Boundary Layers
Two-Dimensional Steady Boundary Layer Equations

$x$ is horizontal direction along direction of main flow velocity $u$. Velocity at outer edge of boundary layer is called $U_\infty$ or $V_\infty$ or $U_e$ or $V_e$.

$y$ is perpendicular to wall and velocity in this direction is $v$.

The boundary layer begins, say, at $x = 0$ and the boundary layer thickness is $\delta$. $\delta \ll x$. Because the boundary layer is thin, to leading order the pressure is constant through the thickness of the boundary layer, $\frac{\partial P}{\partial y} = 0$. Also, $v \ll u$, and $\frac{\partial u}{\partial x} \ll \frac{\partial u}{\partial y}$.

\[
\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0
\]

\[
\frac{u}{\partial x} + v \frac{\partial u}{\partial y} = -\frac{1}{\rho} \frac{\partial P}{\partial x} + \nu \frac{\partial^2 u}{\partial y^2}
\]

\[
\frac{u}{\partial x} + v \frac{\partial u}{\partial y} = -\frac{1}{\rho} \frac{\partial P}{\partial x} + \frac{1}{\rho} \frac{\partial \tau}{\partial y}
\]
Boundary Layer Parameters

Thickness of Boundary Layer defined as location where \( u \) is 99% of \( U_e \).

\[
\delta = y\Big|_{u/U_e=0.99}
\]

The wall shear stress \( \tau_w \) is given by:

\[
\tau_w = \mu \left( \frac{\partial u}{\partial y} \right)_{wall} = \mu \left( \frac{\partial u}{\partial y} \right)_{y=0}
\]

The skin friction coefficient, \( C_f \), is:

\[
C_f = \frac{\tau_w}{\left( \frac{1}{2} \rho U_e^2 \right)} = \frac{2\tau_w}{\rho U_e^2} = \frac{2\nu}{U_e^2} \left( \frac{\partial u}{\partial y} \right)_{y=0}
\]

The displacement thickness, \( \delta^* \) is the thickness of a flow of speed \( U_e \) that carries a flow rate equal to the deficit in the boundary layer because its speed is less than \( U_e \).

\[
U_e \delta^* = \int_0^{\delta} (U_e - u) \, dy \quad \quad \delta^* = \int_0^{\delta} \left( 1 - \frac{u}{U_e} \right) \, dy
\]
Mass Fluxes

\[ \dot{m}_{\text{left}} = \int_0^\gamma \rho u \, dy \]

\[ \dot{m}_{\text{right}} = \int_0^\gamma \rho u \, dy + \frac{d}{dx} \left( \int_0^\gamma \rho u \, dy \right) \delta x \]

\[ \dot{m}_{\text{top}} = -\frac{d}{dx} \left( \int_0^\gamma \rho u \, dy \right) \delta x \]

\[ \dot{m}_{\text{left}} = \dot{m}_{\text{right}} + \dot{m}_{\text{top}} \]

Momentum Equation in \( x \) direction

\[ \dot{M}_{\text{right}} + \dot{M}_{\text{top}} + \dot{M}_{\text{left}} = F_{\text{pressure}} + F_{\text{stress}} \]

\[ \dot{M}_{\text{left}} = \int_0^\gamma \rho u^2 \, dy \]

\[ \dot{M}_{\text{right}} = \int_0^\gamma \rho u^2 \, dy + \frac{d}{dx} \left( \int_0^\gamma \rho u^2 \, dy \right) \delta x \]

\[ \dot{M}_{\text{top}} = \dot{m}_{\text{top}} U_e = -U_e \frac{d}{dx} \left( \int_0^\gamma \rho u \, dy \right) \delta x \]
\[ F_{\text{pressure}} = -\frac{dp}{dx} Y \delta x = \rho U_e \frac{dU_e}{dx} Y \delta x \quad \text{for} \quad F_s = -\tau_w \delta x \]

One additional needed equation is:

\[ Y = \int_0^Y dy \]

Then all the equations on the last two pages can be combined into:

\[ \frac{d}{dx} \int_0^Y u(U_e - u) dy + \frac{dU_e}{dx} \int_0^Y (U_e - u) dy = \frac{\tau_w}{\rho} \]

For \( y > \delta \) the integrands are zero so the upper limits can be changed to \( \delta \).

\[ \frac{d}{dx} \int_0^\delta u(U_e - u) dy + \frac{dU_e}{dx} \int_0^\delta (U_e - u) dy = \frac{\tau_w}{\rho} \]

This is Von Karman’s Momentum Integral Equation. It relates the integrals of the velocity profile in the boundary layer to the shear stress and \( U_e \) and \( U_e^2 \) whose x-derivative is proportional to the pressure gradient.

The momentum thickness \( \Theta \) is defined as:

\[ \Theta = \int_0^\delta \frac{u}{U_e} \left( 1 - \frac{u}{U_e} \right) dy \]

With this definition, the momentum integral equation can be written in the following two forms:

\[ \frac{d}{dx} [U_e^2 \Theta] + \delta^* U_e \frac{dU_e}{dx} = \frac{\tau_w}{\rho} \]

\[ \frac{d\Theta}{dx} + (2 + H) \frac{\Theta}{U_e} \frac{dU_e}{dx} = \frac{C_f}{2} \quad \text{where:} \quad H \equiv \frac{\delta^*}{\Theta} \]
A second boundary layer equation comes from equating the kinetic energy change along $x$ in the boundary layer to the energy input or output from the pressure distribution and the energy dissipation due to shear stresses in the boundary layer.

The kinetic energy thickness, $\theta^*$, is defined as:

$$\theta^* = \int_0^\delta \frac{u}{U_e} \left(1 - \frac{u^2}{U_e^*}\right) dy$$

The kinetic energy dissipation coefficient, $C_D$, is defined as:

$$C_D = \frac{D}{\rho u_e^2}$$

where $D$ is the dissipation per unit area (along and perpendicular to the surface).

Using these definitions, the kinetic energy equation is:

$$\frac{d\theta^*}{dx} + 3\frac{\theta^*}{u_e} \frac{d u_e}{dx} = 2C_D$$

The energy thickness ratio, $H^*$, is defined as: $H^* = \frac{\theta^*}{\theta}$

It is common to combine the kinetic energy equation and Von Karman's momentum equation to obtain:

$$\frac{\theta}{H^*} \frac{dH^*}{dx} = \frac{2C_D}{H^*} - \frac{C_f}{2} + (H - 1) \frac{\theta}{u_e} \frac{d u_e}{dx}$$
Example of Solution of Momentum Integral BL Equation

\[ U_e = 2 \text{m/s} \quad \delta(x) = 0.01(1-e^{-0.1x}) \quad \frac{u(y)}{U_e} = (1 - e^{-k(x)y})^2 \quad \rho = 1000 \text{kg/m}^3 \]

Problem: Determine the shear stress, \( \tau \), at \( x = 5 \) meters.

Determination of \( k \delta \) from BL thickness:

\[ 0.99 = (1 - e^{-k(x)\delta(x)})^2 \quad \rightarrow \quad k(x)\delta(x) = 5.3 \quad k(x) = \frac{5.3}{\delta(x)} \]

At \( x = 5 \)m, \( k = 1347 \text{ m}^{-1} \).

\[
\frac{d}{dx} \int_0^{0.01[1-\exp(-0.1x)]} U_e(1 - e^{-k(x)y})^2 [U_e - U_e(1 - e^{-ky})^2] \, dy + 0 = \frac{\tau}{\rho}
\]

\[ 0.01(1 - e^{-0.1 \times 5}) = 0.01(1 - e^{-0.5}) = 0.00393 \]

\[
\frac{\tau}{\rho} = U_e^2(1 - e^{-5.3})^2 [1 - (1 - e^{-5.3})^2] \frac{d}{dx} [0.01(1 - e^{-0.1x})] 
+ \int_0^{0.00393} \frac{d}{dx} \left\{ U_e(1 - e^{-k(x)y})^2 [U_e - U_e(1 - e^{-k(x)y})^2] \right\} \, dy
= U_e^2(0.000060 + 0.000100) = 0.00016 U_e^2
\]

\[
\tau = 1000 \times 4 \times 0.00016 = 0.64 \text{N/m}^2
\]

\[
c_f = \frac{\tau}{\frac{1}{2} \rho U_e^2} = 0.00032
\]

Calculation of Turbulent Boundary Layer
when Pressure Distribution is Known

This result is approximate since the boundary layer thickness will alter the pressure distribution.

The principal unknowns (quantities to be determined) are: \( \theta(x) \) and \( \delta^*(x) \). An equivalent set of unknowns is \( \theta(x) \) and \( H(x) \).

There are two fundamental equations:

\[
\frac{d\theta}{dx} = -(H + 2) \frac{\theta}{U_e} \frac{dU_e}{dx} + \frac{C_f}{2} \quad (1)
\]

\[
\frac{\theta}{H^*} \frac{dH^*}{dx} = \frac{2C_D}{H^*} - \frac{C_f}{2} + (H - 1) \frac{\theta}{u_e} \frac{du_e}{dx} \quad (2)
\]

To be able to integrate the unknowns along the boundary layer, the derivatives of each of them are required: \( d\theta/dx \) and \( dH/dx \). Equation 1 is in the desired form. To put equation 2 in the desired form, use the chain rule:

\[
\frac{dH^*}{dx} = \frac{dH}{dx} \frac{dH^*}{dH} \quad (3)
\]

Empirical "closure relations" for \( H^*(H) \) and \( dH^*/dH \) exist. Therefore we write the energy equation in the desired form as:

\[
\frac{dH}{dx} = \frac{H^*}{\theta} \frac{1}{dH^*/dH} \left[ \frac{2C_D}{H^*} - \frac{C_f}{2} + (H - 1) \frac{\theta}{u_e} \frac{du_e}{dx} \right] \quad (4)
\]
To do the integrals numerically, we need a means of determining $C_f$, $C_D$, $H^*$ and $dH^*/dH$ in terms of the principal quantities $H$ and $R_\theta$, where $R_\theta = U_e \theta / \nu$. These empirical "closure relations" have been determined by assembling a large amount of experimental data.

**Laminar Closure Relations**

$$H^* = \begin{cases} 
0.76(H - 4)^2/H + 1.515, & H < 4.0 \\
0.015(H - 4)^2/H + 1.515, & H \geq 4.0 
\end{cases}$$

$$C_f = \begin{cases} 
0.03954[(7.4 - H)^2/(H - 1.0)] - 0.134 \big/R_\theta, & H < 7.4 \\
0.044[1.0 - 1.4/(H - 6)^2] - 0.134 \big/R_\theta, & H \geq 7.4 
\end{cases}$$

$$\frac{2C_D}{H^*} = \begin{cases} 
0.00205(4 - H)^{5.5} + 0.207 \big/R_\theta, & H < 4.0 \\
-0.003(H - 4.0)^2/(1 + 0.02(H - 4)^2) + 0.207 \big/R_\theta, & H \geq 4.0 
\end{cases}$$

**Turbulent Closure Relations**

$$H_o = \begin{cases} 
3 + 400/R_\theta, & R_\theta > 400 \\
4, & R_\theta \leq 400 
\end{cases}$$

$$R_{\theta z} = \begin{cases} 
R_\theta, & R_\theta > 200 \\
200, & R_\theta \leq 200 
\end{cases}$$

$$H^* = \begin{cases} 
1.505 + 4/R_\theta + (0.165 - 1.6/\sqrt{R_\theta})(H_o - H)^{1.6} / H, & H < H_o \\
(H - H_o)^2[0.007(H_o - H)/(H - H_o + 4)][\ln(R_{\theta z})] + 0.015/H] + 1.505 + 4.0/R_\theta, & H \geq H_o 
\end{cases}$$

$$C_f = 0.3e^{-1.33H} \left[ \frac{\ln(R_\theta)}{2.3026} \right]^{-0.74 + 0.31H}$$

$$\frac{2C_D}{H^*} = 0.5C_f \frac{4.0/H - 1}{3} + 0.03 \left(1 - \frac{1}{H}\right)^3$$
Sea Waves

Dominated by inviscid irrotational solution ($\nabla^2 \phi = 0$)

**Boundary Conditions**

\[
\frac{\partial \phi}{\partial t} + \frac{\partial \zeta}{\partial z} + \left[ \frac{\partial \phi}{\partial x} \frac{\partial \zeta}{\partial x} + \frac{\partial \phi}{\partial y} \frac{\partial \zeta}{\partial y} \right]_{z=\zeta} = 0 \quad \text{(kinematic)}
\]

\[
\left\{ \frac{\partial \phi}{\partial t} + \frac{1}{2} \left[ \left( \frac{\partial \phi}{\partial x} \right)^2 + \left( \frac{\partial \phi}{\partial x} \right)^2 + \left( \frac{\partial \phi}{\partial y} \right)^2 \right] \right\}_{z=\zeta} + g \zeta = \text{constant} \quad (0) \quad \text{(dynamic)}
\]

**Linearized Boundary Conditions**

Case of onset flow velocity of $-iU$.

Now $\phi$ is the perturbation potential and the total potential is $-Ux + \phi$.

\[
\left[ \frac{\partial \phi}{\partial z} \right]_{z=0} = \frac{\partial \zeta}{\partial t} - U \frac{\partial \zeta}{\partial x} \quad \left[ \frac{\partial \phi}{\partial t} - U \frac{\partial \phi}{\partial x} \right]_{z=0} + g \zeta = 0
\]

For steady flow with onset flow:

\[
\frac{\partial \phi}{\partial z} = -U \frac{\partial \zeta}{\partial x} \quad U \frac{\partial \phi}{\partial x} = g \zeta \quad \frac{\partial \phi}{\partial z} = -\frac{U^2}{g} \frac{\partial^2 \phi}{\partial x^2}
\]

Case of 2D waves and zero onset flow so $\phi$ is the total potential.

\[
\left[ \frac{\partial \phi}{\partial z} \right]_{z=0} = \frac{\partial \zeta}{\partial t} \quad \left[ \frac{\partial \phi}{\partial t} \right]_{z=0} + g \zeta = 0
\]

**Dispersion Relations** for waves of circular frequency $\omega = 2\pi f$ and wavenumber $k = 2\pi/\lambda$ and zero onset flow.

\[
\omega^2 = gk \quad \text{deep water}
\]

\[
\omega^2 = gk \tanh kh \quad \text{water of depth } h
\]
\[ \frac{\partial^2 \phi}{\partial t^2} \bigg|_{z=0} = -g \frac{\partial \zeta}{\partial t} \quad \frac{\partial \phi}{\partial z} \bigg|_{z=0} = -\frac{1}{g} \frac{\partial^2 \phi}{\partial t^2} \bigg|_{z=0} \]

\[ \zeta = Ae^{i(kx-\omega t)} \quad \text{and} \quad \zeta = -\frac{1}{g} \frac{\partial \phi}{\partial t} \]

**Deep Water**

\[ \phi = Be^{kz}e^{i(kx-\omega t)} \quad \text{Traveling wave that satisfies Laplace's Equation} \]

\[ Bke^{kz}e^{i(kx-\omega t)} = \frac{1}{g} \omega^2 Be^{kz}e^{i(kx-\omega t)} \quad k = \frac{\omega^2}{g} \quad \omega^2 = kg \]

\[ \zeta = -\frac{1}{g} (-i\omega) Be^{i(kx-\omega t)} \]

\[ A = \frac{i\omega}{g} B \quad B = -\frac{ig}{\omega} A = -\frac{i\omega}{k} A \]

**Finite Depth**

\[ \phi = B \cosh k(z + h) e^{i(kx-\omega t)} \]

\[ Bk \sinh kh e^{i(kx-\omega t)} = B\omega^2 \frac{1}{g} \cosh kh e^{i(kx-\omega t)} \]

\[ k \tanh kh = \frac{\omega^2}{g} \quad \omega^2 = gk \tanh kh \]

\[ \zeta = -\frac{1}{g} (-i\omega) Be^{i(kx-\omega t)} = \frac{i\omega}{g} B \cosh(kh) e^{i(kx-\omega t)} \quad A = \frac{i\omega}{g} \cosh(kh) B \]
Generation of Random Wave Form From Sinusoidal Components

All curves have zero mean. Individual wave contributions shown vertically displaced for viewing clarity.

Heavy line is the sum of the individual wave contributions.
Example of Simulation

Suppose a two dimensional (long crested) wave is generated with a wave-maker in a wave tank with an elevation at a specified location given by \( z(t) \), where:

\[
z(t) = 0.97 \sin(5.2t + 0.82) + 0.99 \sin(7.8t + 1.24) + 1.08 \sin(9.8t + 2.72)
\]

What is the maximum elevation that occurs in the time interval of 0 to 120 seconds (2 minutes). The usual way of finding maxima of analytic functions by setting the derivative to zero is not practical here because there are a great many maxima and the largest of these must be determined. However, because of the great computational speed of common computers, this can be done numerically without much effort.

```
Sea Spectra

We consider wave fields whose statistics are both stationary and homogeneous in the horizontal plane.

A sea spectrum function $S_T(k, \omega, \theta)$ is a partial description of the statistics of the wave field defined such that $S_T(k, \omega, \theta) \delta k \delta \omega \delta \theta$ is the contribution to the average wave energy per unit surface area, $E$, in the wavenumber, wave circular frequency and propagation angle bands; $\delta k \delta \omega \delta \theta$.

For surface elevation $\zeta(x, t)$ the average wave energy is defined as:

$$E = \langle \zeta^2 \rangle$$

where $\langle \rangle$ signifies the statistical, temporal or spatial average.

Thus: 

$$\langle \zeta^2 \rangle = \int_0^{2\pi} \int_0^\infty \int_0^\infty S_T(k, \omega, \theta) \delta k \delta \omega \delta \theta$$

Similar definitions apply when frequency, $f$, is used instead of circular frequency, $\omega$, and/or when spatial frequency, $1/\lambda$, is used instead of wavenumber, $k$.

For the frequently encountered case of linear, deep water gravity waves the circular frequency and the wavenumber are related to each other through the dispersion relation

$$\omega^2 = gk$$

so that $\omega$ and $k$ are not independent of each other. Then the spectrum is a function of only one or the other of these variables and can be written as: $S_t(\omega, \theta)$ or $S_x(k, \theta)$. These functions are related by:

$$S_x(k, \theta) = \frac{g}{2\omega} S_t(\omega, \theta)$$

Hence: 

$$\langle \zeta^2 \rangle = \int_0^{2\pi} \int_0^{\infty} S_x(k, \theta) dk d\theta = \int_0^{2\pi} \int_0^{\infty} S_x(\omega, \theta) d\omega d\theta$$

For unidirectional (long crested) seas, all the waves are in a single direction and the spectra are described by $S_t(\omega)$ or $S_x(k)$.

$$\langle \zeta^2 \rangle = \int_0^{\infty} S_t(\omega) d\omega = \int_0^{\infty} S_x(k) dk$$
The fundamental linearized plane progressive wave is:

\[ \zeta = Ae^{i(kz - \omega t)} \]

\[ \phi = \frac{i\omega A}{k} e^{kz} e^{i(kz - \omega t)} \]

Random sea waves have spectrum \( S(\omega, \theta) \).
For the 2D case the spectrum is \( S(\omega) \).

\[ \int_{\omega_1}^{\omega_2} S(\omega) \, d\omega \] is the contribution to \( \zeta^2 \) of waves with circular frequencies between \( \omega_1 \) and \( \omega_2 \).
Fourier Transforms

Fourier Transforms are valuable tools in numerical hydrodynamics because a number of problems can be described in the form of Fourier transforms and they can be computed very quickly by the Fast Fourier Transform (FFT) method. Two of these problems are solving a certain class of differential equations, and in simulating sea waves.

\[ X(f) = \mathcal{F} x(t) = \int_{-\infty}^{\infty} x(t)e^{-i2\pi ft}dt \]

\[ x(t) = \mathcal{F}^{-1} X(f) = \int_{-\infty}^{\infty} X(f)e^{i2\pi ft}df \]

As an example, consider a differential equation with constant coefficients of the form:

\[ A_n \frac{d^n y}{dx^n} + A_{n-1} \frac{d^{n-1} y}{dx^{n-1}} + \ldots + A_0 y(x) = g(x) \]

Consider Fourier Transforms from x to f where:

\[ \mathcal{F}[y(x)] \equiv Y(f) \quad \text{and} \quad \mathcal{F}[g(x)] \equiv G(f) \]

Take the Fourier transform of the differential equation to get:

\[ (i2\pi f)^n A_n Y(f) + (i2\pi f)^{n-1} A_{n-1} Y(f) + \ldots + A_0 Y(f) = G(f) \]

This is an algebraic equation which can be numerically solved for \( Y(f) \):

\[ Y(f) = \frac{G(f)}{(i2\pi f)^n A_n + (i2\pi f)^{n-1} A_{n-1} + A_0} \]

\( y(x) \) can be determined by inverse Fourier transformation. Not only is this less computationally intensive than solving the differential equation by direct numerical methods, but the error in the integration rule is avoided.
Fourier Transforms (continued)

\[ X(f) = \mathcal{F}x(t) = \int_{-\infty}^{\infty} x(t)e^{-i2\pi ft}dt \]

\[ x(t) = \mathcal{F}^{-1}X(f) = \int_{-\infty}^{\infty} X(f)e^{i2\pi ft}df \]

Suppose \( x(t) \approx 0 \) for \( t < 0 \) and \( t > T \). Then:

\[ X(f) \approx \int_{0}^{T} x(t)e^{-i2\pi ft}dt \]

Also, suppose \( x(t) \) is band limited such that: \( X(f) = 0 \) for \( |f| \geq F_{\text{max}} \). Then:

\[ x(t) = \mathcal{F}^{-1}X(f) = \int_{-F_{\text{max}}}^{F_{\text{max}}} X(f)e^{i2\pi ft}df \]

Now, consider a periodic function having period \( T \) that is identical to \( x(t) \) for \( 0 \leq t \leq T \). This function has a Fourier series given by:

\[ x(t) = \sum_{n=-\infty}^{\infty} A_ne^{i2\pi nt/T}, \quad A_n = \frac{1}{T} \int_{0}^{T} x(t)e^{-i2\pi nt/T}dt \]

The expression for \( A_n \) is identical to \( \frac{1}{T} \) times the Fourier Transform evaluated at \( f = \frac{n}{T} \). These Fourier coefficients, \( A_n = \frac{1}{T}X\left(\frac{n}{T}\right) \) can be numerically evaluated very quickly by an algorithm called the Fast Fourier Transform (FFT).

From the \( A_n \)'s, the function \( x(t) \) can be constructed over the \( t \)-range \( 0 < t < T \). Outside this range the reconstruction is periodic whereas the real value of \( x(t) \approx 0 \).

Evaluate \( A_n \) by the following rectangular rule integration:

\[ \delta t = \frac{1}{2F_{\text{max}}} \quad t = j\delta t \quad j_{\text{max}} \equiv N \quad T = N\delta t \quad x_j \equiv x(j\delta t) \]

\[ A_n = \frac{1}{N\delta t} \sum_{j=0}^{N-1} x(j\delta t) \exp\left[-\frac{i2\pi nj\delta t}{N\delta t}\right] \delta t = \frac{1}{N} \sum_{j=0}^{N-1} x_j e^{-i2\pi nj/N} \]
\[
T = \frac{\Delta t}{T} \\
F_{\text{max}} = \frac{M}{T} \quad M = TF_{\text{max}}
\]

\[
ST = \frac{1}{2F_{\text{max}}} \quad \text{Sampling Theorem}
\]

\[
F_{\text{max}} = \frac{1}{2ST} \quad M = \frac{1}{2ST}
\]

\[
F_{\text{max}} = M \delta f \quad \frac{1}{2ST} = \frac{1}{2ST} \delta f
\]

\[
\delta f = \frac{1}{T}
\]

\[
T = jST \quad T = j_{\text{max}} ST
\]

\[
M = \frac{j_{\text{max}} \delta t}{2ST} \quad j_{\text{max}} = \frac{2}{M}
\]

Let \(2M = N\) \quad j_{\text{max}} = N

\[
ST = \frac{1}{2M} = \frac{1}{N}
\]

\[
\delta f = \frac{1}{T} = \frac{1}{M/F_{\text{max}}} = \frac{F_{\text{max}}}{M} = \frac{2F_{\text{max}}}{4N}
\]

\[X(t)\]

0 \quad T \quad t

\[
T = N \delta t
\]

\[N \delta f\]

\[2F_{\text{max}} = N \delta f\]
\[- \frac{\frac{1}{N} \sum \delta t}{T} = - \frac{2 \pi n j \delta t}{N \delta t} = - \frac{\pi n J}{N} \]

\[F_{\text{max}} = M \delta f = M \frac{1}{f} = N \frac{1}{N \delta f} = \frac{1}{\delta f} \]

\[f = n \delta f = \frac{n}{\delta f} \]

\[n_{\text{max}} = T F_{\text{max}} = T \frac{1}{\delta f} = \frac{N}{\delta f} \]

\[\delta t = \frac{1}{N} \quad df = \frac{1}{f} \quad dt \, df = \frac{1}{N} \]
Fourier Transforms (continued)

\[ X(f) = 0 \text{ for } f \geq F_{\text{max}} = \frac{1}{2\delta t} \quad \text{and} \quad f = \frac{n}{T}, \quad \text{so} \quad \delta f = \frac{1}{T} \quad \text{and} \quad n_{\text{max}} = Tf_{\text{max}} = \frac{N}{2} \]

\[ \delta t = \frac{1}{2F_{\text{max}}}, \quad \delta f \delta t = \frac{1}{2F_{\text{max}}T} = \frac{1}{N} \]

\[ x(j\delta t) = x_j = \sum_{n=-N/2}^{N/2} T A_n \exp \left[ \frac{i2\pi nj\delta t}{N\delta t} \right] \frac{1}{T} = \sum_{n=-N/2}^{N/2} A_n e^{i2\pi nj/N} \]

Fast Computing

Computing speed is minimized by minimizing the number of complex exponentials that must be computed.

Let: \( q_1 = e^{-i2\pi/N} \quad q_2 = e^{i2\pi/N} \)

\[ e^{-i2\pi nj/N} = e^{-i2\pi(n-1)j/N} q_1^n \]

\[ e^{i2\pi nj/N} = e^{i2\pi(n-1)j/N} q_2^n \]

Even the powers of q can be avoided:

\[ e^{-i2\pi(0)(0)/N} = 1 \]
\[ e^{-i2\pi(1)(1)/N} = e^{-i2\pi(0)(0)/N} q_1 \]
\[ e^{-i2\pi(1)(2)/N} = e^{-i2\pi(1)(1)/N} q_1 \]
\[ e^{-i2\pi(2)(1)/N} = e^{-i2\pi(1)(1)/N} q_1 \]
\[ e^{-i2\pi(1)(3)/N} = e^{-i2\pi(1)(2)/N} q_1 \]
\[ e^{-i2\pi(2)(2)/N} = e^{-i2\pi(1)(3)/N} q_1 \]

etc.
Fourier Transforms (continued)

Periodicity

The actual integral transforms are of limited extent.

\[ x(t) = 0 \text{ except for } 0 \leq t \leq T \]

\[ X(f) = 0 \text{ except for } -F_{\text{max}} \leq f \leq F_{\text{max}} \]

However, the mathematical constructions, while consistent with the integral transforms for \( 0 \leq t \leq T \), and \(-F_{\text{max}} \leq f \leq F_{\text{max}} \), are periodic outside these ranges.

\[
A_{n+N} = \frac{1}{N} \sum_{j=0}^{N-1} x_j e^{-i2\pi(n+N)j/N} = \frac{1}{N} \sum_{j=0}^{N-1} x_j e^{-i2\pi nj/N} e^{-i2\pi j} = \frac{1}{N} \sum_{j=0}^{N-1} x_j e^{-i2\pi nj/N} = A_n
\]

\[
x_{j+N} = \sum_{n=-N/2}^{N/2} A_n e^{i2\pi n(j+N)/N} = \sum_{n=-N/2}^{N/2} A_n e^{i2\pi nj/N} e^{i2\pi n} = \sum_{n=-N/2}^{N/2} A_n e^{i2\pi nj/N} = x_j
\]

Therefore: \( x_j = \sum_{n=0}^{N-1} A_n e^{i2\pi nj/N} \)
Computational FFT and iFFT of Real Numbers

\[ A_n = \frac{1}{N} \sum_{j=0}^{N-1} x_j e^{-i 2\pi nj/N}, \quad x_j = \sum_{n=-N \atop 0 \leq n < N} A_n e^{i 2\pi nj/N} \]

\[ A_N = \frac{1}{N} \sum_{j=0}^{N-1} x_j e^{i 2\pi jN/N} = \frac{1}{N} \sum_{j=0}^{N-1} x_j e^{i 2\pi jN/N} \]

If \( x_j \)'s are real, \( A_N \) is real

\[ A_1 = A_{N-1} \]
\[ A_2 = A_{N-2} \implies A_{-k} = A_{N-k} \]
\[ A_{-N/2} = A_{N/2} \]

Also, if the \( x_j \) are real,

\[ A_{-n} = \frac{1}{N} \sum_{j=0}^{N-1} x_j e^{i 2\pi (-n)j/N} = A_n^* \]

Since \( e^{i 2\pi (-n)j/N} = e^{i 2\pi (N-n)j/N} \)

\[ A_{-n} e^{i 2\pi (-n)j/N} = A_n^* e^{i 2\pi (N-n)j/N} \]

\[ A_{-N/2} e^{i 2\pi (-N/2)^2/N} = A_{N/2} e^{i 2\pi (N-N/2)j/N} \]

\[ = A_{N/2} e^{i 2\pi N/2 \cdot j/N} \]

\[ \therefore \quad x_j = \sum_{n=0}^{N-1} A_n e^{i 2\pi nj/N} \]

where \( A_n' = \sum_{0 \leq n' \leq N/2-1} A_n \) for \( \frac{N}{2} \leq n < N \)

\[ A_{n'} = A_n \begin{cases} \frac{N}{2} < n' < N \\ \end{cases} \]
Simulation of Random Waves

Here we consider two-dimensional (long crested) waves. The waves are approximated as hydrodynamically linear in the sense that wave breaking and other nonlinear effects are neglected.

\[
\zeta(x, t) = \sum_{n=0}^{\infty} Z_n \cos \left( -\frac{\omega_n^2}{g} x + \omega_n t + \alpha_n \right)
\]

where the \( Z_n \)'s are chosen to provide the desired wave spectrum and the \( \alpha_n \)'s are random numbers uniformly distributed on \( 0 \leq \alpha < 2\pi \).

An alternate expression is:

\[
\zeta(x, t) = \sum_{n=-\infty}^{\infty} Z_n \exp \left[ i \left( -\frac{\omega_n^2}{g} x + \omega_n t + \alpha_n \right) \right]
\]

Combining \( e^{i\alpha_n} \) into \( Z_n \), the surface elevation vs time at \( x = 0 \) is:

\[
\zeta(t) = \sum_{n=-\infty}^{\infty} Z_n e^{i\omega_n t}
\]
The region in the "almost trapezoid" is represented by a sinusoidal wave having frequency $\omega_o$ and the same energy, $E$, of this region of the spectrum. The sinusoidal wave $A e^{i\omega_o t}$ has energy $|A^2|$. Thus,

$$|A^2| = S(\omega_o)\delta\omega$$

The waves are random processes and can be represented in two different ways. One way is to have stochastic waves and a stochastic spectrum whose expectation is equal to the spectrum being simulated (Type 1). The other way has stochastic waves and a deterministic spectrum equal to the spectrum being simulated (type 2).
Similarly, at \( t = 0 \) the surface elevation vs \( x \) is:

\[
\zeta(x) = \sum_{n=-\infty}^{\infty} Z_n e^{-i k_n x} = \sum_{n=-\infty}^{\infty} Z_n e^{i k_n x} \quad \text{where} \quad k_n = \frac{\omega_n^2}{g}
\]

With \( \omega_n = 2\pi n \delta f, \quad k_n = 2\pi n \delta b, \quad (b = 1/\lambda), \quad t = j \delta t, \quad x = j \delta x, \) and \( n \) limited to \(-\frac{N}{2} \leq n \leq \frac{N}{2}\) with \( \delta f \delta t \) or \( \delta b \delta x \) equal to \( 1/N \), the expressions for \( \zeta \) have the form of an inverse discrete Fourier transform. Hence, by first choosing the \( Z_n \)'s so they are consistent with the wave spectrum, the surface elevation for all values of \( t \) or for all values of \( x \) can be computed very rapidly by using an FFT program.

Either set \( Z_{-n} = Z_n^* \) or use non-negative \( n \) and take the real (or imaginary) part.

We will use the method in which \( Z_{-n} = Z_n^* \).

This corresponds to a two-sided spectrum whose levels are half the levels of the corresponding 1-sided spectrum.
Type 1

At a fixed value of \( x \), the sea elevation is \( \zeta(t) \) which is a sample function of a random process having a 2-sided power density function, \( S_w(\omega) \). The associated 1-sided spectrum is \( S_W(\omega) = 2S_w(\omega) \) for \( \omega = 0 \). The fourier transform of \( \zeta(t) \) is \( Z(\omega) \). The spectrum and the Fourier transform of \( \zeta(t) \) are truncated at \( |\omega| = \omega_c = 2\pi f_c \).

\( \zeta(t) \) is discretized with the time interval \( \delta t = \pi/\omega_c \) to satisfy the sampling theorem. Thus, \( \zeta(t) \) is specified at the discrete times \( \zeta_j = \zeta(j\delta t) \), \( j = 0, 1, 2, ..., N \).

The Fourier coefficient \( Z_j \) corresponds to the circular frequency \( \omega_j = j\delta\omega \), \( j = -\frac{N}{2} + 1, ..., 0, ..., \frac{N}{2} \), where \( \delta\omega = \frac{2\pi}{N\delta t} \). \( N \) is usually chosen as a power of 2 for computational efficiency.

For the Type 1 approach, each Fourier coefficient is separated into its real and imaginary parts and each of these is an uncorrelated Gaussian variate.

\[
Z_j = Z_{r_j} + iZ_{i_j}
\]

\( Z_{r_j} \) and \( Z_{i_j} \) are identically distributed with the probability density function:

\[
p(Z_{r_j}) = \frac{1}{\sigma_j\sqrt{2\pi}} \exp\left(-\frac{Z_{r_j}^2}{2\sigma_j^2}\right)
\]

From the physics of the modeling, where here \( E \) means "Expectation":

\[
E\left[|Z_j^2|\right] = S_w(\omega_j)\delta\omega
\]

\[
E[Z_{r_j}^2] = E[Z_{i_j}^2] = \frac{1}{2}S_w(\omega_j)\delta\omega
\]

From the mathematics of the Gaussian pdf: \( \sigma_j^2 = E[Z_{r_j}^2] \)

\[
\sigma_j = \sqrt{\frac{1}{2}S_w(\omega_j)\delta\omega} = \sqrt{\frac{1}{4}S_W(|\omega_j|)\delta\omega}
\]

There are computer programs which give Gaussian distributed random numbers for which the user specifies \( \sigma_j \).

Type 2 \( Z_j = e^{i\alpha_j}\sqrt{S_w(\omega_j)\delta\omega} = e^{i\alpha_j}\sqrt{\frac{1}{2}S_W(\omega_j)\delta\omega}, \quad \omega_j \geq 0 \)

\( \alpha_j \) is uniformly distributed on \( 0 \leq \alpha_j < 2\pi \) and can be obtained from a random number computer program.
We truncate the spectrum at frequencies $\pm N/2\delta\omega$.

Thus the expression for a simulated two-dimensional (long-crested) random wave elevation at a point on the ocean surface is:

$$
\zeta(t) = \sum_{-N/2}^{N/2} e^{i\alpha_n} \sqrt{\frac{1}{2} S_W(|n\delta\omega|)} \delta\omega \: e^{i(n\delta\omega)t}
$$

where $\alpha^n$ is a random number, $\leq \alpha_n < 2\pi$, and $\alpha_n = -\alpha_{-n}$.

This can be extended to a long-crested wave field, dependent on $x$ and $t$ as:

$$
\zeta(x, t) = \sum_{-N/2}^{N/2} e^{i\alpha_n} \sqrt{\frac{1}{2} S_W(|n\delta\omega|)} \delta\omega \: e^{i(n\delta\omega)t-(n\delta\omega)|n\delta\omega|x/g]}
$$

This is because $|k| = \omega^2/g$.

title('Simulated Sea Waves at a Point');
Review of Fourier Transforms, Inverse Fourier Transforms, FFT's, IFFT's and Wave Simulation

\[
X(f) = \int_{-\infty}^{\infty} x(t) e^{-j2\pi ft} \, dt, \quad x(t) = \int_{-\infty}^{\infty} X(f) e^{j2\pi ft} \, df
\]

Consider functions of the form:
\[
x(t) = 0 \text{ except for } 0 < t < T \\
x(f) = 0 \text{ except for } -F_{\text{max}} < f < F_{\text{max}}
\]

Then:
\[
X(f) = \int_{0}^{T} x(t) e^{-j2\pi ft} \, dt, \quad x(t) = \int_{-F_{\text{max}}}^{F_{\text{max}}} X(f) e^{j2\pi ft} \, df
\]

Construct a periodic function, \( x_p(t) \) of period \( T \)

\( x_p(t) = x(t) \), for \( 0 \leq t < T \)

\( x_p(t) \) has a Fourier Series Representation

\[
x_p(t) = \sum_{n=-\infty}^{\infty} A_n e^{jn2\pi ft}
\]

where:
\[
A_n = \frac{1}{T} \int_{0}^{T} x(t) e^{-jn2\pi ft} \, dt
\]

Note that \( X(f) = T A_n \)

If \( T \) is very large, values of \( n \) \( \sim \) \( n=0,1,2,\ldots \) are dense so \( X(f) \) can be determined from the Fourier coefficients at closely spaced frequencies.

215
Note that \( A_n = \frac{1}{T} X\left( \frac{\omega}{T} \right) \)

Since \( F = \frac{n}{T} \), \( A_n = 0 \) for \( |n| > TF_{\text{max}} \), also \( \delta f = \frac{1}{T} \)

In the range \( 0 \leq t \leq T \),

\[
x(t) = \sum_{n=-TF_{\text{max}}}^{TF_{\text{max}}} A_n e^{i2\pi nt/T}
\]

Let \( TF_{\text{max}} = M \)

\[
x(t) = \sum_{n=-M}^{M} A_n e^{i2\pi nt/T}
\]

\( 2M = N \)

Set \( dt = \frac{T}{2M} \), \( t = j\delta t \), \( x(j\delta t) \equiv x_j, dt = \frac{T}{N} \)

We need to evaluate \( e^{i2\pi nt/T} = e^{i2\pi jnt/N} \)

\[
e^{i2\pi jnt/N} = e^{i2\pi \frac{nj}{N}}
\]

Discretized approximation of \( A_n = \frac{1}{T} X\left( \frac{\omega}{T} \right) \)

\[
A_n \approx \frac{1}{N\delta t} \sum_{n=0}^{N/2-1} x_j e^{-i2\pinj/N}
\]

\[
x(j\delta t) = x_j = \sum_{n=-N/2}^{N/2-1} A_n e^{i2\pi nj/N} = \sum_{n=0}^{N/2-1} A_n e^{i2\pi nj/N}
\]

In \( x(t) \) is \( \text{real} \)

\[
A_n' = \begin{cases} 
A_n, & 0 \leq n \leq \frac{N}{2} - 1 \\
2A_n, & n = \frac{N}{2} \\
A_{N-n}^*, & \frac{N}{2} < n < N 
\end{cases}
\]
To simulate waves having a one-sided frequency spectrum $S_f(f)$ whose equivalent two-sided spectrum is $S_f(f) = \frac{1}{2} S_F(1f1)$; the elevation $s(t)$ at a point is

$$s(t, \delta t) = \sum_{n=0}^{N-1} A_n e^{i 2 \pi n j / N}, \quad \delta t = \frac{T}{N}$$

where:

$$A_n = \sqrt{S_f(n \delta f) \delta f}$$

$$A_n' = e^{i \chi_n} \sqrt{\frac{1}{2} S_F(n 8f) \delta f}$$

where $\chi_n$ is a random number in the range $0 < \chi_n < 2\pi$ and the rules for $A_n'$ are as given on the previous page for real $f$.

This is precisely the form of an inverse Fast Fourier transform
Generating Gaussian Random Numbers

This note is about the topic of generating Gaussian pseudo-random numbers given a source of uniform pseudo-random numbers. This topic comes up more frequently than I would have expected, so I decided to write this up on one of the best ways to do this. At the end of this note there is a list of references in the literature that are relevant to this topic. You can see some code examples that implement the technique, and a step-by-step example for generating Weibull distributed random numbers.

There are many ways of solving this problem (see for example Rubinstein, 1981, for an extensive discussion of this topic) but we will only go into one important method here. If we have an equation that describes our desired distribution function, then it is possible to use some mathematical trickery based upon the fundamental transformation law of probabilities to obtain a transformation function for the distributions. This transformation takes random variables from one distribution as inputs and outputs random variables in a new distribution function. Probably the most important of these transformation functions is known as the Box-Muller (1958) transformation. It allows us to transform uniformly distributed random variables, to a new set of random variables with a Gaussian (or Normal) distribution.

The most basic form of the transformation looks like:

\[
\begin{align*}
    y_1 &= \sqrt{ -2 \ln(x_1) } \cos( 2 \pi x_2 ) \\
    y_2 &= \sqrt{ -2 \ln(x_1) } \sin( 2 \pi x_2 )
\end{align*}
\]

We start with two independent random numbers, \( x_1 \) and \( x_2 \), which come from a uniform distribution (in the range from 0 to 1). Then apply the above transformations to get two new independent random numbers which have a Gaussian distribution with zero mean and a standard deviation of one.

This particular form of the transformation has two problems with it,
1. It is slow because of many calls to the math library.
2. It can have numerical stability problems when \( x_1 \) is very close to zero.
These are serious problems if you are doing stochastic modelling and generating millions of numbers.

The polar form of the Box-Muller transformation is both faster and more robust numerically. The algorithmic description of it is:

```c
float x1, x2, w, y1, y2;

do {
    x1 = 2.0 * ranf() - 1.0;
    x2 = 2.0 * ranf() - 1.0;
    w = x1 * x1 + x2 * x2;
    } while ( w >= 1.0 );

    w = sqrt( -2.0 * log( w ) ) / w ;
    y1 = x1 * w;
    y2 = x2 * w;
```

where \( \text{ranf()} \) is the routine to obtain a random number uniformly distributed in [0,1]. The polar form is faster because it does the equivalent of the sine and cosine geometrically without a call to the trigonometric function library. But because of the possibility of many calls to \( \text{ranf()} \), the uniform
random number generator should be fast (I generally recommend \textbf{R250} for most applications).

**Probability transformations for Non Gaussian distributions**

Finding transformations like the Box-Muller is a tedious process, and in the case of empirical distributions it is not possible. When this happens, other (often approximate) methods must be resorted to. See the reference list below (in particular Rubinstein, 1981) for more information.

There are other very useful distributions for which these probability transforms have been worked out. Transformations for such distributions as the Erlang, exponential, hyperexponential, and the Weibull distribution can be found in the literature (see for example, MacDougall, 1987).

        use_last = 1;
    }

    return( m + y1 * s );
}
Simulated Sea Waves at a Point
Simulated Sea Waves at a Point

SURFACE ELEVATION (m)

TIME (sec)
Wave Statistics

One way to calculate wave statistics is directly from long-term simulations.

Example What is the expected value of the largest wave elevation in a day?

Solution by simulation from a known wave spectrum.

1. Simulate waves for many days.
2. List the largest elevation in each day.
3. Calculate the average of the values in the list.

Another Example What is the probability that the largest wave elevation in one day is less than the value V. Solution by simulation.

1. Simulate waves for many days.
2. Determine the fraction of days that the elevation does not exceed V.
3. This fraction is an estimate of the desired probability.

The above direct approach is cumbersome and computationally intensive. Many wave statistics have been theoretically determined in terms of the wave spectrum. The associated formulae can be determined using numerical integration.
Results from Theory

The spectral moments, \( m_n \), are defined in terms of the one-sided spectrum, \( S_W(\omega) \), as:

\[
m_n = \int_0^\infty S_W(\omega) d\omega
\]

The following results apply when the surface elevation is a Gaussian random process.

Number of Waves per Unit Time

The average number of times the wave elevation, \( \zeta \), crosses the mean sea level (\( \zeta = 0 \)) per unit time while increasing is called \( f_o \) and given by:

\[
f_o = \frac{1}{2\pi} \sqrt{\frac{m_2}{m_0}}
\]

The average number of wave crests per unit time is called \( f_c \) and is given by:

\[
f_c = \frac{1}{2\pi} \sqrt{\frac{m_4}{m_2}}
\]

The bandwidth, \( \epsilon \), is given by:

\[
\epsilon = \sqrt{1 - \frac{f_o^2}{f_c^2}}
\]
Definition of a gaussian random process For any number of variables, the joint probability density (pdf) of all the variables is a joint gaussian random variable at each time for a gaussian random process. This probability density function is given by:

$$p(x_1, x_2, ..., x_n) = \frac{1}{\sqrt{(2\pi)^n|\Delta|}} \exp \left\{ -\frac{1}{2} [X]^T \Delta^{-1} [X] \right\}$$

$[X]$ is the column vector of the variables. $\Delta$ is the $n$-by-$n$ covariance matrix whose elements are given by:

$$\Delta_{ij} = E[x_i x_j]$$

For most wave statistics of interest, the doubly joint pdf between surface elevation, $\zeta$ and vertical surface velocity, $\dot{\zeta}$, and the triply joint pdf where the surface acceleration, $\ddot{\zeta}$, is included are all that are needed.

$$p(\zeta, \dot{\zeta}) = \frac{1}{2\pi \sqrt{m_0 m_2}} \exp \left[ -\frac{m_2 \zeta^2 + m_0 \dot{\zeta}^2}{2m_0 m_2} \right]$$

$$p(\zeta, \dot{\zeta}, \ddot{\zeta}) = \frac{1}{(2\pi)^{3/2} \sqrt{m_2 (m_0 m_4 - m_2^2)}} \exp \left[ -\frac{m_2 m_4 \zeta^2 + (m_0 m_4 - m_2^2) \dot{\zeta}^2 + m_0 m_2 \zeta^2 + 2m_2^2 \zeta \ddot{\zeta}}{2m_2 (m_0 m_4 - m_2^2)} \right]$$
The normalized Gaussian probability distribution function (pdf), $\Psi(x)$, is:

$$\Psi(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} e^{-z^2/2} dz$$

Call the crest height $\xi$.

The normalized crest height, $\eta$, is defined by: $\eta = \frac{\xi}{\sqrt{m_0}}$

The probability distribution function for $\eta$ is:

$$P(\eta) = \Psi\left(\frac{\eta}{\epsilon}\right) - \sqrt{1 - \epsilon^2} e^{-\eta^2/2} \Psi\left(\frac{\sqrt{1 - \epsilon^2}}{\epsilon} \eta\right)$$

and the pdf for $\eta$ is:

$$p(\eta) = \frac{\epsilon}{2\pi} \exp\left[-\frac{\eta^2}{2\epsilon^2}\right] + \sqrt{1 - \epsilon^2} \eta e^{-\eta^2/2} \Psi\left(\frac{\sqrt{1 - \epsilon^2}}{\epsilon} \eta\right)$$

![Figure 7.5](image)  
Probability density function of $\eta$ for various values of the bandwidth $\epsilon$.

Typically, $\epsilon \approx 0.6$.

For engineering purposes we are interested in large seas ($\eta >> 1$). This corresponds to the tail of the pdf for $\eta$. In this region:

$$p(\eta) = \sqrt{1 - \epsilon^2} \eta e^{-\eta^2/2} \quad P(\eta) = 1 - \sqrt{1 - \epsilon^2} e^{-\eta^2/2}$$
Average Amplitude of the 1/n’th Highest waves

Call the smallest normalized wave amplitude in the 1/n’th highest Waves $\eta_{1/n}$.

\[ \frac{1}{n} = 1 - P(\eta_{1/n}) \]

Example: $n = 10$.
1 - (probability that a wave amplitude is less than the smallest of the 10% largest waves) is 1/10.
This is because the probability that a (random) wave is smaller than 10% is 90%.

For $n \gg 1$, use the approximate $P$.

\[ \frac{1}{n} = \sqrt{1 - e^2} \exp \left[ -\frac{1}{2} \frac{\eta_{1/n}^2}{\eta_{1/n}} \right] \]

\[ \eta_{1/n} = \sqrt{2 \ln(n \sqrt{1 - e^2})} \]

Amongst the 1/n’th highest waves, the conditional pdf is:

\[ p_{\eta>\eta_{1/n}}(\eta) = n p(\eta) = n \sqrt{1 - e^2} \eta \exp(-\eta^2/2), \quad \eta_{1/n} < \eta < \infty \]

The expectation of these amplitudes is the average of the 1/n’th highest waves.

\[ \bar{\eta}_{1/n} = n \sqrt{1 - e^2} \int_{\eta_{1/n}}^{\infty} \eta^2 e^{-\eta^2/2} d\eta \]

Let $n' = \sqrt{1 - e^2} n$. Then, $n'$ is the number of zero up-crossings in a record with $n$ crests. The result of the integration is:

\[ \bar{\eta}_{1/n} = n' \left\{ \frac{\sqrt{2 \ln n'}}{n'} + \sqrt{2\pi} \left[ 1 - \Psi(\sqrt{2 \ln n'}) \right] \right\} \]
Extreme Waves

Consider \( n \) non-dimensional random wave Amplitudes. Each has same pdf.

What are the probabilities of the largest waves in the set?

Approach

Order the waves from smallest to largest.
\( \phi_1 \) is the smallest and \( \phi_n \) is the largest wave amplitude. Now, each of the \( \phi \)'s has a different pdf.

We want to find the pdf for \( \phi_n \).

Probability that \( \phi_n \) is less than a particular value \( \phi_{n_o} \) is equal to the probability that all the waves are smaller than \( \phi_{n_o} \).

\[
P_{\phi_n}(\phi_{n_o}) = [P_\eta(\phi_{n_o})]^n
\]

The amplitude that has a probability, \( \alpha \), of being exceeded by \( \phi_n \) is called \( \alpha \phi_n \).

\[
P_{\phi_n}(\alpha \phi_n) = [P_\eta(\alpha \phi_n)]^n = 1 - \alpha
\]

Meaning of the Nomenclature

Suppose \( \alpha = 0.01 \). Then the amplitude whose probability of being exceeded by \( \phi_n \) is 0.01 is named \( 0.01 \phi_n \).

The probability that \( \phi_n \) is less than \( 0.01 \phi_n \) is 0.99.

\[
P_\eta(\alpha \phi_n) = (1 - \alpha)^{1/n}
\]

\[
\Psi \left( \frac{\alpha \phi_n}{\epsilon} \right) - \sqrt{1 - \epsilon^2} \exp \left[ - \frac{1}{2} \alpha \phi_n^2 \right] \Psi \left( \frac{\sqrt{1 - \epsilon^2}}{\epsilon} \alpha \phi_n \right) = (1 - \alpha)^{1/n}
\]
Since we are interested in large waves, we can use the expressions for the tails of the probability functions:

$$P(\eta) = 1 - \sqrt{1 - \epsilon^2} e^{-\eta^2/2}$$

Then,

$$1 - \sqrt{1 - \epsilon^2} \exp \left[ -\frac{1}{2} \alpha \phi_n^2 \right] = (1 - \alpha)^{1/n}$$

Solve for $\alpha \phi_n$:

$$\alpha \phi_n = \sqrt{2 \ln \left( \frac{\sqrt{1 - \epsilon^2}}{1 - (1 - \alpha)^{1/n}} \right)}$$

Note: The value of $n$ for a given period of time $T$ can be obtained from:

$$f_c = \frac{1}{2\pi} \sqrt{\frac{m_4}{m_2}}$$

$$n = f_c T = \frac{T}{2\pi} \sqrt{\frac{m_4}{m_2}}$$
Stiff Equations

\[ \frac{dy}{dx} = -100y + 100 \]  
Initial condition, \( y(0) = y_0 \)

Exact solution \( y(x) = (y_0 - 1)e^{-100x} + 1 \)

This is stable in sense that small change in initial condition causes small change in solution.

Example, if \( y(0) = y_0 + \varepsilon \)

\[ y(x) = (y_0 + \varepsilon - 1)e^{-100x} + 1 \]

Change in solution, \( \delta y \) is \( \varepsilon e^{-100x} \)

Solution by the forward Euler method

\[ y_{n+1} = y_n + (-100y_n + 100) \delta x \]

This difference equation has an exact solution

\[ y_n = (y_0 - 1)(1 - 100 \delta x)^n + 1 \]

For example, if \( y_0 = 2 \),

\[ y(x) = e^{-100x} + 1 \]

\[ y_n = (1 - 100 \delta x)^n + 1 \]

Note: if \( \delta x > 0.02 \), the solution (numerical) diverges \( (1 - 100 \delta x)^n \) is an approximation to \( e^{-100x} \). It is a poor approximation unless \( \delta x \) is very small even though \( e^{-100x} \) hardly contributes to the solution for \( x > 0.01 \)
This problem is often overcome by implicit methods. One is the backward Euler method.

\[ y_{n+1} = y_n + f(x_n, y_n) \Delta x \]

For our example, \( f(x_n, y_{n+1}) = (-100y_{n+1} + 100) \)

\[ y_{n+1} = y_n + (-100y_{n+1} + 100) \Delta x \]

\[ y_{n+1}(1 + 100 \Delta x) = y_n + 100 \Delta x ; y_{n+1} = \frac{y_n + 100 \Delta x}{1 + 100 \Delta x} \]

The exact solution to this is:

\[ y_n = \frac{1}{(1 + 100 \Delta x)^n} + 1 \]

This is not unstable for any \( \Delta x \)
Dynamics of Horizontal Shallow Sag Cables in Water

Static Solution

$H$ is the horizontal component of the Tension.
$w$ is the weight in water/unit length.
$T$ is the tension.
$L$ is the static length.

\[
y = \frac{H}{w} \cosh \left( \frac{w}{H} x \right) - \frac{H}{w} \quad \quad T = H \cosh \left( \frac{w}{H} x \right)
\]

For $T \gg wL$

\[
y = \frac{T_o}{w} \left[ 1 + \frac{w}{2T_o} x^2 + \ldots \right] - \frac{T_o}{w} \quad \quad T \equiv T_o \cong H
\]

\[
\frac{dy}{dx} = \frac{wx}{T_o}
\]

\[
\frac{d^2y}{dx^2} = \frac{w}{T_o} \equiv \alpha \quad \text{static curvature} = \alpha
\]
Dynamics

vertical mechanical force/unit length = \( (T_o + \tilde{T}) \left( \alpha + \frac{\partial^2 q}{\partial t^2} \right) \)

where: \( q \) is the displacement normal to the cable towards the inside of the static curvature.

dynamic vertical mechanical force/unit length = \( (T_o + \tilde{T}) \left( \alpha + \frac{\partial^2 q}{\partial s^2} \right) - T_o \alpha \)

hydrodynamic vertical force/unit length = \(-b \frac{dq}{dt} \left| \frac{dq}{dt} \right|\)

where: \( b = \frac{1}{2} \rho C_d D \), \( \rho \) is the density of water, \( C_d \) is the drag coefficient and \( D \) is the diameter of the cable.

Equation of Motion

\[
m \frac{\partial^2 q}{\partial t^2} = (T_o + \tilde{T}) \left( \alpha + \frac{\partial^2 q}{\partial s^2} \right) - b \frac{dq}{dt} \left| \frac{dq}{dt} \right| - T_o \alpha
\]

Strain Compatibility

Tension increase due to \( q \) = increased length \( \times \frac{EA}{L} \)

where: \( p_o \) is the sum of the tangential extensions of the ends of the cable.
