseoflavus} Tu4000, which grew predominantly as substrate mycelium, did not take up \textit{H}_2. We propose that the impaired development (i.e. lack of aerial hyphae and/or spores) of \textit{S. griseoflavus} Tu4000 may impair the production or activity of its high-affinity hydrogenase. In culture, \textit{S. griseoflavus} Tu4000 is smooth and waxy, and does not produce the aerial hyphae typical of \textit{Streptomyces} grown on solid culture (Figure S1 and S2). \textit{S. griseoflavus} Tu4000 may belong to a class of \textit{bld} (bald) mutants that are often deficient in aerial hyphae production (Kieser et al., 2000). Sporulation efficiency is also often reduced in \textit{bld} mutants (Szabó and Vitalis, 1992), and \textit{S. griseoflavus} Tu4000 does not form spores on various types of media (J. Blodgett, personal communication), including our cultures. To our knowledge, \textit{S. griseoflavus} Tu4000 is the first \textit{hhyL}-containing \textit{Streptomyces} sp. found to be unable to oxidize atmospheric \textit{H}_2 under the same experimental
conditions that lead to H₂ oxidation by other *Streptomyces* spp. High-affinity H₂ uptake is also absent from Cluster 1 *hhyL* containing cultures of a gram-negative beta-proteobacterium *Ralstonia eutropha* H16 (formerly known as *Alcaligenes eutropha* 16) grown on solid medium and tested for uptake in suspensions (Conrad et al., 1983b). Future experiments could compare sporulating *Streptomyces* with their *bld* mutants or stimulate the formation of aerial hyphae and/or sporulation in *bld* *Streptomyces* spp. mutants by application of exogenous δ-butyrolactone factor (Ueda et al., 2000; Straight and Kolter, 2009), and determine the effect of this stimulation on H₂ oxidation or *hhyL* expression. In summary, the combined lack of aerial hyphae, spores, and H₂ uptake in *S. griseoflavus* Tu4000 and the co-occurrence of these phenotypes in strain HFI8 underscored a strong developmental control of atmospheric H₂ uptake in *Streptomyces*. These observations motivate the use of *Streptomyces* mutants arrested at different points in the developmental cycle to investigate the regulation and physiological role of *hhyL* in sporulating actinobacteria.

Our measurements of H₂ uptake in HFI8 colonies disturbed by glass beads indicate that H₂ uptake depends on the physical structure of *Streptomyces* aggregates. Cultures treated by glass beads take up less H₂, suggesting that the activity of the hydrogenase is impaired by the disturbance of the aerial structures. H₂ uptake by the disrupted colony could decrease because of loss in structural support, loss in signaling and nutrient transport within the bacterial lawn (Miguélez et al., 1999), or reduction in the aerial hyphae surface area in contact with the air. Therefore, we attribute the observed decrease in H₂ uptake to physical destruction of the lawn and colony structure of *Streptomyces*.

The H₂ uptake by non-sporulating batch cultures of *R. equi* occurs only during late exponential and stationary phase, suggesting that its H₂ consumption may support metabolism
under nutrient-limiting conditions. Similarly, H₂ uptake by strain HFI8 is present only during 
those stages of its life cycle associated with nutrient-limiting conditions, suggesting that H₂ may 
be an important energy source for *Streptomyces* under stress. This is consistent with previous 
reports of H₂ oxidation by *M. smegmatis*, a non-sporulating Actinobacterium with a Cluster 1 
high-affinity [NiFe]-hydrogenase that can persist for many years in host tissue in a nutrient-
deprived stationary phase (Smeulders et al, 1999; King, 2003b). *M. smegmatis* expresses the 
hydrogenase gene under starvation conditions and mutants lacking this hydrogenase have a 
reduced growth yield under these conditions (Berney and Cook, 2010). Therefore, the ability to 
scavenge low concentrations of H₂ may be an important adaptation of various sporulating and 
non-sporulating actinobacteria (Prescott, 1991; Smeulders et al, 1999; Scherr and Nguyen, 
2009). This could be particularly true in terrestrial environments were nutrient concentrations are 
often low for extended periods and atmospheric H₂ is available.

**Implications for soil H₂ uptake in the environment**

Uptake of atmospheric H₂ by spores, which are often considered to be metabolically 
dormant, may have consequences for both the sporulating microbes and the cycling of H₂ in the 
environment. H₂ oxidation rates in cultures of strain HFI8 continue to increase for two days after 
the onset of sporulation. This could reflect heterogeneity in the sample, because not all cells 
sporulate simultaneously, or maximum H₂ uptake by already formed spores. In any case, 
measurable H₂ oxidation in sporulated cultures persists for over a month, such that the time-
integrated H₂ oxidation in any culture is much larger in spore state than at any other stage in the 
life cycle. Net H₂ consumption by HFI8 is at least tenfold larger in the spore state (days 4-44) 
than during the growth of substrate mycelium (through day 1.1) and formation of aerial hyphae 
(after day 1.8) combined. One should also keep in mind that the H₂ uptake rates measured in
culture studies depend on the specific medium, and may not be directly translated to different media or soil types, where the nutritional characteristics, moisture levels, and cell abundances likely differ. The persistence of H$_2$ oxidation by *Streptomyces* spp. may have consequences for environmental H$_2$ cycling and environmental conditions that promote the removal of atmospheric H$_2$. Conditions that favor germination and growth, including soil moisture and nutrient availability (Kieser et al., 2000), may increase the population of *Streptomyces* spp. in the substrate mycelium phase and actually limit the amount of H$_2$ oxidized by soils. During moisture- or nutrient-limiting conditions, a greater fraction of the population of *Streptomyces* spp. will be in life cycle stages linked with H$_2$ uptake (aerial hyphae and spores). Counterintuitively, H$_2$ uptake by *Streptomyces* spp. may be most significant when the environmental conditions are the harshest. H$_2$ uptake in spores under our experimental conditions is reduced to negligible levels after about a month (Figure 1), indicating that H$_2$ uptake may be very low in environments where conditions are harsh for long periods, such as deserts.

Ultimately, the goal of studying microbial influences on trace gas fluxes is to understand and predict emergent biogeochemical cycling in the environment. This study describes H$_2$ consumption by two developmentally distinct actinobacteria under nutrient-limiting conditions. Field measurements along a chronosequence of recent volcanic deposits support this notion by suggesting that relative uptake of H$_2$ by the soil microbial community (normalized by soil respiration rates) is most important when soils were limited by organic carbon (King, 2003a). However, insignificant or even opposing trends also exist (Conrad and Seiler, 1985; Rahn et al., 2002), which may be driven by other factors. Future studies are also needed to determine the impact of nutrient- and moisture-limiting conditions on H$_2$ uptake by soils and to consider the significance and implications of the energetic supply from H$_2$ for the microorganisms in the
competitive soil environment. A better understanding of the process-level controls on microbe-mediated H$_2$ soil uptake is critical for evaluating the impact of a changing climate on the soil H$_2$ uptake and the impact of continued anthropogenic H$_2$ emissions on atmospheric chemistry and climate.

**Experimental Procedures**

**Microbial Strains**

*S. spp.* were isolated from soils within the footprint of the Environmental Measurement Site (EMS) atmospheric trace gas flux tower at the Harvard Forest Long Term Ecological Research site in Petersham, MA (42°32'N, 72°11'W). Atmospheric H$_2$ fluxes were concurrently measured at the same site (Meredith, 2012). Harvard Forest is a mixed deciduous forest with acidic soils originating from sandy loam glacial till (Allen, 1995). Most H$_2$ consumption occurs within the first few centimeters of soil beneath the litter layer (Yonemura et al., 2000; Smith-Downey et al., 2008); therefore, samples were collected from the uppermost six inches of soil after removal of the leaf litter. Sporulating soil organisms such as *S. spp.* were enriched for using desiccation and chemical destruction (El-Nakeeb and Lechavalier, 1963; Schrempf, 2008). Soils were dried for 3-4 hours at 55°C. Dry soil samples (1 g) were ground with a mortar and pestle and were combined with CaCO$_3$ (1 g). The soil mixtures were incubated for 2 days at 28°C in 100x15 mm polystyrene Petri dishes (sterile, polystyrene, 100x15 mm, VWR, Radnor, PA), with moistened filter paper (11.0 cm diameter, Grade 1, Whatman®, Kent, ME) fitted in the lids to maintain a humid environment. After this period, incubated soil mixtures were suspended in 100 ml sterile water and thoroughly vortexed. After
settling for 30 min, soil suspensions were serially diluted, and the $10^0$, $10^{-2}$, and $10^{-4}$ dilutions were spread onto R2A plates (Difco™ R2A, BD, Franklin Lakes, NJ) that had been treated with 88 mg cycloheximide / L medium (Porter et al., 1960). After incubation at 30°C for 3-5 days, microbial colonies were screened for the presence of any of the following four distinctive 

*Streptomyces* traits: 1) antibiotic inhibition of neighboring growth (*i.e.*, zone of clearing), 2) a fuzzy appearance indicating the production of aerial hyphae (Figures S1 and S2), 3) pigmentation, or 4) the distinctive earthy scent of geosmin (Schrempf, 2008). Those exhibiting any of the traits were serially transferred onto fresh R2A plates until pure isolates were obtained. The resulting set of isolates, henceforth referred to as Harvard Forest Isolates (HFI), was maintained in culture on R2A agar at room temperature. Strains HFI6, HFI7, HFI8, and HFI9 were deposited to the United States Department of Agriculture NRRL Culture Collection for preservation as NRRL B-24941, NRRL B-24943, NRRL B-24942, and NRRL B-24940, respectively.

Strains from culture collections that were used in this study have published genomes accessible in the National Center for Biotechnology Information (NCBI) databases.

*Streptomyces griseoflavus* Tu4000 (accession NZ GG657758) was kindly provided by the genome authors and collaborators (Michael Fischbach, John Clardy, Joshua Blodgett). The following strains were obtained from culture collections: *Rhodococcus equi* ATCC 33707™ (accession CM001149) and *Streptomyces cattleya* NRRL 8057 (accession NC 016111).

**DNA extraction and PCR amplification**

DNA was extracted using the PowerSoil® DNA Extraction Kit (MoBio Laboratories, Carlsbad, CA) from colonies. PCR amplification of 16S rRNA and *hyl* genes, respectively, was
performed using a Mastercycler® pro (Eppendorf, Hamburg, Germany) in 25 µl reaction volumes with the following reaction mixture: 12.125 µl ddH2O, 1.25 µl BSA (Roche, Indianapolis, IN), 2.5 µl 10x Ex Taq Buffer (TaKaRa), 0.125 (5 units/µl) Ex Taq (TaKaRa), 2 µl dNTP (2.5 mM TaKaRa), 2.5 µl of each primer suspended at 3µM (IDT, Coralville, IA). The 16S rRNA gene was amplified using universal primers 27F:5'-AGA GTT TGA TCC TGG CTC AG-3' and 1492R:5'-ACG GCT ACC TTG TTA CGA CTT-3' (Lane, 1991), and hhyL gene was amplified using NiFe244F:5' - GGG ATC TGC GGG GAC AAC CA -3' and NiFe-1640R:5'-TGC ACG GCG TCC TCG TAC GG -3' (Constant et al., 2010). The following program was used: 5 min initial denaturation at 95°C, followed by 30 cycles consisting of 30 s template denaturation at 95°C, 30 s hold at the primer annealing temperature, 1.5 min extension at 72°C, and a final extension at 72°C for 5 min. Annealing temperatures of 50°C and 60.7°C were used for the amplification of the 16S rRNA and hhyL genes, respectively. The hhyL annealing temperature was optimized over a temperature gradient spanning eight temperatures between 50°C and 62.2°C using S. griseoflavus Tu4000 DNA as template.

Each HFI strain was evaluated for the presence of a putative group 5 [NiFe]-hydrogenase by gel electrophoresis of the hhyL gene PCR reaction product. Gels were cast (1% agarose, 5µl GelRed nucleic acid stain (Biotum, Hayward, CA)), loaded (5µl PCR product and 2µl DNA loading dye (Fermentas, Glen Burnie, MD)), run (100 V for 1 hr), and visualized (UVP MultiDoc-It™ Digital Imaging System (UVP, Upland, CA)) to verify successful PCR amplification. Migration of HFI strain PCR product was compared to the S. griseoflavus Tu4000 hhyL gene as a positive control and to the DNA Molecular Weight Marker X (Roche, Indianapolis, IN) ladder for reference.

Gene sequencing and sequence analysis
PCR products were sequenced at Genewiz (Cambridge, MA) following the manufacturer’s sample preparation guidelines. Both 16S rRNA and *hhyL* gene sequences (trimmed for >Q30) were identified by BLASTN (Altschul et al., 1990) and listed in Table S1. Hydrogenase *hhyL* amino acid sequences were aligned using ClustalW (Larkin et al., 2007) and phylogenetic analyses were carried out in Mega 5.2 (Tamura et al., 2011). Relationships were determined using a Maximum Likelihood method based on the Whelan and Goldman model (Whelan and Goldman, 2001) and checked for consistency using parsimony. The *hhyL* gene from archaeon *Sulfolobus islandicus* HVE10/4 was used as an outgroup. A 100 bootstrap maximum likelihood tree was constructed using Mega 5.2.

The gene sequences obtained for strains HFI6, HFI7, HFI8, and HFI9 were deposited in GenBank under accession numbers KC661265, KC661266, KF444073, and KF444074 for the 16S rRNA genes and under accession numbers KC661267, KC661268, KC661269, and KC661270 for the *hhyL* genes. 16S rRNA gene sequences were compared with published sequences in the National Center for Biotechnology Information (NCBI) gene databases (BLASTN, http://blast.ncbi.nlm.nih.gov) for phylogenetic identification (Table S1).

**H₂ uptake assays**

H₂ oxidation rates were determined routinely by measuring the decrease in H₂ mole fractions in the microbial culture headspace over time. Microbial strains were cultivated aerobically on solid (R2A) or liquid (TSB) medium inside 160 ml glass serum vials. H₂ uptake rate measurements were initiated by isolating the serum vial headspace from the atmosphere with a crimped stopper and vials were slightly pressurized after closure by adding 15 ml of sterile lab air. Liquid cultures were continuously agitated at 200 rpm during the H₂ uptake assay to facilitate gas exchange across the air-liquid interface. The change in headspace H₂ was measured three
times at approximately forty-minute intervals. H₂ uptake followed apparent first-order kinetics
over the small range (0.1 to 4 ppm) of laboratory atmospheric H₂ mole fractions: H₂(t) =
H₂(0)e⁻ⁿᵗ. First-order rate constants were determined from the slope (-b) of the logarithmic
decrease in the headspace H₂ mole fraction. H₂ oxidation rates are reported at a H₂ mole fraction
of 530 ppb, the estimated global mean (Novelli et al., 1999).

H₂ mole fractions were measured using a Gas Chromatograph (GC, Model 2014, Shimadzu Co., Kyoto, Japan) retrofitted with a Helium ionization Pulsed Discharge Detector (HePDD, D-4-I-SH17-R Model, Valco Instruments Co. Inc., Houston, Texas). The instrument is
similar to a recently described system for measuring H₂ at atmospheric levels (approximately
530 ppb) and has an improved precision, linearity and stability compared to methods that use a
mercuric oxide detector (Novelli et al., 2009). Details of the instrument design and performance
are publically accessible in Meredith (2012). Stainless steel flasks containing compressed air
were used as working standards with ambient H₂ mole fractions. These were calibrated using the
GC-HePDD system against a tertiary standard (514.3 ppb H₂ in air, aluminum 150A tank,
Airgas, Radnor, PA) tied to the NOAA CMD/ESRL H₂ scale. Precisions, assessed by repeated
standard measurements, were typically <1% (1 sigma) on the Shimadzu GC-HePDD.

The precision for H₂ oxidation rate measurements is taken as two times the standard
deviation of measurements of the H₂ uptake in sterile control vials containing the same (liquid or
solid) medium as the culture vials. This precision serves as the effective detection limit, that is,
the minimum H₂ oxidation rate that is distinguishable from zero by the measurement. Detection
limits were determined separately for the time series of H₂ uptake rates measured in control vials
for strain HFI8 and R. equi because of the difference in medium, and were between (±0.12 and
H₂ uptake thresholds were determined after allowing the cultures to take up H₂ mole fractions for at least 90 minutes until headspace H₂ mole fractions reached stable values.

The Michaelis-Menten substrate affinity (Kₘ) describes the affinity of H₂ uptake, relevant to the broad range of H₂ concentrations that occur in soils (H₂ mole fractions ranging from 0.01 to 1000 ppm) (Schink, 1997; Constant et al., 2008). Kinetic parameters of H₂ uptake were determined in sporulated *Streptomyces* cultures and in the stationary phase cultures of *R. equi*.

The dependency of H₂ uptake rates on initial H₂ mole fractions were determined over a range of initial headspace H₂ mole fractions (set at about eight levels between 0.5 and 35 ppm H₂ by injecting a 1% H₂ in N₂ mix into the sealed headspace). Headspace H₂ was measured twice, 15 minutes apart in each culture containing different initial H₂ concentrations, and H₂ uptake was calculated from the linear uptake rate. The Kₘ and the maximum reaction rate (Vₘₐₓ) for each strain was determined from Lineweaver-Burk (LB) plots of the inverse of the uptake rate (1/V) versus the inverse of the substrate concentration (1/S) the initial H₂ mole fraction. Kₘ was determined as the Kₘ = -1 / x-intercept and Vₘₐₓ as Vₘₐₓ = 1/y-intercept (Constant et al., 2008).

As a crosscheck for the quality of the reported kinetic parameters, Eadie-Hofstee (EH) plots of V versus V/S were used to determine Kₘ from Kₘ = -slope. Kₘ and Vₘₐₓ values were reported for a given strain only if the LB and EH Kₘ values methods agreed within 50%. A typical LB and EH plot is shown in Figure S7. H₂ uptake thresholds were determined after allowing the cultures to take up H₂ mole fractions for at least 90 minutes until headspace H₂ mole fractions reached stable values.

**Lifecycle analysis of *Streptomyces* spp.**

The life cycle of *Streptomyces* spp. cultures was tracked in parallel with the H₂ uptake to test the influence of developmental stage on atmospheric H₂ uptake. Serum vials (160 mL)
containing 10 ml of R2A medium were inoculated with 100 μl of the spore suspension onto the agar surface. Control vials were supplemented with 100 μl sterile H₂O. The developmental stages were assessed by microscopy, using a Zeiss Axio Imager.M1 microscope and Axio Cam MRm camera using Axio Vision (4.8) software (Zeiss, Peabody, MA).

Growth rates of filamentous organisms grown on solid media are difficult to measure; instead, photographs of the fractional area covered by *Streptomyces* colonies in the serum vial were used as an indication of growth rate. Final aerial biomass was quantified by a protein assay. Aerial biomass was aseptically harvested using a metal spatula and transferred to 1.5 ml tubes containing 0.3 g of glass beads (0.2 mm diameter) and 0.7 ml water. Cells were vortexed for 5 min at 2000 rpm followed by cooling on ice and then sonicated with three 30 s bursts and 1 min intermittent cooling on ice. Residues of membranes and nucleic acids were removed by transferring 0.5 ml of the protein extract to Costar® Spin-X® microcentrifuge filter tubes (Corning, Inc., Corning, NY) and centrifuging at 10,000 rpm for 15 minutes. Protein concentrations were determined using the Pierce BCA protein assay kit (Thermo Scientific, Rockford, IL) and a Synergy 2 Microplate Reader (BioTek, Winooski, VT) controlled by Gen5 (1.04.5) software.

To determine whether H₂ uptake in the aerial fraction (containing hyphae and spores) of a *Streptomyces* culture would continue to take up H₂ when separated from the substrate mycelium and medium, H₂ uptake rates were measured before and after by gently rolling between 2.5 and 10 g of 4 mm glass beads (Table 2) over *Streptomyces* sp. HFI8 lawns of various ages (2-15 days). The lawns grew on R2A solid medium in a serum vial and the aerial biomass was transferred to a sterile glass serum vial containing no medium (Figure S5). H₂ uptake rates were measured in the original culture vial, the lawn was treated with the glass beads and aerial
biomass was transferred immediately by moving the glass beads to a sterile vial. H₂ uptake rates were measured over the next 2-4 h in the sterile vial containing the isolated aerial biomass on glass beads, and in the original vial containing medium and the remaining substrate mycelium. The amount of biomass that was transferred was quantified using the protein assay described above. This procedure was performed for six replicates at different time points after sporulation and with different amounts of glass beads (Table 2, Samples 1-6). In addition, the effect of the glass beads on H₂ uptake in the absence of transfer was tested in six control samples. These samples were treated with the glass beads, but the beads remained in the original vials (Table 2, Samples 7-12) and H₂ uptake rates were measured in the same vials before and after disruption by glass beads.

**Growth phase analysis of *R. equi***

The relationship between the growth phase and H₂ uptake of *R. equi* was assessed in liquid cultures. *R. equi* was inoculated by adding 100 μl of a cell suspension into 20 ml sterile TSB (Bacto™ Triptic soy broth, BD) liquid medium in 160 ml glass serum vials. All cultures were incubated at 30°C and shaken at 200 rpm. Growth was monitored by measuring the optical density (OD) of *R. equi* cultures as the absorbance at 600 nm at 25°C in the Synergy 2 Microplate Reader. The relationship between OD and protein concentration was established by constructing a calibration curve between OD measurements of serial dilutions with known protein concentrations. *R. equi* protein concentrations were determined using the same general procedure as described for the *Streptomyces* spp. The growth phase in *R. equi* cultures were established using the semilogarithmic plot of the growth curve (Figure 2), where the exponential growth phase is taken as the period with the maximum, sustained positive slope. Late exponential phase was defined as the time when the growth rate slowed down, as identified by a
decreasing slope of the growth curve. Finally, stationary phase occurred where the growth curve slope was zero.

H₂ uptake by *R. equi* was low. A concentration/dilution experiment was performed to test whether the negligible H₂ oxidation rates at low cell densities in early exponential growth phase were the result of a lack of H₂ oxidation activity or the low signal-to-noise ratio due to the small number of active cells. *R. equi* cultures were inoculated at the beginning of the experiment, concentrated in exponential phase on day 1.9 by centrifugation at 8000 rpm for 10 min, and re-suspended into either fresh TSB or in sterile H₂O to final densities of 160 and 110-μg protein ml⁻¹ in TSB and H₂O, respectively. This was within the range of densities observed in late exponential and stationary phases (100-230 μg protein ml⁻¹). Additionally, a sample was taken on day 7.8 in stationary phase (at a density of 190 μg protein ml⁻¹) and was diluted in TSB or sterile H₂O to cellular densities of 45 and 38 μg protein ml⁻¹ respectively, to match the density in the early exponential phase (10-100 μg protein ml⁻¹). For both the concentration and dilution experiments, the cell pellets resulting from centrifugation were not washed during the procedure so that some extracellular material and original culture medium (< 1 ml) was diluted into fresh TSB or H₂O to a maximum final concentration of 1/5th. H₂ uptake rates in the headspace of the concentrated or diluted samples were measured as described above.

**Acknowledgements**

The authors are grateful to Paula Welander for advice in the lab and to Diane Ivy for assistance with measurements. Strain *Streptomyces griseoflavus* Tu4000 was kindly contributed to this study by genome authors Michael Fischbach and John Clardy via Joshua Blodgett. L.K.M. is grateful for the opportunity to attend the MBL Microbial Diversity Course. L.K.M. was supported by from the following funding sources: NSF Graduate Research Fellowship, multiple
grants from NASA to MIT for the Advanced Global Atmospheric Gases Experiment (AGAGE),
MIT Center for Global Change Science, MIT Joint Program on the Science and Policy of Global
Change, MIT Martin Family Society of Fellows for Sustainability, MIT Ally of Nature Research
Fund, MIT William Otis Crosby Lectureship, and MIT Warren Klein Fund. D. R. was funded
through MIT Undergraduate Research Opportunities Program (UROP) with support from the
Lord Foundation and Jordan J. Baruch Fund (1947) and was supported by the Harvard Forest
REU Program.

Table and Figure Legends
Table 1. H₂ oxidation rates weighted by biomass (final protein mass) for Harvard Forest Isolate (HFI) strains and strains from culture collections (\textit{S. cattleya}, \textit{S. griseoflavus}, \textit{R. equi}) at typical atmospheric (~0.53 ppm) H₂ mole fractions. H₂ uptake affinity (\(K_m\)), the maximum reaction rate (\(V_{\text{max}}\)), and the minimum threshold for consumption are listed for each culture.

Table 2. Effect of physical disturbances of the aerial structure on H₂ oxidation rates in sporulated cultures of \textit{Streptomyces} sp. HFI8. Gently rolling 4 mm diameter glass beads over culture lawns (Figure S5) reduced the observed H₂ uptake. The H₂ oxidation rates (the 5\textsuperscript{th} column) in twelve whole cultures of strain HFI8 growing in serum vials on solid R2A medium were measured between 2 and 15 days after inoculation (the 2\textsuperscript{nd} column). In samples 1-6, the aerial biomass was isolated from substrate biomass using glass beads to transfer aerial biomass to an empty, sterile vial. The amount of transferred biomass was measured by protein assay (the 4\textsuperscript{th} column). We tested using different amounts (2.5 and 10g) of 4 mm diameter glass beads (the 3\textsuperscript{rd} column). H₂ uptake is reported for the fraction of aerial biomass transferred to glass beads (the 6\textsuperscript{th} column) and for the fraction of the lawn remaining in the original vial in the medium (the 7\textsuperscript{th} column) measured within 2-4 hours. In samples 7-12, all biomass was left in the original vial, and H₂ oxidation rates were measured before and after treatment with glass beads. The difference in uptake due to the procedure (the sum of the uptake rates reported in the 6\textsuperscript{th} and the 7\textsuperscript{th} column minus the uptake before transfer in the 5\textsuperscript{th} column) is reported in the 8\textsuperscript{th} column.

Figure 1. High-resolution time series of H₂ uptake in three replicate cultures of \textit{Streptomyces} sp. HFI8. The lettered arrows at various time points correspond to the micrographs of the life cycle shown in Figure S4: (A) the substrate mycelium, (B) the formation of aerial
hyphae and onset of sporulation, (C-H) cultures contain mainly spores. Enlarged inset shows the higher resolution measurements taken during the first four days. The detection limit (dashed lines) of ±0.24 nmol h\(^{-1}\) is reported as the double standard deviation of four values measured in uninoculated control vials (black dots).

**Figure 2.** Consumption of H\(_2\) by *Rhodococcus equi* in liquid culture. (a) H\(_2\) oxidation rate, (b) cell biomass (protein concentration). All data are shown for three liquid culture replicates. The detection limit (dashed lines) is of ±0.12 nmol h\(^{-1}\) and calculated as the double standard deviation of ten values measured in uninoculated control vials (black dots). Colored triangles show the results of concentration and dilution experiments. Cells in exponential phase were concentrated in either fresh TSB medium (green) or water (orange) to match protein concentrations in late exponential and stationary phase. Alternatively, cells from stationary phase were diluted in either fresh TSB medium (green) or water (orange) to protein concentrations similar to those in exponential phase cultures.

**Table S1.** The top database matches for strain HFI6 - HFI9 16S rRNA gene and *hhyL* nucleotide sequences indicate that the strains are *Streptomyces* spp. containing *hhyL* sequences. The GenBank accession number is listed for each deposited sequence. The results of NCBI Megablast BLAST search are listed for each sequence, where queries were made for the 16S rRNA sequences against the 16S rRNA gene sequence database and for the *hhyL* sequences against the entire nucleotide sequence database. The top match for each BLAST search is listed along with the total score, E value, and maximum identity of the match. Strain HFI6 - HFI9 16S rRNA gene sequences were 100% identical to several different strains of *Streptomyces* spp.
Strain HFI6 - HFI9 hhyL sequences are highly similar to published cultured and uncultured hhyL sequences, of which some were submitted to public databases as hydB-like genes, though the hhyL terminology has been more recently adopted (Constant et al., 2011b).

Figure S1. Photographs of *Streptomyces griseoflavus* Tu4000 and *Streptomyces* sp. HFI6 - HFI9 soil isolate colonies on R2A medium plates. *S. griseoflavus* Tu4000 had the smooth and waxy appearance of a *bld* (bald) *Streptomyces* mutant, while strains HFI6 - HFI9 formed fuzzy colonies consistent with the presence of aerial hyphae. The pigmentation of strains HFI6 - HFI8 was light pink and strain HFI9 was darker with a brown exudate secreted into the surrounding medium. HFI6 - HFI9 strains had the strong scent of geosmin, while *S. griseoflavus* Tu4000 did not.

Figure S2. Photomicrographs of *Streptomyces griseoflavus* Tu4000 and *Streptomyces* sp. HFI6 - HFI9 soil isolate cultures on R2A medium plates. The same samples are photographed in Figure S1. Only substrate mycelia are visible in the *S. griseoflavus* Tu4000 colony, while HFI6 - HFI9 strains had plentiful aerial hyphae.

Figure S3. Molecular phylogenetic analysis of hhyL sequences by the Maximum Likelihood method. The diversity of the high-affinity group 5 [NiFe]-hydrogenase (hhyL) sequences of the strains (bold) we tested for H₂ uptake (Table 1) are compared with hhyL sequences from the NCBI microbial genome database in this amino acid tree. The hhyL-containing *Streptomyces* sequences form two distinct clusters at a deep 99% bootstrap branch:
Cluster 1 and Cluster 2. Isolates that have been tested for H$_2$ uptake are marked to indicate whether (*) or not (†) high-affinity H$_2$ uptake was observed. Culture collection strains investigated in this study were selected to broaden representation across the clusters and genera: *Streptomyces griseoflavus* Tu4000 (Cluster 1), *Rhodococcus equi* (*Actinobacterium*, Cluster 1), and *Streptomyces cattleya* (Cluster 2). Strains HFI6, HFI7, HFI8, and *S. griseoflavus* Tu4000 *hhyL* are closely related to Cluster 1 *Streptomyces* spp. soil isolates that take up H$_2$ (summarized in Constant et al., 2011b), while strain HFI9 *hhyL* is more closely related to the *R. equi* *hhyL*. Cluster 2 *S. cattleya* *hhyL* is closely related to *Streptomyces* sp. AP1 *hhyL*, which also consumes H$_2$ (Constant et al., 2011b). Other culture collection strains that have been tested for H$_2$ uptake include *Ralstonia eutropha* H16 (Conrad et al., 1983b) and *Mycobacterium smegmatis* (King, 2003). The evolutionary history was inferred by using the Maximum Likelihood method based on the Whelan and Goldman, 2010 model. The *hhyL* gene from an archaeon *Sulfolobus islandicus* HVE10/4 was used as the outgroup. The bootstrap values are shown next to the branches. Initial tree(s) for the heuristic search were obtained automatically by applying Neighbor-Join and BioNJ algorithms to a matrix of pairwise distances estimated using a WAG model, and then selecting the topology with superior log likelihood value. A discrete Gamma distribution was used to model evolutionary rate differences among sites (5 categories (+G, parameter = 1.2590)). The tree is drawn to scale, with branch lengths measured in the number of substitutions per site. The analysis involved 58 amino acid sequences. There were a total of 427 positions in the final dataset. Evolutionary analyses were conducted in MEGA5 (Tamura et al., 2011).
Figure S4. Microscopic observations of the development of *Streptomyces* sp. HFI8 show that strain HFI8 underwent the full lifecycle from spore to spore in less than 1.8 days, after which nearly all the viable cells existed as spores. Each panel shows a representative micrograph of the culture taken on a different day after the inoculation. Image A shows the substrate mycelium that grows after the germination of inoculated spores. By day 1.8 (B), septated aerial hyphae (punctuated tubular branches) and fully formed spores (round cells) are present. Mainly spores are present from day 2.9 to 22 (C-H) and the same persists until day 44 (not shown).

Figure S5. Photograph of serum vials during the aerial biomass removal experiments (Table 2, Samples 1-6) illustrates the separation of the aerial hyphae and spores from the substrate mycelium: a) vial containing an *whole* intact strain HFI8 culture (Table 2, column 5); b) vial from which the aerial biomass had been isolated using glass beads leaving behind the remaining *substrate* mycelium (Table 2, column 7); and c) vial containing the isolated *aerial* biomass on the surface of the glass beads (Table 2, column 6). In some samples, glass beads were rolled on the whole colony surface (a) and were left in the same vial with no biomass transfer (Table 2, Samples 7-12).

Figure S6. Scatter plot of the initial H$_2$ oxidation rate versus the reduction in H$_2$ uptake by *Streptomyces* sp. HFI8 during the glass bead procedure (Table 2; 5$^{th}$ and 8$^{th}$ columns). The larger the initial H$_2$ oxidation rate, the larger percentage reduction by the glass beads ($R^2$=0.93), regardless of culture age or the amount of glass beads used for transfer.
Figure S7: Determination of H$_2$ uptake kinetic parameters by the Lineweaver-Burk (LB) and Eadie-Hofstee (EH) methods for *Streptomyces* sp. HFI8. The H$_2$ uptake rate (V) nmol h$^{-1}$ and initial H$_2$ concentration (S) in ppm are used to generate the LB plot as 1/V versus 1/S and EH as V versus V/S. $K_m$ was determined from the LB plot as $K_m = -1/x$-intercept (38 ppm) and $V_{\text{max}}$ as $V_{\text{max}} = 1/y$-intercept (30 $\mu$mol min$^{-1}$ g$^{-1}$). $K_m$ was determined from the EH plot as $K_m = -$slope (22 ppm). $K_m$ and $V_{\text{max}}$ values were reported for a given strain only if the LB and EH $K_m$ values methods agreed within 50%. 
Table 1. H$_2$ oxidation rates weighted by biomass (final protein mass) for Harvard Forest Isolate (HFI) strains and strains from culture collections (\textit{S. cattleya}, \textit{S. griseoflavus}, \textit{R. equi}) at typical atmospheric (~0.53 ppm) H$_2$ mole fractions. H$_2$ uptake affinity (K$_m$), the maximum reaction rate (V$_{max}$), and the minimum threshold for consumption are listed for each culture.

* Determined by the Lineweaver-Burke method over a 0-35 ppm H$_2$ range, which is less precise than the non-inverse approach, but avoids interference by low-affinity hydrogenases.

** Kinetic parameters determination did not pass quality check (Experimental Procedures).
Table 2. Effect of physical disturbances of the aerial structure on H₂ oxidation rates in sporulated cultures of *Streptomyces* sp. HFI8. Gently rolling 4 mm diameter glass beads over culture lawns (Figure S5) reduced the observed H₂ uptake. The H₂ oxidation rates (the 5th column) in twelve whole cultures of strain HFI8 growing in serum vials on solid R2A medium were measured between 2 and 15 days after inoculation (the 2nd column). In samples 1-6, the aerial biomass was isolated from substrate biomass using glass beads to transfer aerial biomass to an empty, sterile vial. The amount of transferred biomass was measured by protein assay (the 4th column). We tested using different amounts (2.5 and 10g) of 4 mm diameter glass beads (the 3rd column). H₂ uptake is reported for the fraction of aerial biomass transferred to glass beads (the 6th column) and for the fraction of the lawn remaining in the original vial in the medium (the 7th column) measured within 2-4 hours. In samples 7-12, all biomass was left in the original vial, and H₂ oxidation rates were measured before and after treatment with glass beads. The difference in uptake due to the procedure (the sum of the uptake rates reported in the 6th and the 7th column minus the uptake before transfer in the 5th column) is reported in the 8th column.

Table S1. The top database matches for strain HFI6 - HFI9 16S rRNA gene and hhyL nucleotide sequences indicate that the strains are *Streptomyces* spp. containing *hhyL* sequences. The GenBank accession number is listed for each deposited sequence. The results of NCBI Megablast BLAST search are listed for each sequence, where queries were made for the 16S rRNA sequences against the 16S rRNA gene sequence database and for the *hhyL* sequences against the entire nucleotide sequence database. The top match for each BLAST search is listed along with the total score, E value, and maximum identity of the match. Strain HFI6 - HFI9 16S rRNA gene sequences were 100% identical to several different strains of *Streptomyces* spp. Strain HFI6 - HFI9 hhyL sequences are highly similar to published cultured and uncultured hhyL sequences, of which some were submitted to public databases as hydB-like genes, though the *hhyL* terminology has been more recently adopted (Constant et al., 2011b).
