Abstract

Endometriosis remains a challenge to understand and to diagnose. This is an observational cross-sectional pilot study to characterize the gut and vaginal microbiome profiles amongst endometriosis patients and control subjects without the disease, and to explore their potential use as a less-invasive diagnostic tool for endometriosis. Overall 59 women were included, n=35 with endometriosis and n=24 controls. Rectal and vaginal samples were collected in two different periods of the menstrual cycle from all subjects. Gut and vaginal microbiomes from patients with different rASRM (revised-American Society for Reproductive Medicine) endometriosis stages and controls were analyzed. Illumina sequencing libraries were constructed using a two-step 16S rRNA gene PCR amplicon approach. Correlations of 16S rRNA gene amplicon data with clinical metadata were conducted using a random forest-based machine-learning classification analysis. Distribution of vaginal CSTs (Community State Types) significantly differed between follicular and menstrual phases of the menstrual cycle ($p=0.021$, Fisher's exact test). Vaginal and rectal microbiome profiles and their association to severity of endometriosis (according to rASRM stages) were evaluated. Classification models built with machine-learning methods on the microbiota

composition during follicular and menstrual phases of the cycle were built and it was possible to accurately predict rASRM stages 1-2 versus rASRM stages 3-4 endometriosis. The feature contributing the most to this prediction was an OTU (Operational Taxonomic Unit) from the genus *Anaerococcus*. Gut and vaginal microbiomes of women with endometriosis have been investigated. Our findings suggest for the first time that vaginal microbiome may predict stage of disease when endometriosis is present.

Introduction

Endometriosis is a chronic gynecological condition defined as the presence of endometrial glands and/or stroma in ectopic sites that leads to a severe inflammatory state [1]. Pathogenesis of endometriosis is not yet fully understood and different genetic, hormonal, environmental and immunological factors have been implicated [2]. Studies have shown a significant association of aberrant immune response and maintenance of disease activity in women with endometriosis [3]. Although distinct immunological abnormalities have been reported in patients with disease, the specific mechanism in the pathogenesis of endometriosis is not yet fully understood [4,5].

The non-surgical diagnosis of endometriosis remains an immense challenge. Although ovarian endometrioma and deep endometriosis are easily identified by means of transvaginal ultrasound (TVUS) and MRI (magnetic resonance imaging), superficial disease is currently not detected by any of these tools [6,7]. Surgery is the only way to diagnose all cases and it is considered the gold standard with definitive confirmation obtained with histology [7]. A noninvasive test for diagnosing all types of endometriosis does not yet exist, despite several studies evaluating biomarkers from blood, peritoneal fluid and endometrial samples [8-10].

The concept that the human microbiome influences homeostasis and alters states of disease and health has been explored. Microbiota contribute to the equilibration of the immune system and help to maintain host homeostasis [11]. Recently, advances in technology and the use of next generation sequencing (NGS) facilitated the study of the human microbiome and its impact or response to different disease conditions

[12]. The role of the gut microbiome in inflammatory and autoimmune diseases are well established but not yet fully understood [13]. Intestinal microbiota dysbioses are correlated not only with bowel inflammatory disorders such as Crohn's disease, but also non-intestinal related autoimmune diseases, such as multiple sclerosis, type-1 diabetes, Grave's diseases, systemic lupus erythematosus, autism spectrum disorders, and psoriasis [14,15].

Evaluation of the gut microbiome has been utilized as a potential and putative noninvasive diagnostic tool in colorectal cancer; furthermore, there is an optimistic perspective that in the near future the gut microbiome might be a diagnostic tool for other chronic inflammatory gastrointestinal disorders such ulcerative colitis, Crohn's disease, Irritable Bowel Syndrome (IBS) and Inflammatory Bowel Disease (IBD) [16,17].

More recently, evaluation of the vaginal microbiota has been suggested to be useful for identification of common diseases in the upper genital tract [18]. *Mycoplasma genitalium*, has been noted to play a role in the immune tolerance process and in modulating local immune response in women with endometriosis. Cells from the peritoneal fluid from women with endometriosis manifested a down-regulation of genes associated with the inflammatory response. This down-regulation profile was higher when *Mycoplasma genitalium* was present **in the uterine cervix** [19].

Given the inflammatory condition of patients with endometriosis and its similarities with autoimmune disorders [20,21], the main goals of this pilot study are to characterize the microbiome from the gut and vagina of women with diagnosed endometriosis compared to women who do not have the disease as well as to explore the potential of using the gut and/or vaginal microbiome profiles as a diagnostic tool for endometriosis.

Methods

Study approval, subjects and sample collection

The Internal Review Boards of the University of Sao Paulo (CAPPesq #814.743) and the Massachusetts Institute of Technology (COUHES protocol # 1107004572) approved this protocol. Written informed consent was obtained from all participants. This is an **observational cross-sectional** study and it was based on the STROBE (Strengthening the Reporting of Observational studies in Epidemiology) statement from the EQUATOR (Enhancing the Quality and Transparency of Health Research) guideline. All consecutive patients between the ages of 21 – 49 years old who underwent laparoscopy between 2012-2014 due to suspected or confirmed endometriosis by imaging (TVUS or MRI) or previous surgery were included in the study. Patients were excluded if they were on hormones (GnRH analogues, progestogens, combined oral contraceptives) and antibiotics in the past 3 months prior to sample collections, if they had active systemic infection, a history of autoimmune diseases, active vaginosis, or history of sexually transmitted diseases; also, if they had acquired or primary immunodeficient diseases (including HIV), pregnancy, and malignant neoplasia. Control subjects (group B) included women who do not have endometriosis and any inflammatory conditions who underwent laparoscopic surgery for other gynecologic indications.

Rectal and vaginal samples were collected from all patients (study and control) 2 months prior to surgery and during two different phases of the menstrual cycle – menstrual period (days 1-3 of the cycle) and follicular phase (days 8-12 of the cycle). The menstrual and follicular phases were selected as they represented known higher and lower inflammation states during the menstrual cycle [22]. All samples were obtained using Sterile Catch-All sample collection swabs (Fisher Scientific, Pittsburgh, PA, USA). Rectal samples were collected by swabbing the rectal tissue at a depth of 3cm. Vaginal samples were collected in the mid-vagina at the site of the vaginal introitus. No speculums or lubricants were used prior to collection. Immediately after collection all swabs were immersed in the lysis buffer of Mobio PowerBead tubes (MoBio Laboratories Inc., Carlsbad, CA, USA) and held against the sides of the tube three times for 20 seconds each to ensure transfer of biological material. All tubes were then transferred on wet ice to a clinical lab in less than two hours and then stored at -80°C until extraction. Vaginal exams were performed after all vaginal collections to ensure patients did not have any active vaginal infections.

DNA extraction, 16S rRNA amplicon library, sequencing data processing and OTU analysis, vaginal community state type assignment

All samples were extracted using the MoBio Powersoil extraction kit (MoBio Laboratories Inc., Carlsbad, CA, USA). Paired-end Illumina sequencing libraries were constructed using a two-step 16S rRNA gene PCR amplicon approach described previously elsewhere [23]. The v4 variability region of the 16S rRNA gene was amplified using the 515F (GTGCCAGCMGCCGCGGTAA) and 806R (GGACTACHVGGGTWTCTAAT) primers. All paired-end libraries were multiplexed into one lane and sequenced on the Illumina MiSeq platform at the Biomicro Center (MIT, Cambridge, MA). Libraries were sequenced with 2x250 bases. From the sequencing data, forward and reverse reads were merged and filtered by estimated error per read using USEARCH (version 8). Further processing and clustering of 97% sequence based Operational Taxonomic Units (OTUs) was performed using an in-house pipeline (S1 Text). OTUs represent clusters of organisms, grouped by DNA sequence similarity of a specific taxonomic marker gene (16S rRNA) [23]. OTUs were taxonomically classified using the Ribosomal Database Project with a confidence cut off of 0.5 [24].

Microbiomes were categorized according to Community State Types (CSTs). Studies that profile vaginal and gut microbiomes have showed that there is a large variation among individuals as well as within individuals over a period of time. In order to gain greater understanding of their clinical utility, efforts were made to categorize the microbiome profiles into smaller clusters of microbiomes, known as CSTs. Previous studies have already used CSTs to summarize the microbial communities observed in the human vagina and the human gut [25].

As previously published, vaginal CSTs are in this way divided: CST I is dominated by *Lactobacillus crispatus*; CST II by *Lactobacillus gasseri*; CST III by *Lactobacillus inners*; CST IV is the only one not dominated by *Lactobacillus spp.*, with higher diversity of predominantly anaerobic bacteria; and CST V is dominated by *Lactobacillus jensenii* [26].

To determine if the five CSTs (Community State Types) and eight sub-CSTs observed in other vaginal microbiome studies were present in this study, CST assignment was determined using a model trained on data derived from previous vaginal microbiome studies (S3 Text). CST assignment was not determined using hierarchical clustering of samples within our study alone. Species level classification is required for discriminating between many of the *Lactobacillus* dominated CST groups. In order to perform the CST assignment, an environment specific species level classification table was generated using speciateIT and MCclassifier. After the species table was generated, a support vector machine-learning model, previously trained on data derived from multiple vaginal microbiome studies, was utilized to predict the CST of each sample (S3 Text).

Statistical analysis

16S rRNA amplicon data was used to generate a random forest-based machine-learning classification to identify correlations between OTU relative abundances and clinical metadata (disease state, self-reported pain) [27]. All OTU abundance data were analyzed with log transformation and all metadata categories were analyzed without transformation.

All statistical tests were performed using custom scripts and publically available statistical packages (S4 Text). A power calculation was not performed to estimate the sample size given that this is a pilot study and no previous studies have yet been published.

Results

A total of 64 women with endometriosis (n=40) and without endometriosis (n=24) were included in this study. Five patients from the study group (group A) were excluded due to missing data. Patient demographics and disease characteristics are summarized in Table 1. There was no statistical difference in the age and BMI between the study and control groups. However, race did show statistically significant differences between the two groups (p=0.008, Chi-square test). **It is important to note that our subject cohort included white, mixed race, and black subjects, 61%, 22%, and 16.9% of the cohort, respectively. It is possible that the CST distributions observed in this study are due to more than half of the subjects being white. Endometriosis is more common in Caucasian and Asian populations and CST distribution has been suggested to vary by race [26,33]. As this is the first time that we know of, that the distribution of CSTs has been investigated in a South American population, we highlight these findings with caution, as the sample size was limited.**

Also, as expected, there were statistically significant differences amongst groups regarding clinical symptoms such as dyspareunia (p=0.011, Mann-Whitney test), dysmenorrhea (p<0.001, Mann-Whitney test) and infertility (p=0.001, Fisher's exact test). Control subjects (n=24) included 18 women submitted to tubal ligation (75%), two cystectomies for ovarian benign teratoma – dermoid cyst (8%), one

diagnostic laparoscopy for pelvic pain (4%), one hysterectomy for uterine bleeding (4%), one myomectomy (4%) and one cystectomy for ovarian serous cystadenoma (4%).

Amongst the 35 study patients, 13 patients were found to have deep bowel endometriosis (37.1%), 14 with deep retrocervical endometriosis (40%), four with deep bladder endometriosis (11%), two with ovarian endometriomas alone (5.7%), one with peritoneal superficial endometriosis (2.8%) and one with abdominal wall endometriotic nodule (2.8%). When staged using the rASRM endometriosis classification system (rASRM, 1996), nine patients were found to have rASRM stage 1 (25.7%), 12 stage 2 (34.2%), four stage 3 (11.4%) and ten stage 4 (28.5%). For comparative analysis of patients and controls with this relatively small patient cohort, patients with rASRM (revised American Society for Reproductive Medicine, 1996) stages 1 and 2 were grouped together as rASRM stage 1-2, as were patients with stages 3 and 4 for rASRM stage 3-4, following common conventions [28].

Given the correlation between the gut microbiome and other chronic inflammatory disorders observed in other studies [16,17] we investigated if the rectal microbiome profile was predictive of patients having deep bowel endometriosis. A random-forest based classification model was built using the rectal microbiome during the menstrual phase of 10 patients with deep bowel endometriosis and 12 patients with other presentations of the disease. The accuracy of the classification models was determined using area under the curve (AUC) analysis of receiver operating characteristic curves. This model while predictive of site of disease (p-value = 0.03) was determined to not be sufficiently accurate to pursue in the context of this study (AUC = 0.29).

Rectal and vaginal samples collected during the menstrual and follicular phases of the menstrual cycle from the study and control patients underwent 16S rRNA analysis. In this cohort of women, there were no differences in the gut and vaginal microbiomes between study and control groups for both periods of the menstrual cycle – follicular and menstrual phases (Fig 1). In order to better understand the correlation between the microbiome and status of disease – endometriosis patients and control subjects – a

hierarchical linkage clustering was performed based on the CSTs (Community State Types) composition and OTU (Operational Taxonomic Units) abundance of samples for each sample type in the two periods of the cycle they were sampled.

The distribution of vaginal CSTs differed significantly between follicular and menstrual phases of the menstrual cycle within the same individuals. There was an increase in the number of patients with CST IV microbiomes during menstrual phase for both endometriosis (by 30%) and control subjects (by 25%), while CSTs II and V were lost during the menstrual phase ($p=0.021$, Fisher's exact test) (Fig 2). A two-sided Fisher exact test for count data was used in R (version 3.3.1) to test the significance of CST distributions between groups of patients.

Although not statistically significant, the ratio of CST I microbiome, which is dominated by *Lactobacillus crispatus*, was found to be in lower ratio in the control subjects compared to endometriosis patients, especially in the menstrual period (19% vs 30%, $p=0.57$, Fisher's exact test) as illustrated in Figure 2.

The vaginal microbiome profile was predictive of severity of endometriosis (according to rASRM stages) A random-forest based classification model was built using the vaginal microbiome during the menstrual phase of 12 patients with rASRM stages 1-2 and 8 patients with rASRM stages 3-4 of endometriosis demonstrated that the vaginal microbiome was surprisingly predictive of advanced disease (p value = 0.019) (Fig 3), despite the fact that there were no significant differences when comparing patients with either stage of disease to control patients. The accuracy of the classification models was determined using area under the curve (AUC) analysis. The highest contributing feature of the classification was an OTU of genus *Anaerococcus* (phylum *Firmicutes*) (Fig 3). Contributions of specific OTUs to the classification analysis were ranked using mean decrease accuracy (S2 Text). Associations between log-transformed OTU abundance and disease state were calculated using a two-tailed T-test for independent samples.

The relative abundance of the top predictive OTU significantly differed between stage 1-2 and stage 3-4 disease subjects using a univariate analysis (Fig 4). There was no significant difference in abundance for this OTU between the stage 1-2 or stage 3-4 disease and control subject groups. The significance of OTU

abundance between discrete categories was calculated using the Mann-Whitney U-test and a Benjamini-Hochberg false discovery rate correction. Only OTUs with a relative abundance of at least 10^{-6} were considered.

The species most closely related to this highly predictive *Anaerococcus* OTU were *Anaerococcus lactolyticus* and *Anaerococcus degenerii* species when compared to cultured representatives of this genera in the SILVA database (Fig 5) [29]. 16S rRNA gene sequence similarity was utilized to investigate the phylogenetic relationship between the top predictive OTU identified in the classification models and other closely related representatives of the same genus (S5 Text).

Discussion

The gut microbiota has been indicated in the pathogenesis of endometriosis (30). Similarly, vaginal microbiota has been attributed to be useful in identifying genital tract disorders (18). However, there is a lack of studies investigating the connection between the vaginal and the gut microbiomes with endometriosis in humans. Recently, in an animal study, some data was published providing new insights on the association of endometriosis and gut microbiota using high-throughput sequencing technology. Authors revealed changes in the gut microbiota during endometriosis development in a murine model (31). Their findings showed an elevation in the ratio *Firmicutes/Bacteroidetes* in mice with endometriosis, indicating that endometriosis may induce dysbiosis in the host (31). Women with endometriosis have not been assessed until now.

The preliminary results from this pilot study revealed that the relative abundance of a specific OTU classified as *Anaerococcus* was predictive of endometriosis rASRM stage of disease when assessed during menstruation. Interestingly, it is the same period of the menstrual cycle that other biomarkers have been shown, with reliability and higher sensitivity, to identify endometriosis patients [8]. Patients with endometriosis rASRM stage 1-2 were differentiated from patients with endometriosis rASRM stage 3-4 using the relative abundance of an *Anaerococcus* OTU. This information may prove useful for future

research regarding the role of the vaginal microbiome and *Anaerococcus* species specifically, in the pathogenesis and diagnosis of advanced stages of endometriosis.

The vaginal microbiome sampled from different locations within the same individual have been shown to vary [18]. Chen et al. (2017) explored the vaginal microbiome in three different locations – lower third of vagina, posterior fornix and cervical mucus – in a healthy reproductive-age Chinese population. The microbiome profile from the samples collected in the lower third of the vagina, which is very similar to the collection protocol used in the present study, comprised only of CSTs I, III and IV [18]. The same two CSTs II and V that were lost in our cohort during the menstrual period, were both absent in Chen et. al's cohort. Curiously, none of those patients were in the menstrual phase of the cycle in the occasion of sample collection [18]. This may suggest differences in the vaginal microbiome profile between the two populations, considering that a cohort of reproductive-age women without endometriosis was also included in the present pilot study as controls. Conversely, the microbiome profile of the disease and control cohorts in the present study revealed the presence of all five CSTs in the samples collected during follicular phase, revealing the loss of CSTs II and V in the samples collected during menstruation.

The distribution of CSTs obtained from Brazilian patients in this study, were similar to those of other studies conducted with women of European descent. It was found that the CSTs distributions of bacteria for both endometriosis and control subjects during the follicular phase were the same of those observed in non-pregnant reproductive age women of European descent [32-35]. Moreover, the definition of each CST in the present study is in agreement with that described by Ravel et. al. (2010) and Gajer et. al. (2012) [26,33], as well as with the one described by Chen et al. (2017), which included only Chinese women [18].

Interestingly, in addition to differences in the distribution of CSTs, a flux directed mainly into CST IV during the menstrual period was observed (Fig 2). CST IV is defined by a vaginal community that is not dominated by *Lactobacillus* but is instead a heterogeneous community of anaerobic bacteria [26,35]. Two *Lactobacillus* dominated CSTs, II and V, dominated by high abundances of *Lactobacillus gasseri* and *L. jensenii*, respectively, were lost during the menstrual phase in both groups of women (Fig 2). The loss of

CST II and V during menstrual phase observed in this study could be related to a lack of power due to a small sample size used to identify these CSTs in both periods. However, an alternative hypothesis could be the fall in estrogen levels that occurs during menstruation [35]. It has been previously demonstrated that during follicular phase, which is associated with higher estrogen levels and increased vaginal secretions, there is an accumulation of glycogen that potentially culminates in the growth of *Lactobacillus* species [36,37]. Interestingly, CST I (*Lactobacillus crispatus*-dominated) appears to be in lower ratio among control subjects compared to endometriosis patients, especially in the menstrual period. Although this result is not statistically significant, probably due to the small sample size included in this pilot study, it is possible that it is reflective of the population if one takes in to consideration known biological properties from *Lactobacillus crispatus*. This lower ratio of CST I might be related to the inflammatory profile and response observed in endometriosis. It has been demonstrated that a specific strain of *Lactobacillus crispatus* grants an anti-inflammatory phenotype to dendritic cells (DCs) by up-regulating anti-inflammatory/regulatory IL-10 cytokine production as well as inducing CD4(+) CD25(+) FOXP3(+) T cells at great dosage [38]. It is already known that endometriosis itself may up-regulate IL-10 yield [20] and induce CD4(+) CD25(+) FOXP3(+) T cells [39]. It is plausible that *Lactobacillus crispatus* is somehow involved within the local immune response of patients with endometriosis. This potential immunological role of *Lactobacillus crispatus* could explain why CST I (*Lactobacillus crispatus*-dominated) might be in higher concentration among patients with endometriosis compared to patients without the disease., future studies should consider investigating the possible role of *Lactobacillus crispatus* in patients with endometriosis. The use of bigger cohorts would make it possible to identify statistical differences in the concentration of CST I between women with and without endometriosis. Additionally, immunological aspects should be measured to understand the role of the vaginal microbiome within immune response regulation in endometriosis.

Given that there was no difference in the vaginal and gut microbiome profiles between endometriosis and control patients assessed during the follicular and menstrual phases within this cohort of patients, two hypotheses were raised. First, this lack of difference might reflect the high inter-subject and intra-subject

variability of the gut and vaginal microbiomes as previously reported [26,35,40]. Second, this is a pilot study with a small sample size and current results might be related to a lack of power. **This might also be the case for the results we had comparing the gut microbiome of patients with bowel endometriosis with patients presenting with other sites of endometriosis lesions. However, we hope that including this information will encourage future studies with larger cohorts to investigate this hypothesis.**

Ideally, a prospective, collaborative work, including women from different populations will fulfill the gaps left by this pilot study.

Our findings suggest for the first time that the vaginal microbiome may predict stage of disease when endometriosis is present.

Conclusion

An OTU within the genus *Anaerococcus* differed significantly in abundance between women with endometriosis rASRM stage 1-2 and stage 3-4 during menstrual phase, predicting these different stages of disease. Moreover, *L. crispatus* might be involved in immune response regulation within endometriosis patients. This is the first study investigating both gut and vaginal microbiome in patients with endometriosis and control women without the disease. Current findings bring new insights on the pathogenesis of endometriosis and the further potential use of the human vaginal microbiome as a diagnostic tool. **As this is a pilot study, it has limitations, specially the small sample size, and therefore** these current finding should be considered with caution until more data from larger cohorts are published.

Figure 1. Rectal and vaginal microbial communities do not cluster by disease state. We illustrate the hierarchical linkage clustering of samples based upon the community composition and OTU abundance for patient rectal and vaginal samples collected during the follicular and menses time points. Patient disease status is indicated as endometriosis or control group, blue and black respectively. OTU abundances are displayed as log relative abundance.

Figure 2. The distribution of vaginal community state types differs between follicular and menses phases of the menstrual cycle. Distribution of vaginal community state types observed in endometriosis and control subjects during follicular and menses phases. The number of subjects included is 27, 18, 21, and 16; top left, right, bottom left, and right, respectively.

Figure 3. Microbiota composition predicts stage of disease. Here we illustrate (A) accuracy, as determined by AUC analysis of ROC curves, of the model built to predict stage 1-2 versus stage 3-4

endometriosis from the composition of the vaginal microbial community during the menses time point. **(B)** The top contributing OTU features for this model, ranked by Mean Decreased Accuracy. Taxonomic level for each OTU displayed is genus except in the case of a single OTU where f indicates the family level. Correlations of OTU abundance with stage of disease, calculated using a two-sided T-Test, are indicated as positive (blue, T statistic > 0 and p-value < 0.05), negative (red, T statistic < 0 and p-value < 0.05), and no correlation (grey, p-value > 0.05).

Figure 4. The relative abundance of the top predictive feature differs between stage 1-2 and stage 3-4 endometriosis patients. We illustrate the abundance in vaginal samples during the menses time point of the most predictive feature from our machine learning model, an OTU classified as belonging to the genera *Anaerococcus*. Log relative abundances for this OTU are shown for control, stage 1-2 stage endometriosis, and stage 3-4 endometriosis subjects. Corrected p-values shown were calculated using the Mann-Whitney U-Test with an Benjamini-Hochberg false discovery rate correction as described in the materials and methods.

Figure 5. The phylogenetic relationship between the predictive *Anaerococcus* OTU and other cultured representatives of this genus. We illustrate the phylogenetic relationship between the *Anaerococcus* OTU identified in this study as predictive of stage of disease (highlighted with a grey box) and *Anaerococcus* representatives in the SILVA database. There are three major clades: (blue) a clade including the predictive OTU, *A. lactolyticus*, *A. tetradius*, and *A. prevotii* strains; (red) a clade of *A. tetradius*, and *A. prevotii* strains; (purple) and a clade of *A. hydrogenalis*, *A. senegalensis*, and *A. vaginalis* strains.

Table 1. Clinical features of included subjects				
Variable	Group		Total (n=59)	p
