Abstract

This paper describes a programming language, Javari, that is capable of expressing and enforcing immutability constraints. The specific constraint expressed is that the abstract state of the object to which an immutable reference refers cannot be modified using that reference. The abstract state is (part of) the transitively reachable state: that is, the state of the object and all state reachable from it by following references. The type system permits explicitly excluding fields from the abstract state of an object. For a statically type-safe language, the type system guarantees reference immutability.

The type system distinguishes the notions of assignability and mutability; integrates with Java's generic types and with multi-dimensional arrays; provides a mutability polymorphism approach to avoiding code duplication; and has type-safe support for reflection and serialization. This paper describes a core calculus including formal type rules for the language.

Additionally, this paper describes a type inference algorithm that can be used to convert existing Java programs to Javari. Experimental results from a prototype implementation of the algorithm are presented.

Chapter 1

Introduction

The Javari programming language extends Java to allow programmers to specify and enforce reference immutability constraints. An immutable, or read-only, reference cannot be used to modify the object, including its transitive state, to which it refers. A type system enforcing reference immutability has a number of benefits: it can increase expressiveness; it can enhance program understanding and reasoning by providing explicit, machine-checked documentation; it can save time by preventing and detecting errors that would otherwise be very difficult to track down; and it can enable analyses and transformations that depend on compiler-verified properties.

Javari's type system differs from previous proposals (for Java, C++, and other languages) in a number of ways. First, it offers reference, not object, immutability; reference immutability is more flexible, as it provides useful guarantees even about code that manipulates mutable objects. For example, many objects are modified during a construction phase but not thereafter. As another example, an interface can specify that a method that receives an immutable reference as a parameter does not modify the parameter through that reference, or that a caller does not modify a return value. Furthermore, a subsequent analysis can strengthen reference immutability into stronger guarantees, such as object immutability, where desired.

Second, Javari offers guarantees for the entire transitively reachable state of an object — the state of the object and all state reachable by following references through its (non-static) fields. A programmer may use the type system to support reasoning

about either the representation state of an object or its abstract state; to support the latter, parts of a class can be marked as not part of its abstract state. Third, Javari combines static and dynamic checking in a safe and expressive way. Dynamic checking is necessary only for programs that use immutability downcasts, but such downcasts can be convenient for interoperability with legacy code or to express facts that cannot be proved by the type system. Javari also offers parameterization over immutability.

Experience with over 160,000 lines of Javari code, including the Javari compiler itself, indicates that Javari is effective in practice in helping programmers to document their code, reason about it, and prevent and eliminate errors [5]. Despite this success, deficiencies of a previous proposal for the Javari language limit its applicability in practice. Many of the limitations of [5] were addressed in [48], an abbreviated version of this paper. In addition to the contributions of [48], this paper describes a type inference that is capable of converting Java programs to the Javari language and discusses the results of a prototype implementation of the analysis. Furthermore, this paper rectifies a flaw in the core calculus that was previously presented.

This paper demonstrates that it is possible to implement a usable extension to Java that enforces reference immutability. In particular, for the language to be useful to programmers it must obey the following design goals.

Non-conversion Must disallow the conversion, through assignment or unsafe casts, of a read-only reference to a mutable reference. This goal allows reference immutability serve as a way to protect the abstract state of objects from mutation.

Transitive Provide transitive (deep) immutability that protects the entire abstract state of an object. This goal enables programmers to use reference immutability as a means to reason abstractly about the mutation of objects.

Flexible Allow programmers sufficient means to exclude an parts of an object's concrete state from the object's abstract state. This goal ensures that the language is usable in real-world programs that cache information, use complex data structures, and use utility and debugging classes such as loggers.

Compatible Be backwards compatible with existing programs to allow programmers to easily move to Javari without losing current programs.

Usable Naturally extend the Java language in a way that is intuitive to current programmers. This goal is a necessity for the language to be adopted by the mainstream Java programming community.

The rest of this document is organized as follows. Chapter 2 presents examples that motivate the need for reference immutability in a programming language. Chapter 3 describes the Javari language. Chapter 4 formalizes the type rules of Javari. Chapter 5 discusses extensions to the basic Javari language to make the language more useful in practice. Chapter 6 presents a type inference algorithm used to automatically add Javari's immutability constraints to an existing Java program. Chapter 7 discusses related work, including a previous dialect of the Javari language. Chapter 8 concludes with a summary of contributions. Appendix A gives examples of each of Javari's assignability and mutability types being used. Finally, appendix B explains why Java's annotation mechanism is not expressive enough to encode Javari's constraints.

Chapter 2

Motivation

Reference immutability provides a variety of benefits in different situations. Many other papers and books (see chapter 7) have justified the need for immutability constraints. The following simple examples suggest a few uses of immutability constraints and give a flavor of the Javari language.

Consider a voting system containing the following routine:

```
ElectionResults tabulate(Ballots votes) { ... }
```

It is necessary to safeguard the integrity of the ballots. This requires a machine-checked guarantee that the routine does not modify its input `votes`. Using Javari, the specification of `tabulate` could declare that `votes` is read-only:

```
ElectionResults tabulate(readonly Ballots votes) {  
    ... // cannot tamper with the votes  
}
```

and the compiler ensures that implementers of `tabulate` do not violate the contract.

Accessor methods often return data that already exists as part of the representation of the module. For example, consider the `Class.getSigners` method, which returns the entities that have digitally signed a particular implementation. In JDK 1.1.1, its implementation is approximately:

```

class Class {
    private Object[] signers;
    Object[] getSigners() {
        return signers;
    }
}

```

This is a security hole, because a malicious client can call `getSigners` and then add elements to the `signers` array.

Javari permits the following solution:

```

class Class {
    private Object[] signers;
    readonly Object[] getSigners() {
        return signers;
    }
}

```

The `readonly` keyword ensures that the caller of `Class.getSigners` cannot modify the returned array.

An alternate solution to the `getSigners` problem, which was actually implemented in later versions of the JDK, is to return a copy of the array `signers` [6]. This works, but is error-prone and expensive. For example, a file system may allow a client read-only access to its contents:

```

class FileSystem {
    private List<Inode> inodes;
    List<Inode> getInodes() {
        ... // Unrealistic to copy
    }
}

```

Javari allows the programmer to avoid the high cost of copying `inodes` by writing the return type of the method as:

```

readonly List<readonly Inode> getInodes()

```

This return type prevents the `List` or any of its contents from being modified by the client. As with all parameterized classes, the client specifies the type argument, including whether it is read-only or not, independently of the parameterized typed.

A similar form of dangerous, mutation-permitting aliasing can occur when a data structure stores information passed to it (for instance, in a constructor) and a client retains a reference. Use of the `readonly` keyword again ensures that either the client's copy is read-only and cannot be modified, or else the data structure makes a copy, insulating it from changes performed by the client. In other words, the annotations force programmers to copy only when necessary.

As a final example, reference immutability can be used, in conjunction with a subsequent analysis, to establish the stronger guarantee of object immutability: a value is never modified, via any reference, if all references are immutable. For example, there is only one reference when an object is first constructed. As another simple example, some data structures must be treated as mutable when they are being initialized, but as immutable thereafter; an analysis can build upon Javari in order to make both the code and the reasoning simple.

```
Graph g1 = new Graph();
... construct cyclic graph g1 ...
// Suppose no aliases to g1 exist.
readonly Graph g = g1;
g1 = null;
```

Chapter 3

Language Design

In Java, each variable or expression has an *assignability* property, controlled by the `final` keyword, that determines whether it may be the lvalue (left-hand side) of an assignment. In Javari, each (non-primitive) reference additionally has a *mutability* property that determines whether its abstract state may be changed (for example, by setting its fields). Both properties are specified in the source code, checked at compile time, and need no run-time representation. The assignability and mutability properties determine whether various operations, such as reassignment and calling side-effecting methods, are permitted on a reference.

Javari extends Java by providing additional constraints that may be placed on the assignability and mutability of a reference. Javari's keywords are those of Java, plus five more: `assignable` (the complement of `final`); `readonly` and its complement `mutable`; `romaybe`, a syntactic convenience that reduces code duplication; and `? readonly`, which is used to create wildcards that vary over mutability.¹

For ease of presentation, this chapter introduces the various aspects of the Javari language incrementally then concludes with a summary of the language as a whole. While some aspects of the language are explained in great detail, they are merely results of the application of Javari's simple design goals: preventing the conversion of a read-only reference into a mutable reference, providing transitive immutability,

¹For ease of reading, we present Javari's immutability as keywords; however, as discussed in appendix B, Javari can be implemented using extended Java annotations.

allowing programmers the flexibility to exclude parts of an object’s concrete state from the object’s abstract state, provide backwards compatibility, and naturally extending Java.

The rest of the section explains how Javari’s assignability and mutability concepts interact with the constructs of Java. Sections 3.1 and 3.2 introduce the concepts of assignability and mutability, respectively, and discuss their application to local variables. Section 3.3 introduces read-only methods and section 3.4 presents immutable classes. Section 3.5 discusses the assignability and mutability of fields. Section 3.6 applies assignability and mutability to generic classes, and section 3.7, to arrays. Finally, section 3.8 summarizes Javari’s syntax.

3.1 Assignability and final references

Assignability determines whether a reference may be reassigned. By default, a local variable is assignable: it may be reassigned. Java’s `final` keyword makes a variable unassignable: it cannot be reassigned. Javari retains the `final` keyword, but provides greater control over the assignability of references via the `assignable` keyword (see section 3.5.3) and the concept of this-assignability (see section 3.5.1). The following is an example of assignable and unassignable references.

```
final      Date d = new Date(); // unassignable
/*assignable*/ Date e = new Date(); // assignable
e = new Date(); // OK
d = new Date(); // error: d cannot be reassigned
```

Above, “`/*assignable*/`” is not a part of the program’s semantics but a comment to remind the reader that Java references are assignable by default. Except in section 5.3.5, all errors noted in code examples are compile-time errors.

Assignability does not affect the type of the reference. Assignability constraints add no new types to the Java type hierarchy, and there is no type `final T` (for an existing type `T`).

3.2 Mutability and read-only references

Mutation is any modification to an object's abstract state. The abstract state is (part of) the transitively reachable state, which is the state of the object and all state reachable from it by following references. It is important to provide transitive (deep) immutability guarantees in order to capture the full abstract state represented by a Java object. Clients of a method or other construct are typically interested in properties of the abstraction, not the concrete representation. (Javari provides ways to exclude selected fields from the abstract state; see section 3.5.3.)

Javari's `readonly` type modifier declares immutability constraints. A reference that is declared to be of a `readonly` type cannot be used to mutate the object to which it refers. For example, suppose a variable, `rodate`, is declared to have the type `readonly Date`. Then `rodate` can only be used to perform actions on the `Date` object that do not modify it:

```
readonly Date rodate = ...; // readonly reference to a Date object
rodate.getMonth();         // OK
rodate.setYear(2005);      // error
```

For every Java reference type `T`, `readonly T` is a valid Javari type and a supertype of `T`; see figure 3-1. A mutable reference may be used where a read-only reference is expected, because it has all the functionality of a read-only reference. A read-only reference may not be used where a mutable reference is expected, because it does not have all the functionality of a mutable reference: it cannot be used to modify the state of the object to which it refers.

The type `readonly T` can be thought of as an interface that contains a subset of the methods of `T` (namely, those that do not mutate the object) and that is a supertype of `T`. However, Java interfaces are less powerful and cannot be used in place of the `readonly T` construct; see section 7.2 for details.

Given the type hierarchy shown in figure 3-1, Java's existing type-checking rules enforce that mutable methods cannot be called on read-only references and that the

Figure 3-1: A portion of the Javari type hierarchy, which includes read-only and mutable versions of each Java reference type. Arrows connect subtypes to supertypes.

value referenced by a read-only variable cannot be copied to a non-read-only variable (non-conversion).

```

readonly    Date rodate = new Date(); // read-only Date
/*mutable*/ Date date   = new Date(); // mutable Date

rodate = date;                // OK
rodate = (readonly Date) date; // OK
date = rodate;                // error
date = (Date) rodate;        // error: Java cast cannot make a read-only reference
                               // mutable. See section 5.3.5 for details.
  
```

A read-only reference type can be used in a declaration of any variable, field, parameter, or method return type. Local variables, including method parameters and return types, are by default mutable (non-read-only). Primitive types, such as `int`, `float`, and `boolean`, are immutable—they contain no modifiable state. Thus, it is not meaningful to annotate them with `readonly`, and Javari’s syntax prohibits it.

Note that `final` and `readonly` are orthogonal notions in a variable declaration: `final` makes the variable not assignable, but the object it references remains mutable, while `readonly` makes the referenced object non-mutable (through that reference), but the variable may remain assignable. Using both keywords gives a variable whose transitively reachable state cannot be changed, except through a mutable aliasing reference.

3.3 Read-only methods (this parameters)

Just as `readonly` may be applied to any explicit formal parameter of a method, it may be applied to the implicit `this` parameter by writing `readonly` immediately following the parameter list. For example, an appropriate declaration for the `StringBuffer.charAt` method in Javari is:

```
public char charAt(int index) readonly { ... }
```

Such a method is called a read-only method. In the context of the method, `this` is `readonly`. Thus, it is a type error for a read-only method to change the state of the receiver, and it is a type error for a mutable (non-read-only) method to be called through a read-only reference.

3.3.1 Overloading

Javari's immutability annotations should not affect the runtime-behavior of programs. This approach allows class files generated by Javari to be backwards compatible and for Javari to be implemented using erasure, as parametric types are implemented in Java 1.5. One consequence of this approach is that two overloaded methods cannot differ only in the mutability of its parameters. For example, the following pair methods are can not overload one another:

```
void foo(/*mutable*/ Date d) { ... }  
void foo(readonly Date d) { ... }
```

This restriction is similar to Java's restriction that overloaded methods may not differ only by type arguments. For example, the following methods may not overload one another:

```
void baz(List<Date> x) { ... }  
void baz(List<Integer> x) { ... }
```

Similarly, methods cannot be overloaded based on the mutability of the methods' receivers. For example, the following methods may not overload one another:

```
void bar() /*mutable*/ { ... }  
void bar() readonly   { ... }
```

3.4 Immutable classes

A class or an interface can be declared to be immutable via the `readonly` modifier in its declaration.²

This is a syntactic convenience: the class's non-static fields default to read-only and final, and its non-static methods (and, for inner classes, constructors) default to read-only. As a further syntactic convenience, every reference to an object of immutable type `T` is implicitly read-only. For example, `String` means the same thing as `readonly String` (the latter is forbidden, for syntactic simplicity), and it is impossible to specify the type “mutable `String`”.

An immutable class may extend only other immutable classes. Furthermore, subclasses or subinterfaces of immutable classes and interfaces must be immutable.

3.5 Fields

Controlling mutation is a central theme of Javari; therefore, Javari's handling of fields is of key importance to the language design. This section begins by discussing how Javari reaches its goal of providing transitive immutability using fields that default to being this-assignable and this-mutable (section 3.5.1). Next, this section shows how Javari naturally handles field accesses that occur within methods (section 3.5.2). Third, this section shows how Javari reaches its flexibility design goal by providing assignable and mutable fields (section 3.5.3). Finally, this section concludes by demonstrating the details of the Javari type system that ensure fields cannot be used

²A “read-only type” is `readonly T`, for some `T`. An “immutable type” is a primitive type, or a class or interface whose definition is marked with `readonly`.

as a mechanism to convert a read-only reference into a mutable reference; thus, supporting Javari's non-conversion design goal (section 3.5.4).

3.5.1 This-assignability and this-mutability

One of the design goals of Javari is to provide transitive immutability; therefore, a field reached through a read-only reference should not be modifiable by reassignment or mutation. Javari fulfills this goal, by defaulting fields to inherit their assignability and mutability from the mutability of the reference through which the field is reached. These defaults are called *this-assignability* and *this-mutability*, respectively. Transitive immutability is ensured because a this-assignable, this-mutable field read through a read-only reference is unassignable and read-only. The same field read through a mutable reference is assignable and mutable, however. The behavior of this-assignable and this-mutable fields is illustrated below.

```
class Cell {
    /*this-assignable this-mutable*/ Date d;
}

/*mutable*/ Cell c; // mutable
readonly Cell rc; // read-only

c.d = new Date(); // OK: c.d is assignable
rc.d = new Date(); // error: rc.d is unassignable (final)

c.d.setYear(2005); // OK: c.d is mutable
rc.d.setYear(2005); // error: rc.d is read as read-only
```

This-assignability and this-mutability can only be applied to fields. The default of this-assignability can be overridden by declaring a field to be `final` (section 3.1) or `assignable` (section 3.5.3). The default of this-mutability can be overridden by the declaring a field to be `read-only` (section 3.2) or `mutable` (section 3.5.3). This-assignable, `final`, and `assignable` are the three kinds of assignabilities in Javari, and `this-mutable`, `read-only`, and `mutable` are the three kinds of mutabilities.

Section 3.5.4 gives additional information about `assignable` (section 3.5.3), `this-mutable` fields.

3.5.2 Field accesses within methods

No special rules are needed for handling field accesses within method bodies. Within a read-only method, the declared type of `this` is read-only; therefore, all `this`-mutable fields are read as read-only and all `this`-assignable fields are unassignable. Within a mutable method, the declared type of `this` is mutable; therefore, all `this`-mutable fields are mutable and all `this`-assignable fields are assignable. These rules are demonstrated below.

```
class Cell {
  /*this-assignable this-mutable*/ Date d;

  /*mutable*/ Date foo() readonly { // this is readonly
    d = new Date(); // error: this.d is unassignable
    d.setYear(2005); // error: this.d is read as readonly
    return d; // error: this.d is read as readonly
  }

  /*mutable*/ Date bar() /*mutable*/ { // this is mutable
    d = new Date(); // OK: this.d is assignable
    d.setYear(2005); // OK: this.d is mutable
    return d; // OK: this.d is mutable
  }
}
```

3.5.3 Assignable and mutable fields

Javari gives programmers the flexibility to exclude fields from the abstract state of an object by using the `assignable` and `mutable` keywords. By default, fields are `this-assignable` and `this-mutable`. Under these defaults, all the fields are considered to be a part of the object's abstract state and, therefore, can not be modified through a read-only reference. The `assignable` and `mutable` keywords override these defaults by excluding specific fields from an object's abstract state. `assignable` and `mutable` can also be used when the relationship between the object's abstract state and a field is too complicated to be captured by the Javari type system.

assignable fields

Declaring a field `assignable` specifies that the field can always be reassigned, even through a read-only reference. This can be useful for caching or specifying that the identity of a field is not a part of the object's abstract state. For example, `hashCode` is a read-only method: it does not modify the abstract state of the object. In order to cache the hash code, a programmer can use the `assignable` keyword as shown below.

```
class Foo {
    assignable int hc;
    int hashCode() readonly {
        if (hc == 0) {
            hc = ... ;    // OK: hc is assignable
        }
        return hc;
    }
}
```

mutable fields

The `mutable` keyword specifies that a field is mutable even when referenced through a read-only reference. A mutable field's value is not a part of the abstract state of the object (but the field's identity may be). For example, in the code below, `log` is declared `mutable` so that it may be mutated within read-only methods such as `hashCode`.

```
class Foo {
    /** A Log of the method call history. */
    final mutable List<String> log;

    int hashCode() readonly {
        log.add("hashCode() invoked"); // OK: log is mutable
        ...
    }
}
```

If `log` had the default this-mutability, the mutation of `log` would be a compile-time error because within the body of a read-only method `log` would be read as a read-only reference.

3.5.4 Non-conversion

One design goal of the Javari language is to ensure that a read-only reference cannot be converted to a mutable reference. This section discusses how Javari ensure that a field is not used to undertake such a conversion. In short, a read-only reference can not be assigned to a this-mutable field (even if reached through a read-only reference), because the this-mutable field can be read as mutable when reached through a mutable reference.

While a this-mutable field, reached through a read-only reference, is read as read-only, it is incorrect to say that its type is read-only. As an rvalue (an expression in a value-expecting context [1]), such a reference is read-only—it may be *assigned to* a read-only reference but not a mutable reference. However, as an lvalue (an expression in a location-expecting context, such as on the left side of an assignment [1]), such a reference is mutable—it may be *assigned with* a mutable reference but not a read-only reference. For example,

```
class Cell {
    assignable /*this-mutable*/ Date d;
}

readonly Cell rc;

readonly    Date rd;
/*mutable*/ Date md;

rd = rc.d; // OK: rc.d's rvalue is readonly    Date
rc.d = md; // OK: rc.d's lvalue is /*mutable*/ Date
```

A this-mutable field has different rvalue and lvalue types because a read-only type must be a supertype of the corresponding mutable type; else a type system loophole that allows one to convert a read-only reference into a mutable reference would exist. For a subtyping relationship to exist between two classes, the rvalue types of the fields³ must be covariantly related while the lvalue types of the fields must be contravariantly

³Note that this discussion is orthogonal to field shadowing, which involves two *distinct* fields (of the same name) in classes within a subtyping relationship.

related.⁴ Thus, if the field of the mutable version of the class has a mutable lvalue type, then the lvalue type of the corresponding field in the read-only version of the type must also be mutable. Otherwise, the lvalue types would not be contravariantly related.

Furthermore, without making a this-mutable field's lvalue type mutable, one could use an assignable, this-mutable field to convert a read-only reference to a mutable reference as shown below. (In the unsound type system, the compile-time error shown below would not occur.)

```
class DateConverter {
  assignable /*this-mutable*/ Date f;
}

readonly Date rd = ...; // Start with a readonly Date.
/*mutable*/ DateConverter mutView = ...;
readonly DateConverter roView = mutView; // Create a read-only alias.
roView.f = rd; // error: Would be allowed if lvalue type was read-only.
/*mutable*/ Date md = mutView.f; // Created a mutable reference to the Date.
```

The above loop-hole is prevented by not allowing read-only references to be written to a this-mutable field.

Note, that this-mutable fields may always be assigned to other this-mutable fields within the *same* object. For an example, see figure 3-2.

3.6 Generic classes

In Java, the client of a generic class controls the type of any reference whose declared type is a type parameter. A client may instantiate a type parameter with any type that is a subtype of the type parameter's declared bound. One can think of the type argument being directly substituted into the parameterized class wherever the corresponding type parameter appears.

⁴Java normally imposes the even stricter requirement that field types must be invariantly related. Javari loosens this rule only for a field's mutability. Without doing so, Javari would be unable to provide both mutable and read-only references to the same object.

```

class Quadrilateral {
  /*this-assignable*/ /*this-mutable*/ Line side1;
  /*this-assignable*/ /*this-mutable*/ Line side2;
  ...

  // Calculated if needed.
  assignable /*this-mutable*/ Line longestSide;

  readonly Line getLongestSide() readonly {
    if (side1.longer(side2) && side1.longer(side3) ... ) {

      longestSide = side1; // OK: this-mutable fields of the same object

    } else if (...) {
      ...
    }
    ...
  }
}

```

Figure 3-2: An assignable, this-mutable field may be assigned with other this-mutable fields even within read-only methods as shown in the example above.

Javari uses the same rules, extended in the natural way to account for the fact that Javari types include a mutability specification (figure 3-1). A use of a type parameter within the generic class body has the exact mutability with which the type parameter was instantiated.

The rest of this section demonstrates how parametric types in Javari achieve Javari's design goals. First, section 3.6.1 gives basic examples Javari's parameterized types and demonstrates the intuitive nature of Javari's type arguments. Section 3.6.2 show how Javari ensures that parametric types are not be used to violate the non-conversion design goal. In section 3.6.3 we show how Javari provides the flexibility to exclude the type arguments of a field from the abstract state of an object. Section 3.6.4 explains why allowing one to modify the mutability of a type variable results in violating the non-conversion design goal.

3.6.1 Type arguments

As with any local variable's type, type arguments to the type of a local variable may be mutable (by default) or read-only (through use of the `readonly` keyword). Below, four valid local variable, parameterized type declarations of `List` are shown. Note that the mutability of the parameterized type `List` does not affect the mutability of the type argument.

```
/*mutable*/ List</*mutable*/ Date> ld1; // add/remove and mutate elements
/*mutable*/ List<readonly Date> ld2; // add/remove
readonly List</*mutable*/ Date> ld3; // mutate elements
readonly List<readonly Date> ld4; // (neither)
```

As with any instance field's type, type arguments to the type of a field default to this-mutable, and this default can be overridden by declaring the type argument to be `readonly` or `mutable`:

```
class DateList {
    // 3 read-only lists whose elements have different mutability
    readonly List</*this-mutable*/ Date> lst1;
    readonly List<readonly Date> lst2;
    readonly List<mutable Date> lst3;
}
```

As in any other case, the mutability of a type with this-mutability is determined by the mutability of the object in which it appears (not the mutability of the parameterized class in which it might be a type argument⁵). In the case of `DateList` above, the mutability of `lst1`'s elements is determined by the mutability of the reference to `DateList`, not by the mutability of `lst1` itself. The following example illustrates this behavior.

⁵There is no need for a modifier that specifies that the type parameter's mutability should be inherited from the mutability of the parameterized class. The declaration of a reference to a parameterized class specifies the both parameterized class's mutability, and the mutability for the type argument. For example, a `List` where the mutability of the type parameter matches the mutability of the `List`'s `this` type can be declared as: `List<Date>` OR AS `readonly List<readonly Date>`.

```

/*mutable*/ DateList mutDateList;
readonly    DateList roDateList;

// The reference through which lst is accessed determines
// the mutability of the elements.

/*mutable*/ Date d;
d = mutDateList.lst1.get(0); // OK: elements are mutable
d = roDateList.lst1.get(0); // error: elements are read as readonly

```

3.6.2 ? readonly

This section discusses how we prevent parametric types from being used to convert read-only references into mutable references. Similar to the case of a top-level type (section 3.5.4), a this-mutable type argument reached through a read-only reference has different rvalue and lvalue types. Such a type argument’s rvalue (how it is read) must be read-only to provide the transitive immutability provision. However, the type argument’s lvalue (how it is written to) must be mutable. If the lvalue was read-only a type loophole similar to the one shown earlier in section 3.5.4 would exist. For an example of the different reading and writing behaviors of a this-mutable type argument, see lines 16 through 20 of figure 3-3.

A type that is written as mutable and read as read-only can be represented using wildcards that are bounded from above (*extends*) and below (*super*). For example, the type of `roBar.c` (figure 3-3) can be written as:

```
readonly Cell<? extends readonly Date super mutable Date>
```

The upper bound on the wildcard is `readonly Date` while the lower bound is `mutable Date`. Note that the bounds on the wildcard only differs in terms of mutability; Javari does not need arbitrary two-sided wildcards.

Since Java does not allow a wildcard to have both an upper bound and a lower bound, we use the `? readonly` syntax to represent two-sided wildcards that differ (only) in terms of mutability.⁶ We will also use `? readonly` types as meta-syntax to

⁶? `readonly T` can be thought of as the bounded existential type, $\exists X \text{ extends } \text{readonly } T \text{ super}$

```

1  class Bar {
2      assignable Cell</*this-mutable*/ Date> c;
3  }
4
5  class Cell<T extends readonly Object> {
6      assignable T val;
7  }
8
9  // roBar.c's rvalue type is readonly Cell<? readonly Date>
10 // roBar.c's lvalue type is mutable Cell<mutable Date>
11 readonly Bar roBar;
12
13 readonly    Date rd;
14 /*mutable*/ Date md;
15
16 rd = roBar.c.val; // OK: roBar.c.val is read as read-only
17 md = roBar.c.val; // error: roBar.c.val is read as read-only
18
19 roBar.c.val = rd; // error: elems are written to as mutable
20 roBar.c.val = md; // OK: elems are written to as mutable
21
22
23 // cell.val's rvalue type is readonly Date
24 // cell.val's lvalue type is mutable Date
25 readonly Cell<? readonly Date> cell = roBar.c;
26
27 rd = cell.val; // OK: elems are read as readonly
28 md = cell.val; // error: elems are read as readonly
29
30 cell.val = rd; // error: elems are written to as mutable
31 cell.val = md; // OK: elems are written to as mutable
32
33
34 mutable Cell<mutable Date> newCell;
35
36 // roBar.c lvalue type is mutable Cell<mutable Date>
37 roBar.c = newCell; // OK
38 roBar.c = cell;    // error

```

Figure 3-3: Demonstration of a this-mutable field reached through a readonly reference. `Bar.c` and `Cell.val` are assignable so that the fields' lvalue types can be demonstrated.

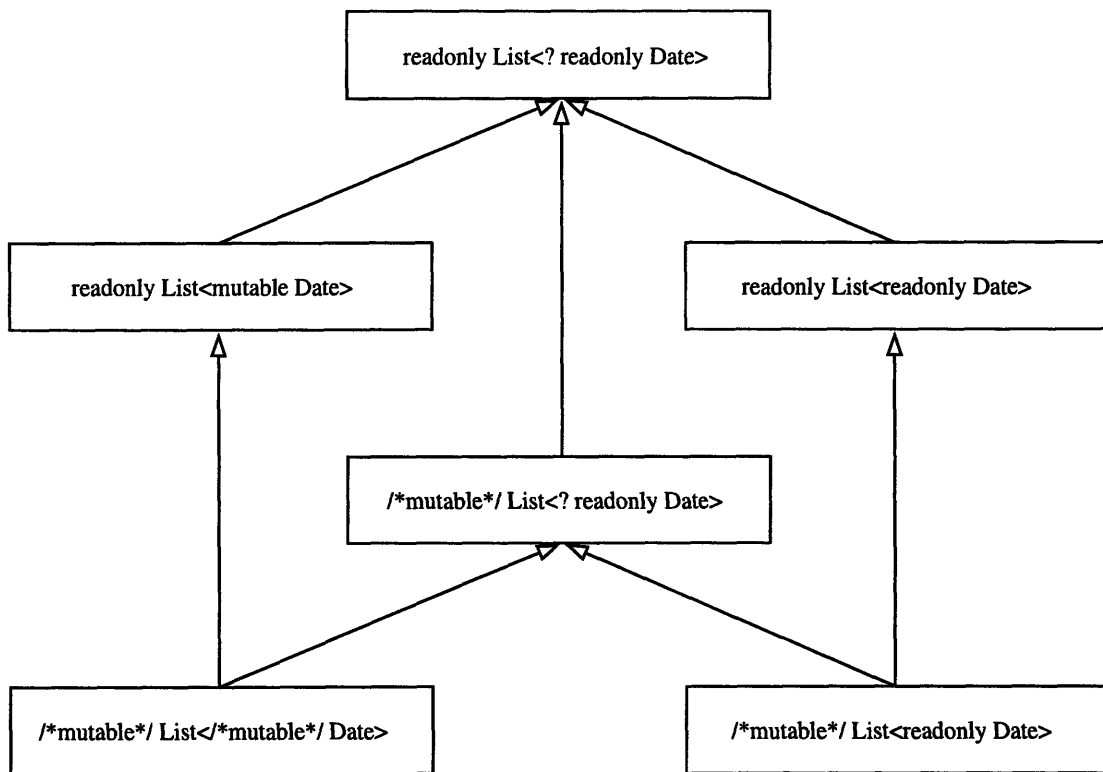

Figure 3-4: The Javari type hierarchy for Lists of Dates. Arrows connect subtypes to supertypes.

represent top-level types that are read-only when read and mutable when written to. However, as with all Java wildcards, `? readonly` cannot appear as a *top-level* type in source code. For example, from figure 3-3, the type of `roBar.c` can be written as `? readonly List<? readonly Date>`.

Lines 23–31 of figure 3-3 give an example of a `? readonly` type argument. `roBar.c` is shown being used as an rvalue on lines 27–31 of the example and `roBar.c` is used as an lvalue on lines 36–38.

Following the normal typing rules for Java, `List<? readonly Date>` is a common supertype of `List<readonly Date>` and `List<mutable Date>`. Figure 3-4 shows a portion of the Javari type hierarchy for lists of Dates.

`? readonly` can also be used in the case of nested parametric types. For example,

`mutable T`. This interpretation is expanded on in the core calculus; see chapter 4.

```

class Baz {
    /*this-mutable*/ List< /*this-mutable*/ Set< /*this-mutable*/ Date>> f;
}

readonly Baz rb;
readonly List<? readonly Set<? readonly Date>> lst = rb.f;

```

Figure 3-5: An example of nested this-mutable types.

in figure 3-5, the type

```
readonly List<? readonly Set<? readonly Date>>
```

desugars to

```

readonly List<? extends readonly Set<? extends readonly Date
                                super /*mutable*/ Date>
                                super /*mutable*/ Set< /*mutable*/ Date>>>

```

From the desugaring, one can see that the list may only have completely mutable types, `/*mutable*/ Set< /*mutable*/ Date>>`, added as elements. However, the list's elements are read as completely immutable: `readonly Set<? extends readonly Date super /*mutable*/ Date>>`. The Set's elements are declared to have type `? extends readonly Date super /*mutable*/ Date` to prevent a `readonly Date` from being inserted into the set. A complete desugaring of `? readonly` into two-sided wildcards is given in figure 4-13.

3.6.3 mutable type arguments

This section discusses how Javari gives one the flexibility to exclude a type argument from a classes abstract state. A type argument to a field's (parametric) type may be declared mutable with the `mutable` keyword as shown below.

```

class MutDateList {
    readonly List<mutable Date> lst; // read-only list of mutable items
}

```

In this case, the mutability of the reference to the `MutDateList` object and the mutability of `lst` have no effect on the mutability of the elements of `lst` because they are explicitly declared mutable. The case that the elements of `lst` are declared `readonly` is symmetric. The following example illustrates this behavior.

```
class DateList {
    readonly List<mutable Date> lstOfMut; // read-only list of mutable items
    readonly List<readonly Date> lstOfRo; // read-only list of readonly items
}

/*mutable*/ Date d;

/*mutable*/ DateList mutDateList;
readonly DateList roDateList;

// The mutability of the elements of lstOfMut is mutable regardless of
// whether the field is reached through a read-only or mutable reference.
d = mutDateList.lstOfMut.get(0); // OK
d = roDateList.lstOfMut.get(0); // OK

// The mutability of the elements of lstOfRo is read-only regardless of
// whether the field is reached through a read-only or mutable reference.
d = mutDateList.lstOfRo.get(0); // error
d = roDateList.lstOfRo.get(0); // error
```

3.6.4 Mutability modifiers on type variables

It may be tempting for some programmers to modify type variables with mutability annotations. For example, one may wish to write `mutable X`, where `X` is a type variable. Javari does not allow such types because (1) it is inconsistent with Java's notation of type variables and (2) such types can result in read-only references being converted into mutable references.

In Java, a client of a generic class controls the type that a type variable is instantiated with. However, the generic class's author can place bounds on what types a type variable may be instantiated with. To maintain an intuitive integration with Java, Javari exactly follows these principles. Since the client of a generic class controls the type that a type variable is instantiated with, the author of the generic class should not be allowed to change that type by modifying it with mutability modifiers. The

author of the generic class can still place bounds on the mutability of a type variable, however. For example, in the class declaration below, the author of the class allows `X` to range over all `Dates` while `Y` can only range over mutable `Dates`.

```
class Foo<X extends readonly Date, Y extends mutable Date> { ... }
```

Additionally, allowing type variables to be modified with `mutable` allows one to convert read-only references to mutable references. For the demonstration of this loophole, assume that one could write `mutable X`, where `X` is a type variable. If `X` was instantiated with a read-only type, an illegal downcast from a read-only type to a mutable type would occur. The type loophole is demonstrated below:

```
class Convert<X extends readonly Object> {  
    X f;  
  
    /*mutable*/ Object convertF() {  
        mutable T val = f;  
        return val;  
    }  
}
```

3.7 Arrays

As with generic container classes, a programmer may independently specify the mutability of each level of an array. As with any other local variable's type, each level of an array is mutable by default and may be declared read-only with the `readonly` keyword. As with any other field's type, each level may be declared mutable with the `mutable` keyword, read-only with the `readonly` keyword, or this-mutable by default. Parentheses may be used to specify to which level of an array a keyword is to be applied. Below, four valid array local variable declarations are shown.

```
                Date [] ad1; // add/remove, mutate  
    (readonly Date)[] ad2; // add/remove  
readonly        Date [] ad3; // mutate  
readonly (readonly Date)[] ad4; // neither
```

The above syntax can be applied to arrays of any dimensionality. For example, the type `(readonly Date[])[]` is a two-dimensional array with a read-only inner-array and that is otherwise mutable.

Java's arrays are covariant. To maintain type safety, the JVM performs a check when a object is stored to an array. To avoid a run-time representation of immutability, Javari does not allow covariance across the mutability of array element types.

```
(/*mutable*/ Date)[] ad1;
(readonly Date)[] ad2;

ad2 = ad1; // error: arrays are not covariant over mutability
```

As in the case with parametric container classes, arrays may use the `? readonly` syntax. For example,

```
class Foo {
    /*this-mutable*/ (/*this-mutable*/ Date)[] dates;
}

readonly Foo rf;
readonly (? readonly Date)[] x = rf.dates;
```

3.8 Summary

Javari enables a programmer to independently declare the assignability and mutability of a reference. Figure 3-6 summarizes the assignability and mutability keywords of Javari:

`final` declares a reference to be unassignable.

`assignable` declares a reference always to be assignable even if accessed through a read-only reference. Redundant for references other than instance fields.

`readonly` declares a reference to be read-only. Redundant for immutable types.

`mutable` declares a reference always to be mutable even if accessed through a read-only reference. Redundant for references other than instance fields. Cannot be applied to type parameters (see section 3.6).

Construct	Assignability			Mutability		
	assignable	unassign- able	this- assign.	mutable	read-only	this- mutable
Instance fields	assignable	final	(default)	mutable	readonly	(default)
Static fields	(default)	final	N/A	(default)	readonly	N/A
Local variables	(default)	final	N/A	(default)	readonly	N/A
Formal param.s	(default)	final	N/A	(default)	readonly	N/A
Return values	N/A	N/A	N/A	(default)	readonly	N/A
this	N/A	(default)	N/A	(default)	readonly	N/A

Figure 3-6: Javari’s keywords. “N/A” denotes assignabilities or mutabilities that are not valid for a given construct. “(default)” denotes that a given assignability or mutability is the default for that construct; no keyword is required, and redundant use of keywords is prohibited (a compile-time error), in order to reduce confusion. This-assignable and this-mutable can only be applied to instance fields because other references do not have a notion of **this** to inherit from. The mutability of **this** is declared after the parameter list.

? **readonly** declares a type argument to have a read-only upper bound and a mutable lower bound.

Figure 3-7 briefly gives the semantics of the keywords. Appendix A gives examples of each of the 9 combinations of assignability and mutability.

Javari is backward compatible with Java: any Java program that uses none of Javari’s keywords is a valid Javari program, with the same semantics. Javari’s defaults have been chosen to ensure this property.

Resolved assignability of a.b

Declared assignability of b	Resolved mutability of a	
	mutable	read-only
assignable	assignable	assignable
unassignable	unassignable	unassignable
this-assignable	assignable	unassignable

Resolved mutability of a.b

Declared mutability of b	Resolved mutability of a	
	mutable	read-only
mutable	mutable	mutable
read-only	read-only	read-only
this-mutable	assignable	? readonly

Figure 3-7: Semantics of Javari's keywords: resolved type of the expression a.b, given the resolved type of a and the declared type of field b. Also see figure 4-12, which presents the same information in a different form.

Chapter 4

Type Rules

This chapter presents the key type rules for Javari in the context of a core calculus, Lightweight Javari, that captures the essential features of Javari. The core language allows one to examine the underlying structure of Javari’s type system without being overwhelmed with the complexity of the full language. Additionally, the core language can be used to prove properties about the language.

Lightweight Javari builds upon Wild FJ (WFJ) [47], a core calculus for Java including generic types. WFJ extends Featherweight Generic Java (FGJ) [22], with wildcard types. WFJ is a functional language: it has no notion of assignment. Therefore, Section 4.1 first introduces Lightweight Java (LJ), an extension of WFJ that builds on CLASSICJAVA [17] to support field assignment and the `final` keyword. Then, Section 4.2 extends LJ to Lightweight Javari (LJR), which adds support for reference immutability.

Before presenting our core languages, we explain, below, how WFJ models capture

```
/** Returns a shallow copy of lst */
static <T extends Object> List<T> copy(List<T> lst) { ... }

List<?> x;
copy(x);    // Disallowed without capture conversion.
```

Figure 4-1: Without capture conversion, the type-safe method invocation of `copy(x)` would be disallowed because, without conversion, `List<?>` is not a subtype of `List<T>` (as explained in figure 4-2).

```

    /** Adds val to lst. */
    static <T extends Object> void insert(List<T> lst, T val) {
        lst.add(val);
    }

    List<Date> lstOfDates;
    List<?>    lstOfUnknowns = lstOfDates; // OK
    insert(lstOfUnknowns, 'hi');          // error: Would be legal if List<?> was
                                          // a subtype of List<T>

```

Figure 4-2: A demonstration of why it would be unsound for `List<?>` to be a subtype of `List<T>` where `T` is any type variable. In the code above, allowing `lstOfUnknowns`, which has type `List<?>`, to be passed as a `List<T>` to method `insert` results a `String` being inserted into a list of dates, `lstOfDates`.

conversion and wildcard capture, two of the most complex aspects of Java's type system.

Java's capture conversion makes wildcards more useful by replacing top-level type argument wildcards with globally fresh type variables. To understand the utility of this technique, consider the method definition and invocation shown in figure 4-1. It appears that the method `copy` can not be used on list `x` because `x`'s type, `List<?>`, is not a subtype of `List<T>`. An explanation for why a list with a wildcard type card type argument, e.g. `List<?>`, is not subtype of a list with an invariant type argument, e.g. `List<T>` is given in figure 4-2. Using capture conversion, one can convert `x`'s type from `List<?>` to `List<X>` where `X` is a fresh type variable. Since `List<X>` is a subtype of `List<T>` (when `T` is inferred to be `X`), the invocation of `copy(x)` succeeds. Note that capture conversion does not allow the method invocation shown in figure 4-2 because `String` is not a subtype of the type variable created by capture converting `List<?>`.

While implementing capture conversion by creating globally fresh type variables is a realist strategy for a compiler, it conflicts with the compositionality of the type rules. Therefore, WFJ models capture conversion using existential types. An existential type, written as $\exists\Delta.K$, consists of (1) a type environment, Δ , which contains a mapping from the the fresh type variables to their bounds of, and (2) a type, K , which is free of any top-level wildcards, K . The typing of an expression (section 4.1.3) returns a existential type where the type environment contains any fresh type variables

that were created during capture conversion, and the top-level wildcard free type represents the type of the expression. Existential types only serve as meta-syntax and does not appear in the source language. WFJ's implementation of capture conversion is given in section 4.1.2.

A concept related but distinct from capture conversion is wildcard capture. In the example given in figure 4-1, we did not discuss how the method invocation inferred that `T`, the method's type parameter, should be instantiated with `X`, the type argument of `x`'s of capture-converted type. This process is called wildcard capture. Normally, in WFJ, a method invocation must supply a type argument for each of the method's type parameters. For example, in the method invocation shown below, the type variable, `T`, of `copy` is explicitly instantiated with the type `Integer`.

```
// Same method as from figure 4-1.
static <T extends Object> List<T> copy(List<T> lst) { ... }

List<Integer> integers = ... ;
List<Integer> myCopy = <Integer>copy(integers);
```

However, since the fresh type variables created by capture conversion can not be referred to by the source code of a program, it is impossible to supply a correct type argument. For example, below, it is impossible for the method invocation to supply the correct type argument.¹

```
List<?> lstOfUnknowns = ... ;
List<?> myCopy = </*Unknown fresh type variable*/>copy(lstOfUnknowns);
```

To solve this dilemma, a programmer is allowed to pass the special symbol `*` as the type argument to such a method invocation. `*` serves as a request for wildcard capture.

Wildcard capture allow capture converted types to serve as type arguments to methods by inferring the correct type arguments to a method invocation. The type inference is implemented by examining the types of actual arguments to a method to determine the type arguments of the method invocation. Since the types of the

¹Note that is it incorrect to use `?` as the type argument to `copy` because `?` is not a type.

method’s actual arguments have already been capture converted, wildcard capture is capable of inferring the fresh type variables that were created by capture conversion. WFJ’s implementation of wildcard capture is given in section 4.1.2.

4.1 Lightweight Java

Lightweight Java (LJ) extends WFJ to include field assignment, expressed via the “set” construct. Fields may be declared `final`; to make LJ’s syntax fully explicit, non-final fields must be declared `assignable`. LJ does not permit parameters to be reassigned: such an extension is straightforward and does not demonstrate any interesting aspects of the Javari type system. LJ omits casts because they are not important for demonstrating the assignability and mutability rules of Javari.

4.1.1 Syntax

The syntax of LJ is largely identical to that of WFJ, with the exception of the new `set` expression and the assignability modifiers, `final` and `assignable`. The syntax of LJ is shown in figure 4-3.

The metavariable C ranges over (unparameterized) class names; X , Y , and Z over type variables; m over method names; f over field names; and x over formal parameter names. Q ranges over class declarations; M over method declarations; and e over expressions. AF (assignability for fields) ranges over assignability modifiers.

S , T , U , and V range over types, which may be either a parameterized type, $C\langle\bar{A}\rangle$, or a type variable, X . A ranges over type arguments to parametric types, which may be either a type, T , or a wildcard, $? B$ or $? \text{readonly } T$. B ranges over type bounds and includes both an upper bound, B_{\triangleleft} , and a lower bound B_{\triangleright} . An upper (lower) bound is either an extends (super) cause, $\triangleleft T$ ($\triangleright T$), or is absent, \bullet . The notation \triangleleft stands for “extends” (LJ has no interfaces), and \triangleright stands for “super”. Parametric method invocations must be provided an explicit type argument, P , which is either a type, T , or a special marker, \star , that is resolved by wildcard capture. N ranges over class types, which are nonvariable types which do not have wildcards as a top-level type

Figure 4-3: Syntax of Lightweight Java (LJ). Changes from WFJ are shown in boxes.

arguments. K ranges over the union on of class types, N , and type variables, X .

\bar{x} serves as shorthand for the (possibly empty) sequence $x_1 \dots x_n$ with the appropriate syntax separating the elements. In cases such as $\bar{T} \bar{f}$, the items are grouped in pairs: $T_1 f_1 \dots T_n f_n$. The empty sequence is written as \bullet , and sequences are concatenated with a comma.

$[a/b]c$ denotes the result of replacing b by a in c .

`this` is considered a special variable implicitly bound to the receiver of a method invocation.

A class is considered to have all the fields that are declared in its body and its superclasses' bodies. The field names of a class must be distinct from the field names of its superclasses—there is no field shadowing. Additionally, there is no method overloading.

WFJ does not model constructors because they do not demonstrate any interesting properties of the type system.

LJ introduces the `set` construct to FGJ. “`set $e_0.f = e_v$ then e_b` ” reassigns the field f of the object to which e_0 evaluates. The field's new value is the value to which e_v evaluates. The `set` expression then evaluates the body expression e_b . The `set` expression's value is the value to which e_b evaluates. The `set` syntax was chosen to avoid the complications of allowing multiple expressions within a method. Method arguments and assignment expressions are evaluated left-to-right (see figure 4-10).

4.1.2 Auxiliary functions

Bound calculation

The subtyping rules use the following auxiliary functions to calculate the bounds of type variables. $bound_{\Delta}^1(X)$ calculates the upper bound of X in type environment Δ . If the upper bound is absent, `Object` is returned. $lbound_{\Delta}^1(X)$, returns the lower bound of X in Δ . $lbound$ is undefined if the lower bound is absent. $bound_{\Delta}(T)$ when T is a type variable, X , recursively applies $bound^1$ until a nonvariable upper bound of X is found. In the case that T is the nonvariable type $C\langle\bar{A}\rangle$, $bound$ returns that type, $C\langle\bar{A}\rangle$.

*bound*¹

$$\frac{\Delta(X) = \bullet B_{\triangleright}}{\mathit{bound}_{\Delta}^1(X) = \mathit{Object}} \qquad \frac{\Delta(X) = \triangleleft T B_{\triangleright}}{\mathit{bound}_{\Delta}(X) = T}$$

lbound

$$\frac{\Delta(X) = B_{\triangleleft} \triangleright T}{\mathit{lbound}_{\Delta}^1(X) = T}$$

bound

$$\frac{\mathit{bound}_{\Delta}^1(X) = C\langle\bar{T}\rangle}{\mathit{bound}_{\Delta}(X) = C\langle\bar{T}\rangle} \qquad \frac{\mathit{bound}_{\Delta}^1(X) = Y \quad \mathit{bound}_{\Delta}(Y) = C\langle\bar{T}\rangle}{\mathit{bound}_{\Delta}(X) = C\langle\bar{T}\rangle}$$

$$\mathit{bound}_{\Delta}(C\langle\bar{T}\rangle) = C\langle\bar{T}\rangle \qquad \frac{\mathit{bound}_{\Delta\Delta'}(K') = C\langle\bar{T}\rangle \quad \mathit{snap}(C\langle\bar{T}\rangle) = \exists\Delta''.N}{\mathit{bound}_{\Delta}(\exists\Delta'.K') = \exists\Delta'\Delta''.N}$$

Figure 4-4: Bound calculation functions. These functions are unchanged from those of WFJ.

See figure 4-4 for the definitions of the bound calculation methods. For convenience, *bound* is also defined on existential types, **E**; see below.

Existential type creation: Snap

The auxiliary functions of figure 4-5 are used to create existential types. Existential types are used to model the capture conversion of wildcards (see the introduction of this chapter). Through the use of existential types the subtyping rules are simplified and do not need to directly deal with wildcards. *snap*(*T*) creates an existential type, $\exists\Delta.K$, from a type, *T*. *snap* replaces each top-level wildcard, $? B$, with a fresh type variable, which is added to the type environment of the existential type. For example, $\mathit{snap}(C\langle? B_{\triangleleft} B_{\triangleright}\rangle) = \exists X \in B_{\triangleleft} B_{\triangleright}.C\langle X \rangle$ where *X* is fresh. *snap* uses *fix*(\bar{A}, \bar{B}) to produce the new type variables, including bounds, for each wildcard type. *merge* is used by *snap* to combine the wildcard's bounds with the declared bound of the relevant type parameter.

Snap:

$$\text{snap}(X) = \exists \emptyset.X$$

$$\frac{\text{class } C \langle \bar{Y} \bar{B}_0 \rangle \triangleleft N \{ \dots \} \quad \text{fix}(\bar{A}, \bar{B}_0) = (\bar{T}, \bar{X}, \bar{B}) \quad \Delta = \bar{X} \in [\bar{T}/\bar{Y}] \bar{B}}{\text{snap}(C \langle \bar{A} \rangle) = \exists \Delta.C \langle \bar{T} \rangle}$$

Fix:

$$\frac{\text{fix}(\bar{A}, \bar{B}_0) = (\bar{T}, \bar{X}, \bar{B})}{\text{fix}(T :: \bar{A}, B_0 :: \bar{B}_0) = (T :: \bar{T}, \bar{X}, \bar{B})}$$

$$\frac{\text{fix}(\bar{A}, \bar{B}_0) = (\bar{T}, \bar{X}, \bar{B}) \quad X \text{ fresh}}{\text{fix}(? B :: \bar{A}, B_0 :: \bar{B}_0) = (X :: \bar{T}, X :: \bar{X}, \text{merge}(B, B_0) :: \bar{B})}$$

$$\text{fix}(\bullet, \bullet) = (\bullet, \bullet, \bullet)$$

Merge:

$$\text{merge}(\bullet \bullet, B_{\triangleleft} B_{\triangleright}) = B_{\triangleleft} B_{\triangleright} \quad \text{merge}(\triangleleft T \bullet, B_{\triangleleft} B_{\triangleright}) = \triangleleft T B_{\triangleright}$$

$$\text{merge}(\bullet \triangleright S, B_{\triangleleft} B_{\triangleright}) = B_{\triangleleft} \triangleright S \quad \text{merge}(\triangleleft T \triangleright S, B_{\triangleleft} B_{\triangleright}) = \triangleleft T \triangleright S$$

Figure 4-5: Auxiliary functions for existential type creation. These functions are unchanged from those of WFJ.

Capture:

$$\begin{array}{c} \text{capture}_\Delta(U, X, \bar{T}, \bar{K}) = U \\ \hline \text{T}_i = C\langle\bar{A}\rangle \quad A_j = X \quad \Delta \vdash K_i \langle C\langle\bar{A}'\rangle \rangle \quad A'_j = V \\ \text{capture}_\Delta(\star, X, \bar{T}, \bar{K}) = V \end{array}$$

Figure 4-6: Wildcard capture auxiliary function. These functions are unchanged from those of WFJ.

Wildcard capture

Wildcard capture is used to allow capture converted types to be passed as type arguments to method invocations (see the introduction of this chapter). Wildcard capture enables this action by inferring the correct type arguments of a method invocation when those types cannot be expressed in the source language. The function $\text{capture}_\Delta(P, X, \bar{T}, \bar{K})$ of figure 4-6 is used to perform wildcard capture on a method invocation where P is the actual type parameter to a method. In the case that P is a type, T , then wildcard capture is not needed and P is returned unchanged. However, if P is a type capture marker, \star , then wildcard capture is performed. X is the type parameter from the signature of the method being invoked. \bar{T} is the parameter types from the signature of the method. \bar{K} is the types of the actual arguments to the method. The definition of capture is given in figure 4-6.

Class member lookup

The typing and reduction rules use the following auxiliary functions. The function $\text{fields}(C\langle\bar{T}\rangle)$ returns a sequence of triplets, $\bar{A}\bar{F} \bar{T} \bar{f}$, with the assignability modifier, type, and name of each of the fields of the nonvariable type $C\langle\bar{T}\rangle$.

The function $\text{mtype}(m, C\langle\bar{T}\rangle)$ (figure 4-7) returns the type of method m of the nonvariable type $C\langle\bar{T}\rangle$. The type of a method is written as $\langle\bar{X} \bar{B}\rangle\bar{U} \rightarrow U$ where \bar{X} , with the bounds \bar{B} , are the type parameters of the method, \bar{U} are the types of the method's parameters, and U is the return type of the method. Because there is no overloading in LJ, mtype does not need to know the types of the arguments to m .

Method type lookup:

$$\frac{\text{class } C \langle \bar{X} \bar{N} \rangle \triangleleft B \{ \overline{AF} \bar{T} \bar{f}; \bar{M} \} \quad \langle \bar{Y} \bar{B}' \rangle U m(\bar{U} \bar{x}) ML \{ \text{return } e; \} \in \bar{M}}{mtype(m, C \langle \bar{T} \rangle) = [\bar{T}/\bar{X}] \langle \bar{Y} \bar{B}' \rangle \bar{U} \rightarrow U}$$

$$\frac{\text{class } C \langle \bar{X} \bar{N} \rangle \triangleleft B \{ \overline{AF} \bar{T} \bar{f}; \bar{M} \} \quad m \notin \bar{M}}{mtype(m, C \langle \bar{T} \rangle) = mtype(m, [\bar{T}/\bar{X}]N)}$$

Valid method overriding:

$$\frac{mtype(m, N) = \langle \bar{Y}' \bar{B}' \rangle \bar{T}' ML' \rightarrow T' \text{ implies} \\ \bar{B} = [\bar{Y}/\bar{Y}'] \bar{B}' \text{ and } \bar{T} = [\bar{Y}/\bar{Y}'] \bar{T}' \text{ and } \bar{Y} \in \bar{B} \vdash T \triangleleft [\bar{Y}/\bar{Y}'] T'}{override(m, N, \langle \bar{Y} \rangle \bar{B} \bar{T} ML \rightarrow T)}$$

Figure 4-7: Lightweight Java (LJ) auxiliary functions. These functions are unchanged from those of WFJ.

The function $mbody(\langle \bar{V} \rangle m, C \langle \bar{T} \rangle)$ returns the pair $\bar{x}.e$ where \bar{x} are the formal parameters to m in $C \langle \bar{T} \rangle$ and e is the body of the method.

Finally, $override(m, N, \langle \bar{Y} \rangle \bar{B} \bar{T} \rightarrow T)$ (figure 4-7) declares that method m with type $\langle \bar{Y} \rangle \bar{B} \bar{T} \rightarrow T$ correctly overrides any methods with the same name possessed by the nonvariable type N .

Details on these auxiliary functions can be found in [47].

4.1.3 Static semantics

Subtyping

WFJ subtyping and typing rules operate over existential types, $E ::= \exists \Delta.K$. Δ is the type environment, a mapping from type variables, X , to bounds, B . Although used in the static semantics, existential types cannot appear in an WFJ program's source. The use of existential types is needed for modeling wildcard capture conversion.

The (reflexive, transitive) subtyping relationship is denoted by “ \triangleleft ”. The subtyping rules of LJ are unchanged from WFJ and are shown in figure 4-8. The subtyping rules operate on existential types, E ; however, WS-SYNTACTIC is provided as a convenient short hand for applying the subtyping rules to types, T .

Subtyping:

$$\frac{\Delta \vdash E < E'' \quad \Delta \vdash E'' < E'}{\Delta \vdash E < E'} \text{ (WS-TRANS)}$$

$$\Delta \vdash \exists \Delta'. X < \exists \Delta'. \text{bound}_{\Delta\Delta'}^1(X) \text{ (WS-VAR)}$$

$$\Delta \vdash \exists \Delta'. \text{lbound}_{\Delta\Delta'}^1(X) < \exists \Delta'. X \text{ (S-LVAR)}$$

$$\frac{\text{class } C < \bar{X} \bar{B} > \triangleleft N \{ \dots \}}{\Delta \vdash \exists \Delta'. C < \bar{T} > < \exists \Delta'. [\bar{T}/\bar{X}]N} \text{ (WS-SUBCLASS)}$$

$$\frac{\Delta\Delta' \vdash \bar{U} \in [\bar{U}/\bar{X}]\bar{B}}{\Delta \vdash \exists \Delta'. [\bar{U}/\bar{X}]K < \exists \bar{X} \in \bar{B}. K} \text{ (WS-ENV)}$$

$$\frac{\Delta \vdash \text{snap}(S) < \text{snap}(T)}{\Delta \vdash S < T} \text{ (WS-SYNTACTIC)}$$

Bound Containment:

$$\Delta \vdash T \in \bullet \bullet \text{ (WB-NONE)}$$

$$\frac{\Delta \vdash S < T}{\Delta \vdash T \in \bullet \triangleright S} \text{ (WB-LOWER)}$$

$$\frac{\Delta \vdash T < S \quad \Delta \vdash T \in \bullet B_{\triangleright}}{\Delta \vdash T \in \triangleleft S B_{\triangleright}} \text{ (WB-UPPER)}$$

Figure 4-8: LJ's subtyping rules. The rules are the same as WFJ's.

Typing judgements

LJ's typing rules calculate existential types for expressions. Γ is defined as the environment, a mapping from variables to types, T . The typing rules are shown in figure 4-9.

The judgment $\Delta \vdash A \text{ ok}$ declares that the type or wildcard A is well-formed under context Δ . A type is well-formed if its type parameters respect the bounds placed on them in the class's declaration. A wildcard is well-formed if its bounds are well formed. The judgment $M \text{ OK IN } C$ declares that method declaration M is sound in the context of class C . The judgment $C \text{ OK}$ declares the class declaration of C to be sound. These judgments are unchanged from WFJ and can be found in [47].

4.1.4 Operational semantics

To support the assignment of fields, we introduce a store, \mathcal{S} , to WFJ's reduction rules. As in CLASSICJAVA [17], the store is a mapping from an object to a pair containing the class type, N , of the object and a field record. A field record, \mathcal{F} , is a mapping from field names to values.

The reduction rules are shown in figure 4-10. Each reduction rule is a relationship, $\langle e, \mathcal{S} \rangle \longrightarrow \langle e', \mathcal{S}' \rangle$, where e with store \mathcal{S} reduces to e' with store \mathcal{S}' in one step.

The addition of the assignment statement requires new reduction and congruence rules to be added to those of WFJ. The reduction rule for `set` binds the field to a new value, then evaluates the “then” part of the expression.

4.1.5 Properties

First we state by a type soundness theorem for LJ. If a term is well typed and reduces to a normal form (an expression that cannot reduce any further and, therefore, is an object, v) then it is a value of a subtype of the original term's type. Put differently, an evaluation cannot go wrong, which in our model means getting stuck.

Theorem 1 (LJ Type Soundness). *If $\emptyset; \emptyset \vdash e : E$ and $\langle e, \mathcal{S} \rangle \rightarrow^* \langle e', \mathcal{S}' \rangle$ with e' a normal form, then e' is a value, v , such that $\mathcal{S}'(v) = \langle N, \mathcal{F} \rangle$ and $\emptyset \vdash \exists \emptyset.N \triangleleft E$.*

Expression typing:

$$\Delta; \Gamma \vdash x : \text{snap}(\Gamma(x)) \quad (\text{T-VAR})$$

$$\frac{\Delta; \Gamma \vdash e_0 : E_0 \quad \text{bound}_{\Delta}(E_0) = \exists \Delta_0.N_0 \quad \text{fields}(N_0) = \boxed{\overline{\text{AF}}} \bar{T} \bar{f} \quad \text{snap}(T_i) = \exists \Delta'.K}{\Delta; \Gamma \vdash e_0.f_i : \exists \Delta_0 \Delta'.K} \quad (\text{T-GET})$$

$$\frac{\Delta \vdash \bar{P} \text{ ok} \quad \Delta; \Gamma \vdash e_0 : E_0 \quad \text{bound}_{\Delta}(E_0) = \exists \Delta_0.N_0 \quad \Delta; \Gamma \vdash \bar{e} : \exists \bar{\Delta}.\bar{K} \quad \Delta_1 = \Delta \Delta_0 \bar{\Delta} \quad \text{mtype}(m, N_0) = \langle \bar{Y} \bar{B} \rangle \bar{U} \rightarrow U \quad \bar{V} = \text{capture}_{\Delta_1}(\bar{P}, \bar{Y}, \bar{U}, \bar{K}) \quad \Delta_1 \vdash \bar{V} \in [\bar{V}/\bar{Y}]\bar{B} \quad \Delta_1 \vdash \bar{K} \prec [\bar{V}/\bar{Y}]\bar{U} \quad \text{snap}([\bar{V}/\bar{Y}]U) = \exists \Delta'.K}{\Delta; \Gamma \vdash e_0.\langle \bar{P} \rangle m(\bar{e}) : \exists \Delta_0 \bar{\Delta} \Delta'.K} \quad (\text{T-INVK})$$

$$\frac{\Delta \vdash N \text{ ok} \quad \text{fields}(N) = \boxed{\overline{\text{AF}}} \bar{T} \bar{f} \quad \Delta; \Gamma \vdash \bar{e} : \bar{E} \quad \Delta \vdash \bar{E} \prec \text{snap}(\bar{T})}{\Delta; \Gamma \vdash \text{new } N(\bar{e}) : \exists \emptyset.N} \quad (\text{T-NEW})$$

$\frac{\Delta; \Gamma \vdash e_0 : E_0 \quad \text{bound}_{\Delta}(E_0) = \exists \Delta_0.N_0 \quad \text{fields}(N_0) = \boxed{\overline{\text{AF}}} \bar{T} \bar{f} \quad \boxed{\text{AF}_i = \text{assignable}} \quad \text{snap}(T_i) = \exists \Delta_i.K \quad \Delta; \Gamma \vdash e_v : E \quad \Delta \Delta_0 \vdash E \prec \exists \Delta_i.K \quad e_b : E'}{\Delta; \Gamma \vdash \text{set } e_0.f_i = e_v \text{ then } e_b : E'} \quad (\text{T-SET})$
--

Method typing:

$$\frac{\Delta \vdash \bar{B}', T, \bar{T} \text{ ok} \quad \Delta = \bar{Y} \in \bar{B}', \bar{X} \in \bar{B} \quad \Delta; \bar{x} : \bar{T}, \text{this} : C\langle \bar{X} \rangle \vdash e_0 : E \quad \Delta \vdash E \prec \text{snap}(T) \quad \text{class } C\langle \bar{X} \bar{B} \rangle \triangleleft N \{ \dots \} \quad \text{override}(m, N, \langle \bar{Y} \bar{B}' \rangle \bar{T} \rightarrow T)}{\langle \bar{Y} \bar{B}' \rangle T m(\bar{T} \bar{x}) \{ \text{return } e_0; \} \text{ OK IN } C\langle \bar{X} \bar{B} \rangle} \quad (\text{T-METHOD})$$

Class typing:

$$\frac{\bar{X} \in \bar{B} \vdash \bar{B}, N, \bar{T} \text{ ok} \quad \bar{M} \text{ OK IN } C\langle \bar{X} \bar{B} \rangle}{\text{class } C\langle \bar{X} \bar{B} \rangle \triangleleft N \{ \boxed{\overline{\text{AF}}} \bar{T} \bar{f}; \bar{M} \} \text{ OK}} \quad (\text{T-CLASS})$$

Figure 4-9: Lightweight Java (LJ) typing rules. Changes from WFJ are indicated by boxes.

$v ::=$ an object

Computation:

$$\frac{\mathcal{S}(v_1) = \langle \mathbf{N}, \mathcal{F} \rangle \quad \mathcal{F}(f_i) = v_2}{\langle v_1.f_i, \mathcal{S} \rangle \longrightarrow \langle v_2, \mathcal{S} \rangle} \text{ (R-FIELD)}$$

$$\frac{\mathcal{S}(v) = \langle \mathbf{N}, \mathcal{F} \rangle \quad \mathcal{S}(\bar{v}) = \langle \bar{\mathbf{N}}, \bar{\mathcal{F}} \rangle \quad mtype(m, \mathbf{N}) = \langle \bar{\mathbf{Y}} \bar{\mathbf{B}} \bar{\mathbf{U}} \rightarrow \mathbf{U} \\ \bar{\mathbf{V}} = capture_{\emptyset}(\bar{\mathbf{P}}, \bar{\mathbf{Y}}, \bar{\mathbf{U}}, \bar{\mathbf{N}}) \quad mbody(\langle \bar{\mathbf{V}} \rangle m, \mathbf{N}) = \bar{\mathbf{x}}.e_0}{\langle v.\langle \bar{\mathbf{P}} \rangle m(\bar{v}), \mathcal{S} \rangle \longrightarrow \langle [\bar{v}/\bar{\mathbf{x}}, v/\text{this}]e_0, \mathcal{S} \rangle} \text{ (R-INVK)}$$

$$\frac{v \notin \text{dom}(\mathcal{S}) \quad \mathcal{F} = [\bar{\mathbf{f}} \mapsto \bar{v}]}{\langle \text{new } \mathbf{N}(\bar{v}), \mathcal{S} \rangle \longrightarrow \langle v, \mathcal{S}[v \mapsto \langle \mathbf{N}, \mathcal{F} \rangle] \rangle} \text{ (R-NEW)}$$

$$\frac{\mathcal{S}(v_1) = \langle \mathbf{N}, \mathcal{F} \rangle}{\langle \text{set } v_1.f_i = v_2 \text{ then } e_b, \mathcal{S} \rangle \longrightarrow \langle e_b, \mathcal{S}[v_1 \mapsto \langle \mathbf{N}, \mathcal{F}[f_i \mapsto v_2] \rangle] \rangle} \text{ (R-SET)}$$

Congruence:

$$\frac{\langle e_0, \mathcal{S} \rangle \longrightarrow \langle e'_0, \mathcal{S} \rangle}{\langle e_0.f, \mathcal{S} \rangle \longrightarrow \langle e'_0.f, \mathcal{S} \rangle} \text{ (RC-FIELD)}$$

$$\frac{\langle e_0, \mathcal{S} \rangle \longrightarrow \langle e'_0, \mathcal{S} \rangle}{\langle e_0.\langle \bar{\mathbf{P}} \rangle m(\bar{e}), \mathcal{S} \rangle \longrightarrow \langle e'_0.\langle \bar{\mathbf{P}} \rangle m(\bar{e}), \mathcal{S} \rangle} \text{ (RC-INVK-RECV)}$$

$$\frac{\langle e_i, \mathcal{S} \rangle \longrightarrow \langle e'_i, \mathcal{S} \rangle}{\langle v.\langle \bar{\mathbf{P}} \rangle m(\bar{v}, e_i, \bar{e}), \mathcal{S} \rangle \longrightarrow \langle v.\langle \bar{\mathbf{P}} \rangle m(\bar{v}, e'_i, \bar{e}), \mathcal{S} \rangle} \text{ (RC-INVK-ARG)}$$

$$\frac{\langle e_i, \mathcal{S} \rangle \longrightarrow \langle e'_i, \mathcal{S} \rangle}{\langle \text{new } \mathbf{N}(\bar{v}, e_i, \bar{e}), \mathcal{S} \rangle \longrightarrow \langle \text{new } \mathbf{N}(\bar{v}, e'_i, \bar{e}), \mathcal{S} \rangle} \text{ (RC-NEW-ARG)}$$

$$\frac{\langle e_0, \mathcal{S} \rangle \longrightarrow \langle e'_0, \mathcal{S} \rangle}{\langle \text{set } e_0.f = e_v \text{ then } e_b, \mathcal{S} \rangle \longrightarrow \langle \text{set } e'_0.f = e_v \text{ then } e_b, \mathcal{S} \rangle} \text{ (RC-SET-LHS)}$$

$$\frac{\langle e_v, \mathcal{S} \rangle \longrightarrow \langle e'_v, \mathcal{S} \rangle}{\langle \text{set } v.f = e_v \text{ then } e_b, \mathcal{S} \rangle \longrightarrow \langle \text{set } v.f = e'_v \text{ then } e_b, \mathcal{S} \rangle} \text{ (RC-SET-RHS)}$$

Figure 4-10: Lightweight Java (LJ) reduction rules. Unlike WFJ, LJ's reduction rules contain a store.

The soundness of LJ can be proved using the standard technique of subject reduction and progress theorems. A sketch of the proof is given below, a full proof is not currently available for WFJ or LJ.

The reduction theorem states that each step taken in the evaluation preserves the type correctness of the expression-store pair. During each step of the reduction, the environment and type environment must be consistent, \vdash_σ , with the store:

$$\begin{aligned}
& \Delta; \Gamma \vdash_\sigma \mathcal{S} \iff \\
& \mathcal{S}(v) = \langle \mathbf{N}, \mathcal{F} \rangle \Rightarrow \\
\Sigma_1 : & \quad \Delta \vdash \mathbf{N} <: \Gamma(v) \\
\Sigma_2 : & \quad \text{and } \text{dom}(\mathcal{F}) = \{f \mid \text{AF } \mathbf{T} \ f \in \text{fields}(\mathbf{N})\} \\
\Sigma_3 : & \quad \text{and } \text{rng}(\mathcal{F}) \subseteq \text{dom}(\mathcal{S}) \\
\Sigma_4 : & \quad \text{and } (\mathcal{F}(f) = v' \text{ and } \text{AF } \mathbf{T} \ f \in \text{fields}(\mathbf{N})) \\
& \quad \Rightarrow ((\mathcal{S}(v') = \langle \mathbf{N}', \mathcal{F}' \rangle) \Rightarrow \Delta \vdash \mathbf{N}' <: \mathbf{T}) \\
\Sigma_5 : & \quad \text{and } v \in \text{dom}(\Gamma) \Rightarrow v \in \text{dom}(\mathcal{S}) \\
\Sigma_6 : & \quad \text{and } \text{dom}(\mathcal{S}) \subseteq \text{dom}(\Gamma)
\end{aligned}$$

Theorem 2 (LJ Subject Reduction). *If $\Delta; \Gamma \vdash e : \mathbf{E}$, $\Delta; \Gamma \vdash_\sigma \mathcal{S}$, and $\langle e, \mathcal{S} \rangle \longrightarrow \langle e', \mathcal{S}' \rangle$, then there exists a Γ' and Δ' such that $\Delta'; \Gamma' \vdash e' : \mathbf{E}$ and $\Delta'; \Gamma' \vdash_\sigma \mathcal{S}'$.*

Proof. The proof can be done by induction on the derivation of $\langle e, \mathcal{S} \rangle \longrightarrow \langle e', \mathcal{S}' \rangle$ with a case analysis on the reduction rule used. For each case, we construct the new environment Γ' and a new type environment Δ' and show that (1) $\Delta'; \Gamma' \vdash e' : \mathbf{E}$ and (2) $\Delta'; \Gamma' \vdash_\sigma \mathcal{S}$. \square

The progress theorem states that a well-typed program can not get stuck. That is, if a expression is well-typed and not a value, there exists some progress rule that may be applied to the expression.

Theorem 3 (LJ Progress). *If $\Delta; \Gamma \vdash e : \mathbf{E}$ and $\Delta; \Gamma \vdash_\sigma \mathcal{S}$, then either e is a value or there exists an $\langle e', \mathcal{S}' \rangle$ such that $\langle e, \mathcal{S} \rangle \longrightarrow \langle e', \mathcal{S}' \rangle$.*

Proof. The proof can be done by an analysis of the possible cases for the current redex in e (in the case that e is not a value). \square

The LJ Type Soundness theorem is immediate from the LJ Subject Reduction and LJ Progress theorems.

In addition to type soundness we would like a guarantee that LJ obeys its assignability rules. We state this property as the LJ Assignment Soundness theorem.

Theorem 4 (LJ Assignment Soundness). *Outside of an object's constructor, assignments may only be made to assignable fields.*

Proof. Immediate from T-Set. □

4.2 Lightweight Javari

We add Javari's concept of reference immutability to LJ to create the language Lightweight Javari (LJR). In LJR, every type is modified by one of the mutability modifiers: `readonly`, `mutable`, or (for field types only) `this-mutable`. In addition to `final` and `assignable`, LJR also allows fields be marked as `this-assignable` with the `this-assignable` keyword.

4.2.1 Syntax

The syntax of LJR is shown in figure 4-11. `ML` and `MF` are introduced to range over the mutability modifiers that may occur in a program. `ML` ranges over the mutabilities that may appear in local variables' types: `readonly` and `mutable`. `MF`, mutability for fields, additionally ranges over `this-mutable`. `C` continues to range over class names. `T` now ranges over both read-only and mutable types. Thus, a type is a pair, `ML C< \bar{A} >`, consisting of a mutability and a "base" type.

`F` ranges over field type declarations, including those with `this-mutability`. A type argument to a field may have `this-mutability`. We denote such type arguments as `FA`. In addition to field types, `FA` ranges over wildcards. The definition of `FA` does not allow the bound of a wildcard type to have `this-mutability` as such an extension is cumbersome to the syntax. All type meta-variables other than `F` may not have `this-mutability`.

T, S, U, V	::= $\boxed{ML} C\langle A \rangle \mid X$	<i>types</i>
A	::= $T \mid ? B$	<i>type arguments</i>

x	<i>variables</i>	
m	<i>method names</i>	

Figure 4-11: Syntax of Lightweight Javari (LJR). Changes from Lightweight Java (LJ, figure 4-3) are indicated by boxes.

Assignability resolving:

```
assignability(this-assignable, mutable) = assignable  
assignability(this-assignable, readonly) = final  
assignability(final, ML) = final  
assignability(assignable, ML) = assignable
```

Mutability resolving:

```
mutability(F, mutable) = [mutable/this-mutable]F  
mutability(F, readonly) = [? readonly/this-mutable]F
```

Figure 4-12: Lightweight Javari (LJR): Resolving assignability and mutability. Also see figure 3-7, which presents the same information in a different form. For *assignability*, the first parameter is the keyword with which the field is declared and the second parameter is the mutability of the reference through which the field is accessed. The first parameter to *mutability* is the type of a field. The second parameter is the mutability of the reference through which the field is accessed.

A mutability modifier, ML or MF, may not be applied to a type that is a type variable (see section 3.6).

AL still ranges over assignable and final, modifiers applicable to method parameters (local variables) and AF ranges over the assignabilities that a field may be declared to have: assignable, final, and this-assignable.

4.2.2 Auxiliary functions

Resolving this-assignability and this-mutability

The assignability/mutability of a this-assignable/this-mutable field is determined by the mutability of the reference used to reach the field (section 3.5).

The function *assignability*(AF, ML) (shown in figure 4-12) is used to resolve the assignability of a field. A this-assignable field resolves to assignable, if reached through a mutable reference, and to final, if reached through a read-only reference. Fields that are declared final or assignable are trivially resolved to final and assignable, respectively.

The function *mutability* (shown in figure 4-12) is used to resolve the mutability of

a this-mutable type. If reached through a mutable reference, *mutability* replaces all instances of `this-mutable` in the type with `mutable`. If reached through a readonly reference, *mutability* replaces all instances of `this-mutable` in the type with `readonly`. Unlike *assignability*, *mutability* must resolve the mutabilities of the type arguments in addition to the top-level type.

Existential type creation: Snap

We extend LJ's *snap* to handle `? readonly` types. `? readonly` types denote the resolved (see previous section) type of this-mutable type (top-level or type arguments) reached through a read-only reference. To ensure transitive immutability, a `? readonly` type can only be read (as determined by the type's upper bound) as read-only. However, a this-mutable type may be read as a mutable when reached through a mutable reference; therefore, only mutable types may be assigned (as determined by the type's lower bound) to a `? readonly` type.² This intuition can be seen in the new *snap* rule (shown, boxed, in figure 4-13). In the rule, a fresh type variable is created with a readonly upper bound and a mutable lower bound. In *snap*, the upper bound's type arguments are set to the non-wildcard types calculated by *fix*. In the case of the lower bound, all instances of `? readonly` are replaced with `mutable` before *snap()* is applied to the type arguments to ensure that only fully mutable types are contained in the lower bound. The new *fix* rule (also shown, boxed, in figure 4-13) is similar but simpler because it does not need to recurse into the type arguments—*snap()* is only required remove wildcards from the top-level type.

Class member lookup

The other auxiliary functions that are changed from LJ's are shown in figure 4-14. The functions for method type lookup and valid method overriding must be modified because the mutability of the receiver is part of a method's signature. In the case of method lookup, the function now returns the mutability of the receiver as a part

²Otherwise, a type loop would exist that could be used to convert read-only types to mutable types; see section 3.

Snap:

$$\text{snap}(X) = \exists \emptyset. X$$

$$\frac{\text{class } C\langle \bar{Y} \bar{B}_0 \rangle \triangleleft N \{ \dots \} \quad \text{fix}(\bar{A}, \bar{B}_0) = (\bar{T}, \bar{X}, \bar{B}) \quad \Delta = \bar{X} \in [\bar{T}/\bar{Y}]\bar{B}}{\text{snap}(C\langle \bar{A} \rangle) = \exists \Delta. C\langle \bar{T} \rangle}$$

$\begin{array}{l} \text{class } C\langle \bar{Y} \bar{B}_0 \rangle \triangleleft N \{ \dots \} \\ \text{fix}(\bar{A}, \bar{B}_0) = (\bar{T}, \bar{X}, \bar{B}) \quad B_{\triangleleft} = \triangleleft \text{readonly } C\langle \bar{T} \rangle \\ \text{fix}([\text{mutable}/? \text{readonly}]\bar{A}, \bar{X}, \bar{B}) = (\bar{T}', \bar{X}', \bar{B}') \quad B_{\triangleright} = \triangleright \text{mutable } C\langle \bar{T}' \rangle \\ Z \text{ fresh} \quad \Delta = Z :: \bar{X}\bar{X}' \in [\bar{T}/\bar{Y}]B_{\triangleleft} B_{\triangleright} :: \bar{B}\bar{B}' \\ \hline \text{snap}(? \text{readonly } C\langle \bar{A} \rangle) = \exists \Delta. Z \end{array}$
--

Fix:

$$\frac{\text{fix}(\bar{A}, \bar{B}_0) = (\bar{T}, \bar{X}, \bar{B})}{\text{fix}(T :: \bar{A}, B_0 :: \bar{B}_0) = (T :: \bar{T}, \bar{X}, \bar{B})}$$

$$\frac{\text{fix}(\bar{A}, \bar{B}_0) = (\bar{T}, \bar{X}, \bar{B}) \quad X \text{ fresh}}{\text{fix}(? B :: \bar{A}, B_0 :: \bar{B}_0) = (X :: \bar{T}, X :: \bar{X}, \text{merge}(B, B_0) :: \bar{B})}$$

$\begin{array}{l} \text{fix}(\bar{A}, \bar{B}_0) = (\bar{T}, \bar{X}, \bar{B}) \\ X \text{ fresh} \quad B'_{\triangleleft} = \triangleleft \text{readonly } C\langle \bar{A}' \rangle \quad B'_{\triangleright} = \triangleright \text{mutable } [\text{mutable}/? \text{readonly}]C\langle \bar{A}' \rangle \\ \hline \text{fix}(? \text{readonly } C\langle \bar{A}' \rangle :: \bar{A}, B_0 :: \bar{B}_0) = (X :: \bar{T}, X :: \bar{X}, B'_{\triangleleft} B'_{\triangleright} :: \bar{B}) \end{array}$

$$\text{fix}(\bullet, \bullet) = (\bullet, \bullet, \bullet)$$

Figure 4-13: LJR's methods for creating existential types. Changes from LJ's methods (figure 4-5) are indicated by boxes. The *merge* function is unchanged and not shown.

Method type lookup:

$$\frac{\text{class } C\langle\bar{X} \bar{N}\rangle \triangleleft B\{\overline{AF} \boxed{\bar{F}} \bar{f}; \bar{M}\} \quad \langle\bar{Y} \bar{B}'\rangle U m(\bar{U} \bar{x}) \boxed{ML} \{ \text{return } e; \} \in \bar{M}}{mtype(m, C\langle\bar{T}\rangle) = [\bar{T}/\bar{X}](\langle\bar{Y} \bar{B}'\rangle \bar{U} \boxed{ML} \rightarrow U)}$$

$$\frac{\text{class } C\langle\bar{X} \bar{N}\rangle \triangleleft B\{\overline{AF} \boxed{\bar{F}} \bar{f}; \bar{M}\} \quad m \notin \bar{M}}{mtype(m, C\langle\bar{T}\rangle) = mtype(m, [\bar{T}/\bar{X}]N)}$$

Valid method overriding:

$$\frac{mtype(m, N) = \langle\bar{Y}' \bar{B}'\rangle \bar{T}' \boxed{ML'} \rightarrow T' \text{ implies} \\ \bar{B} = [\bar{Y}/\bar{Y}']\bar{B}' \text{ and } \bar{T} = [\bar{Y}/\bar{Y}']\bar{T}' \text{ and } \bar{Y} \in \bar{B} \vdash T \triangleleft [\bar{Y}/\bar{Y}']T' \text{ and } \boxed{ML'} = \boxed{ML}}{override(m, N, \langle\bar{Y} \triangleleft \bar{B}\rangle \bar{T} \boxed{ML} \rightarrow T)}$$

Figure 4-14: Lightweight Javari (LJR) auxiliary functions. Changes from Lightweight Java (LJ) (figure 4-7) are indicated by boxes.

$$\frac{\text{class } C\langle\bar{X} \bar{B}\rangle \triangleleft N \{ \dots \}}{\Delta \vdash \exists \Delta'. ML C\langle\bar{T}\rangle \triangleleft \exists \Delta'. ML [\bar{T}/\bar{X}]N} \text{ (WS-SUBCLASS)}$$

$$\Delta \vdash \text{mutable } C\langle\bar{T}\rangle \triangleleft \text{readonly } C\langle\bar{T}\rangle \text{ (WS-MUTABILITY)}$$

Figure 4-15: Lightweight Javari (LJR) subtyping rules. Only changes from LJ's subtyping rules (figure 4-8) are shown.

of the method's type. Because LJ and LJR do not allow method overloading, there cannot be a read-only and a mutable version of a method; thus, the mutability of the receiver does not need to be passed to *mtype*. The rule for valid method overriding now checks that the mutability of the receiver in the overriding method matches the mutability of the receiver in the overridden method.

4.2.3 Static semantics

Subtyping

The subtyping rules of LJ (figure 4-8) must be modified to include mutability. The `this-mutable` construct is not a part of the type hierarchy and, thus, is not shown in the subtyping rules. The mutability of a field declared `this-mutable` must be resolved

before subtyping relations may be calculated.

As with LJ the subtyping rules are applied to existential types.

LJR's subtyping rules (figure 4-15) are little changed from those of LJ. WS-SUBCLASS is modified to take the mutabilities of the subtype and supertype into account. WS-MUTABILITY is added to enforce the fact that a mutable version of a type is a subtype of the readonly version of the type. The other LJ subtyping rules are also subtyping rules of LJR with the exception that they now operate over LJR types instead of LJ types.

Typing judgements

The type rules of LJR are shown in figure 4-16. The rules of LJ are augmented to check that the mutability of an expression is correct for its context.

The RT-GET rule is changed to calculate the mutability of the field using the mutability of the reference, e_0 , used to reach the field. RT-INVK is augmented to check that the mutability of the receiver is legal for the declared mutability of the method. The rule for `new` expressions require that the object created is mutable because the object may be assigned to a mutable reference; therefore, when calculating the mutability of this-mutable fields, the mutability of the reference through which the fields are accessed is given as `mutable`. The changes to RT-SET are the same as to RT-GET. The RT-METHOD rule assigns the receiver's mutability to be equal to the mutability with which the method is declared.

4.2.4 Operational semantics

Javari is only a change to Java's type system³; therefore, Javari should not affect the run-time behavior of a program. As expected, the reduction rules for LJR are unchanged⁴ from those of LJ (see figure 4-10).

³An exception to this is the optional down casts, which are not modeled in LJR. See section 5.3.5.

⁴Technically, the call to *capture* is malformed because the last argument is a class type, which does not contain a top-level mutability, instead of a normal LJR type. This could be fixed by changing *capture* to accept class types for its last argument and replacing the predicate's subtyping judgement with a contains judgement on the class type's type arguments. We do not make this (solely syntactic) change to maintain similarity with WFJ's presentation of *capture*.

Expression typing:

$$\begin{array}{c}
\Delta; \Gamma \vdash \mathbf{x} : \mathit{snap}(\Gamma(\mathbf{x})) \quad (\text{RT-VAR}) \\
\\
\frac{\Delta; \Gamma \vdash e_0 : E_0 \quad \mathit{bound}_\Delta(E_0) = \exists \Delta_0. \boxed{\text{ML}_0} N_0 \quad \mathit{fields}(N_0) = \overline{\text{AF}} \boxed{\overline{\text{F}}} \overline{\text{f}} \quad \boxed{\mathit{mutability}(F_i, \text{ML}_0) = A} \quad \mathit{snap}(A) = \exists \Delta'. K}{\Delta; \Gamma \vdash e_0.f_i : \exists \Delta_0 \Delta'. K} \quad (\text{RT-GET}) \\
\\
\frac{\Delta \vdash \overline{\text{P}} \text{ ok} \quad \Delta; \Gamma \vdash e_0 : E_0 \quad \mathit{bound}_\Delta(E_0) = \exists \Delta_0. \boxed{\text{ML}} N_0 \quad \Delta; \Gamma \vdash \overline{\text{e}} : \exists \overline{\Delta}. \overline{\text{K}} \quad \Delta_1 = \Delta \Delta_0 \overline{\Delta} \quad \mathit{mtype}(m, N_0) = \langle \overline{\text{Y}} \overline{\text{B}} \overline{\text{U}} \boxed{\text{ML}'} \rightarrow \text{U} \quad \boxed{\text{ML } N_0 < \text{ML}' N_0} \quad \overline{\text{V}} = \mathit{capture}_{\Delta_1}(\overline{\text{P}}, \overline{\text{Y}}, \overline{\text{U}}, \overline{\text{K}})}{\Delta_1 \vdash \overline{\text{v}} \in \boxed{\overline{\text{V}}/\overline{\text{Y}} \overline{\text{B}}} \quad \Delta_1 \vdash \overline{\text{K}} < \boxed{\overline{\text{V}}/\overline{\text{Y}} \overline{\text{U}}} \quad \mathit{snap}(\boxed{\overline{\text{V}}/\overline{\text{Y}} \overline{\text{U}}}) = \exists \Delta'. K}{\Delta; \Gamma \vdash e_0. \langle \overline{\text{P}} \rangle_m(\overline{\text{e}}) : \exists \Delta_0 \overline{\Delta} \Delta'. K} \quad (\text{RT-INVK}) \\
\\
\frac{\Delta \vdash N \text{ ok} \quad \mathit{fields}(N) = \overline{\text{AF}} \boxed{\overline{\text{F}}} \overline{\text{f}} \quad \boxed{\mathit{mutability}(\overline{\text{F}}, \text{mutable}) = \overline{\text{A}}} \quad \Delta; \Gamma \vdash \overline{\text{e}} : \overline{\text{E}} \quad \Delta \vdash \overline{\text{E}} < \mathit{snap}(\overline{\text{A}})}{\Delta; \Gamma \vdash \text{new } N(\overline{\text{e}}) : \exists \emptyset. \text{mutable } N} \quad (\text{RT-NEW}) \\
\\
\frac{\Delta; \Gamma \vdash e_0 : E_0 \quad \mathit{bound}_\Delta(E_0) = \exists \Delta_0. \boxed{\text{ML}_0} N_0 \quad \mathit{fields}(N_0) = \overline{\text{AF}} \boxed{\overline{\text{F}}} \overline{\text{f}} \quad \boxed{\mathit{assignability}(\text{AF}_i, \text{ML}_0)} = \text{assignable} \quad \boxed{\mathit{mutability}(F_i, \text{ML}_0) = A} \quad \mathit{snap}(A) = \exists \Delta_i. K \quad \Delta; \Gamma \vdash e_v : E \quad \Delta \Delta_0 \vdash E < \exists \Delta_i. K \quad e_b : E'}{\Delta; \Gamma \vdash \text{set } e_0.f_i = e_v \text{ then } e_b : E'} \quad (\text{RT-SET})
\end{array}$$

Method typing:

$$\frac{\Delta \vdash \overline{\text{B}}', \text{T}, \overline{\text{T}} \text{ ok} \quad \Delta = \overline{\text{Y}} \in \overline{\text{B}}', \overline{\text{X}} \in \overline{\text{B}} \quad \Delta; \overline{\text{x}} : \overline{\text{T}}, \text{this} : \boxed{\text{ML}} \text{C} \langle \overline{\text{X}} \rangle \vdash e_0 : E \quad \Delta \vdash E < \mathit{snap}(\text{T}) \quad \text{class } \text{C} \langle \overline{\text{X}} \overline{\text{B}} \rangle < \text{N} \{ \dots \} \quad \mathit{override}(m, N, \langle \overline{\text{Y}} \overline{\text{B}}' \rangle \overline{\text{T}} \boxed{\text{ML}} \rightarrow \text{T})}{\langle \overline{\text{Y}} \overline{\text{B}}' \rangle \text{T } m(\overline{\text{T}} \overline{\text{x}}) \boxed{\text{ML}} \{ \text{return } e_0; \} \text{ OK IN } \text{C} \langle \overline{\text{X}} \overline{\text{B}} \rangle} \quad (\text{RT-METHOD})$$

Class typing:

$$\frac{\overline{\text{X}} \in \overline{\text{B}} \vdash \overline{\text{B}}, \text{N}, \overline{\text{T}} \text{ ok} \quad \overline{\text{M}} \text{ OK IN } \text{C} \langle \overline{\text{X}} \overline{\text{B}} \rangle}{\text{class } \text{C} \langle \overline{\text{X}} \overline{\text{B}} \rangle < \text{N} \{ \overline{\text{AF}} \boxed{\overline{\text{F}}} \overline{\text{f}}; \overline{\text{M}} \} \text{ OK}} \quad (\text{RT-CLASS})$$

Figure 4-16: Lightweight Javari (LJR) typing rules. Changes from Lightweight Java (LJ) (figure 4-9) are indicated by boxes.

4.2.5 Properties

LJR has a similar Type Soundness theorem as LJ:

Theorem 5 (LJR Type Soundness). *If $\emptyset; \emptyset \vdash e : E$ and $\langle e, S \rangle \rightarrow^* \langle e', S' \rangle$ with e' a normal form, then e' is a value, v , such that $S'(v) = \langle N, \mathcal{F} \rangle$ and $\emptyset \vdash \exists \emptyset.\text{mutable } N < E$.*

In the final the subtyping judgement of the type soundness theorem, the class type N is augmented with `mutable`. This step is needed so that the subtyping judgement may be applied and is safe because every object is in fact mutable at runtime.

The changes to store consistency are similar: class types, N , are converted to types by adding the fact that runtime objects are mutable. Additionally, field types, F , are converted to types using *mutability* assuming that the reference that reaches the field is mutable. This is a requirement to ensure that an object assigned to a field is saved to be later read when the field is reached through a mutable reference.

$$\begin{aligned}
& \Delta; \Gamma \vdash_{\sigma} S \iff \\
& \quad S(v) = \langle \text{mutable } N, \mathcal{F} \rangle \Rightarrow \\
\Sigma_1 : & \quad \Delta \vdash N <: \Gamma(v) \\
\Sigma_2 : & \quad \text{and } \text{dom}(\mathcal{F}) = \{f \mid \text{AF } F f \in \text{fields}(N)\} \\
\Sigma_3 : & \quad \text{and } \text{rng}(\mathcal{F}) \subseteq \text{dom}(S) \\
\Sigma_4 : & \quad \text{and } (\mathcal{F}(f) = v' \text{ and } \text{AF } F f \in \text{fields}(N) \\
& \quad \Rightarrow ((S(v') = \langle N', \mathcal{F}' \rangle) \Rightarrow \Delta \vdash \text{mutable } N' <: \text{mutability}(F, \text{mutable}))) \\
\Sigma_5 : & \quad \text{and } v \in \text{dom}(\Gamma) \Rightarrow v \in \text{dom}(S) \\
\Sigma_6 : & \quad \text{and } \text{dom}(S) \subseteq \text{dom}(\Gamma)
\end{aligned}$$

LJR's subject reduction and progress theorems are unchanged from LJ's.

Chapter 5

Other Language Features

This chapter first discusses a simple template mechanism over mutability used to avoid code duplication. Next, section 5.2 presents Javari's mechanisms for dealing with reflection and serialization. Finally, section 5.3 briefly discusses language features adopted from Javari2004 [5], a previous dialect of Javari (see section 7.1). These features include full interoperability with Java, type-based analyses that build on reference immutability, handling of exceptions, and dynamic casts, an optional feature that substitutes run-time for compile-time checking at specific places in the program.

5.1 Templating methods over mutability to avoid code duplication

In Java, each (non-generic) `class` definition defines exactly one type. By contrast, in Javari, `class C { ... }` creates *two* types: `/*mutable*/ C` and `readonly C`. The type `/*mutable*/ C` contains some methods that are absent from `readonly C`, and a given method may have different signatures in the two classes (even though the method's implementation is otherwise identical).

Javari permits a programmer to specify the two distinct types using a single `class` definition, without any duplication of methods. (The alternative, code duplication, is unacceptable.)

Javari provides the keyword `romaybe` to declare that a method should be templated over the mutability of one or more formal parameters. If the type modifier `romaybe` is applied to any formal parameter (including `this`), then the type checker conceptually duplicates the method, creating two versions of it. (It is not necessary for two versions of a class or method to exist at run time.) In the first version of the method, all instances of `romaybe` are replaced by `readonly` (or `? readonly` in the case of type arguments). In the second version, all instances of `romaybe` are removed, corresponding to the mutability default case: `mutable`. For example, the following code defines a `DateCell` class:

```
class DateCell {
    Date value;
    romaybe Date getValue() romaybe { return value; }
}
```

Its effect is the same as writing the following (syntactically illegal¹) code:

```
class DateCell {
    Date value;
    readonly Date getValue() readonly { return value; }
    /*mutable*/ Date getValue() /*mutable*/ { return value; }
}
```

As demonstrated above, the primary use of the `romaybe` keyword is to avoid declaring two duplicate field accessor methods, one `readonly` and one `mutable`. However, `romaybe` can also be used for static methods as shown below.

```
static |alert[romaybe] Date cellDate(|alert[romaybe] DateCell c) { return c.getValue(); }
```

Above `cellDate`, returns a mutable `Date` if invoked on a mutable `DateCell` and returns a read-only `Date` if invoked on a read-only `DateCell`.

¹Method overloading based on parameter's mutability is illegal. If given different names, these methods would be legal.

5.1.1 Parametric types

When used to modify a type argument, `romaybe` expands to `? readonly` instead of `readonly`. This behavior ensures that `romaybe` is useful for accessor methods of fields with parametric types, as shown below.

```
class Wheel {
    /*this-mutable*/ List</*this-mutable*/ Spoke> spokes;

    romaybe List<romaybe Spoke> getSpokes() romaybe { return spokes; }
}
```

The above method declaration is equivalent to the following two (syntactically illegal) method declarations, which are the correct type signatures for the accessors of `spokes`.

```
readonly List<? readonly Spoke> getSpokes() readonly {
    return spokes;
}

/*mutable*/ List<mutable Spoke> getSpokes() /*mutable*/ {
    return spokes;
}
```

If the `romaybe` expanded to `readonly` in the case of the type argument, the read-only version of the method above would be illegally typed (see section 3). If this was the case, two versions of the method would need to be written, resulting in code duplication.

5.1.2 Discussion

In the majority of cases only one mutability type parameter (`romaybe`) is needed. Within a templated method, the mutability of the method parameters, including `this`, cannot affect the behavior of the method because the method must be valid for both read-only and mutable types. However, templated parameters can affect the types of the method's references, including the method's return type. Hence, the only reason for a `romaybe` template is to ensure that the method has the most specific return type possible. As shown above, if a method's return type's mutability (including type

arguments) depend on only the mutability of a single parameter, then only a single mutability type parameter is needed. Below is a contrived case that breaks this rule.

```
static Pair<romaybe1 Date, romaybe2 Date>
  convert(romaybe1 DateCell c1, romaybe2 DateCell c2) {

    Pair<romaybe1 Date, romaybe2 Date> ret = ... ;
    ret.first = c1.getDate();
    ret.second = c2.getDate();
    return ret;
}
```

The return type's mutability independently depends on both the mutabilities of `c1` and `c2`. If the types of the arguments to `convert` were `Dates` instead of `DateCells`, this method would not require multiple mutability type parameters because it could be written using type parameters. We feel that rare cases, as the one above, do not warrant a more complicated mutability templating mechanism.

5.1.3 Template inference

As an alternative to explicitly specifying method templates, Javari could instead use type inference to create a version of a method with a read-only return type. Many languages, such as ML [29], use type inference to permit programmers to write few or no type annotations in their programs; this is especially important when the types are complicated to write. Javari could similarly infer method templates, reducing the number of template annotations (`romaybe`) in the code.

Lack of explicit immutability constraints would eliminate the documentation benefits of Javari, or would cause method signatures to describe what a method does rather than what it is intended to do. Furthermore, programming environments would need to re-implement the inference, in order to present the inferred types to users.

Despite these problems, there are countervailing advantages to inference. For example, although we have not found it onerous in our experience so far, it is a concern that many methods and arguments would be marked as read-only, cluttering

the code. (Were backward compatibility not an issue, we would have chosen different defaults for our keywords.) In future work, we plan to implement such an inference and determine whether users find it helpful.

5.2 Code outside the type system

Certain Java constructs, such as reflection and serialization, create objects in a way that is not checked by the Java type-checker, but must be verified at run time. We discuss how to integrate checking of mutability with these mechanisms, even though mutability has no run-time representation.

5.2.1 Reflection

Reflection enables calling a method whose return type (including mutability) is unknown at compile time. This prevents checking immutability constraints at compile time. We desire to maintain type soundness (reflective calls that should return a `readonly` reference must do so) and flexibility (reflective calls that should return a mutable reference can do so).

In particular, consider the `invoke` method:

```
package java.lang.reflect;
class Method {
    // existing method in Java (and Javari):
    /*mutable*/ Object invoke(java.lang.Object, java.lang.Object...);
    // new method in Javari:
    readonly Object invokeReadonly(java.lang.Object, java.lang.Object...);
}
```

The three dots at the end of the parameter lists are not an ellipsis indicating elided code, but the Java syntax for variable-argument routines.

Javari requires programmers to rewrite some uses of `invoke` into `invokeReadonly`, where `invokeReadonly` returns a `readonly Object` rather than an `Object` as `invoke` does. For example:

```
Method m1 = ...;
Method m2 = ...;
/*mutable*/ Object o1 = m1.invoke(...);
readonly    Object o2 = m2.invokeReadOnly(...);
```

`invokeReadOnly` returns a read-only reference and does no special run-time checking. `invoke` returns a mutable reference, but performs a run-time check to ensure that the return type of the method being called is mutable. Note that this is a check of the invoked method's signature, *not* a check of the object or reference being returned. This checking is local and fast². To enable this check, the JVM can record the mutability of the return type of each method as the method is loaded.

This proposal takes advantage of the fact that the type-checker knows the compile-time types of the arguments to `invoke`. That is, in a call `foo(d)`, it knows whether the declared type of `d` is read-only. That information is necessary for (1) ensuring that a readonly reference is not passed to a mutable formal parameter and (2) resolving overloading: determining whether `foo(d)` is a call to `foo(Date)` or to `foo(readonly Date)` when both exist.

5.2.2 Serialization

Like reflection, serialization creates objects in a way that is outside the purview of the Java type system. However, deserialization (`readObject`) is guaranteed to return a new object. Therefore, serializing a read-only object then deserializing the object, does not violate immutability constraints. Hence, serialization demands no special treatment by Javari.

5.3 Retained language features

This section briefly explains several Javari features that have not changed from the Javari2004 dialect described in a previous paper and technical report [5, 4]. Full details can be found in those references.

²Unlike the immutability checking that is required to support general downcasts; section 5.3.5.

5.3.1 Interoperability with Java

Javari is interoperable with Java and existing JVMs. The language treats any Java method as a Javari method with no immutability specification in the parameters (including `this`) or return type (and similarly for constructors, fields, and classes). Since the Javari type system does not know what a Java method can modify, it assumes that the method may modify anything.

While all Java methods can be called from Javari, Java code can only call Javari methods that does not use `readonly` in their return types. An implementation could enforce this by using standard Java names for mutable types, methods, and classes, and by “mangling” (at class loading time) the names of read-only types, methods, and classes into ones that cannot be referenced by legal Java code.

5.3.2 Type-based analyses

Javari enforces reference immutability—a read-only reference is never used to side-effect any object reachable from it. Reference immutability itself has many benefits. However, other guarantees may be desirable in certain situations. Four of these guarantees are object immutability (an object cannot be modified), thread non-interference (other threads cannot modify an object), parameter non-mutation (an object that is passed as a `readonly` parameter is not modified), and return value non-mutation (an object returned as a `readonly` result is not modified). One advantage of reference immutability is that a subsequent type-based analysis (which assumes that the program type checks [34]) can often establish these other properties from it, but the converse is not true.

Extending reference immutability to stronger guarantees requires escape analysis or partial information about aliasing. Determining complete, accurate alias information remains beyond the state of the art; fortunately, the analyses do not require full alias analysis. Obtaining alias information about a particular reference can be easier and more precise than the general problem [2]. Programmers can use application knowledge about aliasing, new analyses as they become available, or other mecha-

nisms for controlling or analyzing aliasing, such as ownership types [12, 3, 7], alias types [3], linear types [50, 16], or checkers of pointer properties [14, 19].

5.3.3 Inner classes and read-only constructors

Javari protects a read-only enclosing instance from being mutated through an inner class. Placing `readonly` immediately following the parameter list of a method of an inner class declares the receiver *and all enclosing instances* of the receiver to be read-only.

Inner class constructors have no receiver, but placing the keyword `readonly` immediately following the parameter list of an inner class constructor declares all enclosing instances to be read-only. Such a constructor may be called a read-only constructor, by analogy with “read-only method”. It is important to note that the “read-only” in “read-only constructor” refers to the enclosing instance. Read-only constructors do not constrain the constructor’s effects on the object being constructed, nor how the client uses the newly-constructed object.

It is a type error for a read-only method or constructor to change the state of the enclosing instance, which is read-only. Furthermore, a non-read-only method or constructor cannot be called through a read-only reference.

5.3.4 Exceptions

Javari prohibits read-only exceptions from being thrown. This restriction, which has so far caused no difficulty in practice, is caused by our desire for interoperability with the existing Java Virtual Machine, in which (mutable) `Throwable` is a supertype of every other `Throwable`. It is possible to modify Javari to lift the restriction on throwing read-only exceptions, but the result is complicated, introduces possibilities for error in the type system and the implementation, and provides little practical benefit.

5.3.5 Downcasts

Every non-trivial type system rejects some programs that are safe—they never perform an erroneous operation at run time—but whose safety proof is beyond the capabilities of the type system. Like Java itself, Javari allows such programs, but requires specific programmer annotations (downcasts); those annotations trigger Javari to insert run-time checks at modification points to guarantee that no unsafe operation is executed. Among other benefits, programmers need not code around the type system’s constraints when they know their code to be correct, and interoperation with legacy libraries is eased. The alternatives—prohibiting all programs that cannot be proved safe, or running such programs without any safety guarantee—are unsatisfactory, and are also not in the spirit of Java.

If a program is written in the type-safe subset of Javari, then static type-checking suffices. For our purposes, the unsafe operation is the downcast, which converts a reference to a superclass into a reference to a subclass. (In Java but not in Javari (section 3.7), these can also appear implicitly in certain uses of arrays of references, for which Java’s covariant array types prevent sound static type-checking.) Java inserts checks at each down-cast (and array store), and throws an exception if the down-cast fails.

Javari provides the following syntax for downcasting from a read-only type to a mutable type: “(mutable) *expression*”. Regular Java-style casts may not be used to convert from read-only to mutable types:

```
readonly    Date rd;
/*mutable*/ Date md;
md = (Date) rd; // error: A regular Java cast may not cast away read-only-ness.
```

Special downcast syntax highlights that the cast is not an ordinary Java one, and makes it easy to find such casts in the source code.

Downcasting from a read-only to a mutable type triggers the insertion of run-time checks, wherever a modification (an assignment) may be applied to a reference that has had `readonly` cast away. (In the worst case, every assignment in the program,

including libraries, must be checked.) The run-time checks guarantee that even if a read-only reference flows into a mutable reference, it is impossible for modifications to occur through the mutable reference. Thus, Javari soundly maintains its guarantee that a read-only reference cannot be used, directly or indirectly, to modify its referent.

A previous paper [5] describes an efficient technique for checking these casts at run time. It associates a “readonly” Boolean with each reference (*not* with each object). The readonly Boolean is true for each non-read-only reference derived from a `readonly` reference as a result of a downcast. The readonly Boolean is set when `readonly` is cast away, is propagated by assignments, and is checked whenever a modification (i.e., a field update) is performed on a non-read-only reference.

The following example illustrates the behavior of run-time casts.

```
class Foo {
    Date d;
    void setD() /*mutable*/ {
        this.d = new Date();
    }
}

    Foo f1 = new Foo();
readonly Foo rf = f1;
    Foo f2 = (mutable) rf;

f1.d = new Date(); // OK
f2.d = new Date(); // run-time error
f1.setD();         // OK
f2.setD();         // run-time error: at the first line of setD
```

In a previous experiment, there was approximately one cast per 1000 lines [5]. However, that experiment annotated existing code (without improving its design), did not annotate all the libraries that were used, and used an earlier dialect of the Javari language that extended Java 1.4 and many features that make casts less necessary. Also lessening the need for casts, section 6 presents a technique for automatically converting existing Java libraries to Javari. Just as most new Java 5 code contains few Java casts, we believe that well-written new Javari code will contain few or no mutability downcasts.

Chapter 6

Type inference for Javari

For a programmer to gain the benefits of reference immutability constraints, he must annotate his code with the appropriate immutability constraints. For existing code, this can be a tedious and error prone task. Even worse, a programmer wishing to use reference immutability constraints must first annotate (the signatures of) the libraries he plans to use. Otherwise, a reference immutability type checker would be forced to assume that all methods modify their arguments. Therefore, the programmer would be unable to invoke any of the library's methods on immutable references even if the method, in fact, does not modify its arguments.

To aid programmers with adding reference immutability constraints to Java programs, we have created an algorithm to soundly infer immutable references from Java code. Given a program, our algorithm calculates all the references, including local variables, method parameters, and static and instance fields, that may have Javari's `readonly`, `romaybe`, or `? readonly` keywords added to their declarations. Using this algorithm, programmers can convert Java programs, including libraries, to Javari.

Javari's other annotations, `assignable` and `mutable`, exclude parts of the concrete representation from the abstract state and they cannot be soundly inferred because they require knowing the intent of the programmer. However, without allowing these annotations, the precision of our algorithm would suffer. This problem can occur when a reference is used to modify a part of an object's concrete state that was not intended to be a part of the object's abstract state. Such a reference would be

inferred to be mutable when in reality, it should be read-only. Therefore, to improve the results of our algorithm, we allow users to hand annotate references with Javari's immutability modifiers, including declaring fields as assignable or mutable.

We have implemented our algorithm in the form of the Javarifier tool. Given a Java (possibly partially annotated) program in classfile format¹, Javarifier calculates and returns to the user the references that may be declared `readonly`, `romaybe` or `? readonly`. An example Java program and the corresponding Javari program is shown in figure 6-1.

The rest of this chapter is organized as follows. Section 6.1 explains the algorithm which is used to soundly infer read-only references. Section 6.2 discusses how our algorithm is soundly extended to infer `romaybe` references. Section 6.3 describes the implementation of our algorithm within the Javarifier tool. Finally, section 6.4 provides our experience using Javarifier.

6.1 Inferring read-only references

We use a flow- and context-insensitive algorithm to infer which references may be declared read-only. A read-only reference may have the `readonly` keyword added to its Javari type declaration. The algorithm is sound: Javarifier's recommendations will type check under Javari's rules. Furthermore, our algorithm is precise: declaring any references in addition to Javarifier's recommendations as read-only—without other modifications to the code—will result in the program not type checking.

The read-only inference algorithm does not determine which fields should be declared `mutable` or `assignable`; however, it is capable of inferring in the presence of fields that have been declared `mutable` or `assignable` by an outside source. The read-only inference algorithm declares all other fields not inferred to be read-only to be `this-mutable`. This choice is made because declaring fields to be `mutable` states that the field is not a part of the object's abstract state—an exceptional case.

¹It is important that Javarifier is able to operate on classfiles because programmers may wish convert library code that they only have in classfile format.

```

// Java
class Event {

    Date date;

    Date getDate() {
        return Date;
    }

    void setDate(Date d) {
        this.date = d;
    }
}

// Javari
class Event {

    /*this-mutable*/ Date date;

    romaybe Date getDate() romaybe {
        return Date;
    }

    void setDate(/*mutable*/ Date d) /*mutable*/ {
        this.date = d;
    }
}

```

Figure 6-1: A Java program (above) and the corresponding inferred Javari program (below).

For simplicity, we begin by describing our core algorithm (in section 6.1.1), i.e., the algorithm in the absence of unseen code, subtyping, user-provided reference immutability annotations (including assignable and mutable fields), arrays, and parametric types. We then extend the algorithm to allowing unseen code (section 6.1.2), subtyping (section 6.1.3), user-provided constraints (section 6.1.4), array types (section 6.1.5), and parametric types (section 6.1.6).

6.1.1 Core algorithm

Our algorithm generates, then solves, a set of mutability constraints for a program. A mutability constraint states when a given reference must be declared mutable. The algorithm uses two types of constraints: unguarded and guarded. Unguarded constraints state that a given reference is unconditionally mutable, e.g. “ x is mutable.” Guarded constraints state that a given reference is conditionally mutable if another reference is mutable, e.g. “if y is mutable then x is mutable.” We use *constraint variables* to refer to references in these constraints— x and y in the previous examples. Unguarded constraints are represented by the constraint variable of the reference it is constraining, e.g. “ x .” Guarded constraints are represented as implications with the guard reference’s constraint variable as the predicate and the dependent reference’s constraint variable as the consequence, e.g. “ $y \rightarrow x$ ”.

After generating the constraints, the algorithm solves the constraints yielding a simplified constraint set. The simplified constraint set is the set of all the constraint variables known to be true. A constraint variable is known to be true if it is present as an unguarded constraint or if it is consequence of a guarded constraint that is satisfied either directly by an unguarded constraint or indirectly through the consequence of a different satisfied guarded constraint. The simplified constraint set contains the set of references that must be declared mutable (or this-mutable in the case of instance fields); all other references may safely be declared read-only.

```

Q ::= class {f̄ M̄}
M ::= m(x̄){s̄;}
s ::= x = x
    | x = x.m(x̄)
    | return x
    | x = x.f
    | x.f = x

```

Figure 6-2: Grammar for core language used during constraint generation.

Constraint generation

The first phase of the algorithm generates constraints for each statement in a program. Unguarded constraints are generated when a reference is used to modify an object. Guarded constraints are generated when a reference is assigned to another reference or when a reference is used to reach a field of an object.

We present constraint generation using a core language. The core language is a simple three-address programming language.² The grammar of the language is shown in figure 6-2. We use Q and M to refer to class and method definitions, respectively. m ranges over method names, f ranges over names fields, and s ranges over allowed statements. p , x , y , and z range over variables (method parameters and locals). We use \bar{x} as the shorthand for the (possibly empty) sequence $x_1 \dots x_n$. We also include the special variable this_m , which refers to the receiver of method m . Furthermore, we assume any program that attempts to reassign this_m is malformed. Otherwise, this_m is treated as a normal variable. Without loss of generality and for ease of presentation, we assume that all references and methods are given globally-unique names.

Control flow constructs are not modeled because the our algorithm is flow-insensitive and, therefore, unaffected by such constructs. Java types are not modeled because the core algorithm does not use them. Constructors are modelled as regular methods returning a mutable reference to this_m . Static members are omitted because do not demonstrate any interesting properties.

Each of the statements from figure 6-2 has a constraint generation rule, as shown in figure 6-3. The rules make use of the following auxiliary functions. $\text{this}(m)$ and

²Java source and classfiles can be converted to such a representation.

$\text{params}(\mathbf{m})$ return the receiver reference ($\text{this}_{\mathbf{m}}$) and parameters of method \mathbf{m} , respectively. $\text{retVal}(\mathbf{m})$ returns the constraint variable, $\text{ret}_{\mathbf{m}}$, that represents the reference to \mathbf{m} 's return value.

The constraint generation rules are described as follows:

Assign The assignment of variable y to x causes the guarded constraint $x \rightarrow y$ to be generated because, if x is a mutable reference, y must also be mutable for the assignment to succeed.

Invk The assignment, to x , of the return value of the invocation of method \mathbf{m} , on y , with arguments \bar{y} , generates three kinds of constraints. The guarded constraint $\text{this}_{\mathbf{m}} \rightarrow y$ is generated because the actual receiver must be mutable if \mathbf{m} requires a mutable receiver. Similarly, the constraints $\bar{p} \rightarrow \bar{y}$ are generated because the i^{th} actual argument must be mutable if \mathbf{m} requires the i^{th} formal parameter to be mutable. Finally, the constraint $x \rightarrow \text{ret}_{\mathbf{m}}$ is generated to enforce that \mathbf{m} must have a mutable return type if the value it returns is assign to a mutable reference.

These constraints are extensions of the ASSIGN rule when method invocation is framed in terms of operational semantics: the receiver, y , is assigned to $\text{this}_{\mathbf{m}}$, each actual argument is assigned to the method's corresponding formal parameter, and the return value, $\text{ret}_{\mathbf{m}}$, is assigned to x .

Ret The return statement `return x` adds the constraint $\text{ret}_{\mathbf{m}} \rightarrow x$ because, in the case that the return type of the method is found to be mutable, all references returned by the method must be mutable.

Ref The assignment of $y.f$ to x generates two constraints. The first, $x \rightarrow f$, is required because, if x is mutable, then the field f cannot be read-only. The second, $x \rightarrow y$, is needed because, if x is mutable, then y must be mutable to yield a mutable reference to field f (the core algorithm assumes all non-read-only fields are this-mutable).

$$\begin{array}{c}
x = y : \{x \rightarrow y\} \text{ (ASSIGN)} \\
\\
\frac{\text{this}(m) = \text{this}_m \quad \text{params}(m) = \bar{p} \quad \text{retVal}(m) = \text{ret}_m}{x = y.m(\bar{y}) : \{\text{this}_m \rightarrow y, \bar{p} \rightarrow \bar{y}, x \rightarrow \text{ret}_m\}} \text{ (INVK)} \\
\\
\frac{\text{retVal}(m) = \text{ret}_m}{\text{return } x : \{\text{ret}_m \rightarrow x\}} \text{ (RET)} \\
\\
x = y.f : \{x \rightarrow f, x \rightarrow y\} \text{ (REF)} \\
\\
x.f = y : \{x, f \rightarrow y\} \text{ (SET)}
\end{array}$$

Figure 6-3: Constraint generation rules.

Set The assignment of y to $x.f$ causes the unguarded constraint x to be generated because x has just been used to mutate the object to which it refers. The constraint $f \rightarrow y$ is added because if f is found to be this-mutable, then a mutable reference must be assigned to it.

The constraints for a program is the union of the constraints generated for each line of the program. Figure 6-4 shows constraints being generated for a sample program.

Simplifying constraints

The second phase of the algorithm is to simplify the constraint set. Constraint set simplification checks if any of the unguarded constraints satisfies, i.e. matches, the guard of a guarded constraint. If so, the guarded constraint is “fired” by removing it from the constraint set and adding its consequence to the constraint set as an unguarded constraint. The new unguarded constraint can then be used to fire other guarded constraints. Once no more constraints can be fired, constraint simplification terminates. The unguarded constraints in the simplified constraint set is the set of references that cannot be declared read-only. They must be declared this-mutable for instance fields, and mutable in the case of all other types of references. All other references are safe to be declared read-only.

The constraints generated from the example program in figure 6-4 will be simpli-

```

class {
  f;
  foo(p) {
    x = p;          // Assign: {x -> p}
    y = x.f;       // Ref: {y -> f, y -> z}
    z = x.foo(y); // Invk: {this_foo -> x, p -> x, z -> ret_foo}
    this.f = y;   // Set: {this_foo, f -> y}
    return y;    // Ret: {ret_foo -> y}
  }
}

```

Program constraints:

$$\{x \rightarrow p, \text{this}_{\text{foo}} \rightarrow x, p \rightarrow x, z \rightarrow \text{ret}_{\text{foo}}, \\ y \rightarrow f, y \rightarrow z, \text{this}_{\text{foo}}, f \rightarrow y, \text{ret}_{\text{foo}} \rightarrow y\}$$

Figure 6-4: Example of constraint generation. After each line of code, the constraints generated and the constraint generation rule used for is shown.

fied as shown below. (For clarity, the unguarded constraints are listed first.)

$$\{\text{this}_{\text{foo}}, x \rightarrow p, \text{this}_{\text{foo}} \rightarrow x, p \rightarrow x, z \rightarrow \text{ret}_{\text{foo}}, \\ y \rightarrow f, y \rightarrow z, f \rightarrow y, \text{ret}_{\text{foo}} \rightarrow y\} \Rightarrow \\ \{\text{this}_{\text{foo}}, x, p\}$$

At the end of simplification, the unguarded constraints `thisfoo`, `x` and `p` are present in the simplified constraint set. These references may not be declared read-only. All the other references, `y`, `z`, `retfoo`, and `f`, can be declared read-only. Figure 6-5 shows the result of applying our algorithm to the example program.

6.1.2 Unseen code

Our algorithm as previously described makes the closed-world assumption. That is, it assumes that all code is seen and, therefore, it is safe to change public method return types and types of public fields. In the case that a user is running the algorithm on the whole program, the closed world assumption allows the results to be more precise. However, in order to support analyzing library classes which do not have

```

class {
  readonly f;
  readonly foo(p) {
    /*mutable*/ x = p;
    readonly y = x.f;
    readonly z = x.foo(y);
    this.f = y;
    return y;
  }
}

```

Figure 6-5: The result applying our algorithm’s output to the program originally shown in figure 6-4.

access to their clients, our algorithm needs to be sound even without the presence of all client code. Thus, all non-private³ fields and the return types of non-private methods must be mutable because an unseen client may rely on a mutability of the field or return value. Our algorithm is easily modified to enforce this restriction: an unguarded constraint for every non-private field and non-private method return value is added to the constraint set. Depending on the needs of the user, the algorithm can be executed either under the closed-world assumption or not.

6.1.3 Subtyping

Java and Javari allow subtyping polymorphism, which enables multiple implementations of a method to be specified through overriding⁴. Javari requires that all implementations of an overridden method have identical signatures, including the mutability of parameters. Therefore, our algorithm must infer the same mutabilities for the parameters of all implementations of overridden methods. Overridden methods are also restricted to have covariant return types.

To ensure that our algorithm does not infer different signatures for polymorphic methods, we must place an additional set of constraints in the constraint set. For

³In the case that an entire package is being analyzed, package-protected (default access) methods and fields may be processed as under the closed world assumption.

⁴We use the term *overriding* to specify when a method implements a method from an interface, implements an abstract method, or overrides a concrete method in a superclass. Furthermore, for brevity and to highlight their identical treatment, we will refer to both abstract methods and interface methods *abstract methods*.

every parameter of a overloaded method, we add the constraint that it is equal in mutability to every other implementation of the method. Equality is represented by two guarded constraints, one indicates if the first constraint variable is mutable then the second constraint variable is mutable, the other specifies that if second constraint variable is mutable then the first is mutable. For example, below, the method `toString` is overloaded.

```
class Event {
    Date d;
    String toString() {
        return d.toString();
    }
}

class Birthday extends Event {
    int age;
    String cachedStr;
    String toString() {
        if (cachedStr == null) {
            cachedStr = "I'm " + age + " on " + d + "!";
        }
        return cachedStr;
    }
}
```

Thus, the mutability of the `this` parameter of `Event`'s and `Birthday`'s `toString` methods must be the same. This requirement generates the constraints:

$$\text{this}_{\text{Event.toString}} \rightarrow \text{this}_{\text{Birthday.toString}}$$

$$\text{this}_{\text{Birthday.toString}} \rightarrow \text{this}_{\text{Event.toString}}$$

Although, to preserve overloading, both methods are declared to have mutable `this` parameters, only `Birthday`'s `toString` method actually mutates its receiver. One implementation of the method mutating the receiver while another does not is disconcerting because overloaded methods are suppose to both be implementations of the same specification. Therefore, our algorithm should issue a warning in such

cases.

6.1.4 User-provided annotations

Our read-only inference algorithm can be extended to incorporate user-provided annotations. This capability is required because the read-only inference algorithm is not capable of directly inferring the `assignable` and `mutable` keywords. Additionally, user-provided annotations are needed for native method invocations, on which our algorithm cannot operate. Finally, a user may, using knowledge of the program, wish to override the annotations inferred by our algorithm.⁵

A user may specify that instance fields are `this-mutable`, `read-only`, or `mutable` and that other references (static fields, local variables and parameters) are `read-only` or `mutable`.

A user declaring a reference to be `read-only` causes the algorithm, upon finishing, to check if it is safe to declare the given reference as `readonly`. If not, the algorithm issues an error, stating the conflict with the user annotation. It is expected that this type of declaration will be particularly useful for overridden methods (see section 6.1.3) because declaring a supertype's method to be `read-only` would propagate to all the subtypes. For example, a user could annotate `Object`'s `toString`, `hashCode`, and `equals` methods as having `read-only this` parameters. The user would then be notified if any class's implementation of the above methods are not `read-only`. Such cases may arise from errors or the usage of a cache fields that should be declared `assignable`.

A user declaring a non-field reference `mutable` or a field `this-mutable` results in the system adding an unguarded constraint that the reference cannot be `read-only`. This specification is useful when a programmer knows that a certain reference is not currently used to modify its referent, but that it may be used to do so in the future. This case is expected to be particularly relevant for method return types when running

⁵It is save for a user to override our analysis by stating that a reference inferred to be `read-only` should be declared `mutable`. However, overriding our analysis by stating that a reference inferred to be `mutable` should be declared `readonly` would result in a type error.

the algorithm with the closed world assumption (see section 6.1.2). For example, a user may wish to annotate a program under the closed world assumption but specify that certain public methods return mutable references.

Finally, a user may declare fields to be `assignable` or `mutable`. These annotations are particularly important because our algorithm cannot soundly infer fields to be `assignable` or `mutable` as it would require knowing which fields the programmer intended to be a part of an object's abstract state. Our algorithm, however, can be extended to work with fields that are declared, by an outside source, to be `assignable` or `mutable`. This ability is needed because fields may be determined to be `mutable` or `assignable` by hand.

To extend our algorithm to handle `mutable` and `assignable` fields, the constraint generation rules are extended to check the assignability and mutability of fields before adding constraints. The algorithm is given the set of fields that are declared to be `assignable`, AS , and the set of fields that are declared to be `mutable`, MS . The auxiliary functions `assignable(f)` and `mutable(f)` return true if and only if f is contained in AS or MS , respectively. The changes to the constraint generation rules are shown in figure 6-6 and are described below.

To handle `assignable` fields, the `SET` rule is divided into two rules, `SET-A` and `SET-N`, which depend on the assignability of the field. If the field is `assignable`, `SET-A` does not add the unguarded constraint that the reference used to reach the field must be mutable: an `assignable` field may be assigned through either a read-only or mutable reference. If the field is not `assignable`, `SET-N` proceeds as normal.

To handle `mutable` fields we add the constraint generation rule `MUTABLE`, which adds an unguarded constraint for each `mutable` field. The `REF` rule is again divided into two rules: `REF-M` and `REF-N` depending on the mutability of the field. If the field is `mutable`, then `REF-M` does not add any constraints because, when compared to the original `REF` rule, (1) the consequence of the first constraint, $x \rightarrow f$, has already been added to the constraint set via the `MUTABLE` rule, and (2) the second constraint, $x \rightarrow y$, is eliminated because a `mutable` field is mutable regardless of how it is reached. If the field is not `mutable`, then `REF-N` proceeds as normal.

$$\frac{\text{assignable}(f)}{x.f = y : \{f \rightarrow y\}} \text{ (SET-A)}$$

$$\frac{\neg\text{assignable}(f)}{x.f = y : \{x, f \rightarrow y\}} \text{ (SET-N)}$$

$$\text{mutable } f; : \{f\} \text{ (MUTABLE)}$$

$$\frac{\text{mutable}(f)}{x = y.f : \{f\}} \text{ (REF-M)}$$

$$\frac{\neg\text{mutable}(f)}{x = y.f : \{x \rightarrow f, x \rightarrow y\}} \text{ (REF-N)}$$

Figure 6-6: Modified constraint generation rules for handling assignable and mutable fields. The original SET rule (shown in figure 6-3) is replaced by SET-A and SET-N. The original REF rule is replaced by REF-M and REF-N. Finally, MUTABLE is added to the remaining rules from figure 6-3.

Grammar:

$$s ::= \dots$$

	x[x] = x
	x = x[x]

Figure 6-7: Core language grammar extended for arrays. The original grammar is shown in figure 6-2

6.1.5 Arrays

Next, we extend our algorithm to handle arrays. First, we extend our core language grammar to allow storing and reading from arrays. The extended grammar is shown in figure 6-7.

Javari allows array elements to have two-sided bounded types (section 3.7). For example, the array (`? readonly Date`)[] has elements with upper bound `readonly Date` and lower bound `mutable Date`. All array element types can be written in the form of having an upper bound and a lower bound. For example, (`readonly Date`)[] has elements with upper bound `readonly Date` and lower bound `readonly Date`. Our algorithm will infer an upper bound and a lower bound for the type of an array's

$T, S ::= A \mid C$	<i>types</i>
$A, B ::= T[]$	<i>array types</i>
C, D	<i>class names</i>

Figure 6-8: Type meta-variables.

elements.

In the initial core algorithm, a reference could only have a single read-only-ness annotation; therefore, using a single constraint variable for each reference sufficed. The introduction of arrays, however, enables multiple read-only-ness annotations to be placed on a reference's type: the array's elements' type can be annotated in addition to the array type. Therefore, our analysis must constrain every part of a type. By "part", we refer to a reference's top-level array type; the upper and lower bounds of the elements of the top-level array type; if the elements of the top-level array are array themselves, then the upper and lower bounds of elements of the elements; and so on. For example, the type `Date[][]` has seven type parts: `Date[][]`, the top-level type; `Date[]u`, the upper bound of the element type; and `Date[]l`, the lower bound of the element type, and then four `Date` types corresponding to the upper bound of the upper bound, the upper bound of the lower bound, the lower bound of the upper bound, and the lower bound of the lower bound. To constrain each part of the type, we will use each type part as a constraint variable. To distinguish type parts of an upper bound from the corresponding lower bound, we subscript upper bounds with _u and lower bounds with _l. Additionally, we assume within a program, textually different instances of the same type are distinguishable.

As in section 4.1, T and S ranges over types, and C and D over class names. We add A and B to range over array types. The type meta variables are shown in figure 6-8.

Our type constraint generation rules use the auxiliary function *type*, which returns the declared type of a reference.

Constraint generation

The constraint generation rules are extended to enforce subtyping constraints. For the assignment $x = y$, where x and y are arrays, the extension must enforce that

$$\frac{S[] \rightarrow T[] \quad T \subset S}{T[] \prec S[]} \quad \frac{D \rightarrow C}{C \prec D} \quad \frac{T_d \prec S_d \quad S_b \prec T_b}{T \subset S}$$

Figure 6-9: Simplified subtyping rules for mutability in Javari.

$$\begin{aligned}
& \mathbf{x = y} : \{type(y) \prec type(x)\} \text{ (ASSIGN)} \\
& \frac{\mathbf{this(m) = this_m} \quad \mathbf{params(m) = \bar{p}} \quad \mathbf{retVal(m) = ret_m}}{\mathbf{x = y.m(\bar{y})} : \{type(y) \prec type(this_m), type(\bar{y}) \prec type(\bar{p}), type(ret_m) \prec type(x)\}} \text{ (INVK)} \\
& \frac{\mathbf{retVal(m) = ret_m}}{\mathbf{return x} : \{type(x) \prec type(ret_m)\}} \text{ (RET)} \\
& \mathbf{x = y.f} : \{type(f) \prec type(x), type(x) \rightarrow type(y)\} \text{ (REF)} \\
& \mathbf{x.f = y} : \{type(x), type(y) \prec type(f)\} \text{ (SET)} \\
& \mathbf{x = y[z]} : \{type(y[z]) \prec type(x)\} \text{ (ARRAY-REF)} \\
& \mathbf{x[z] = y} : \{type(x), type(y) \prec type(x[z])\} \text{ (ARRAY-SET)}
\end{aligned}$$

Figure 6-10: Constraint generation rules in presence of arrays.

y is a subtype of x . Simplified subtyping rules for Javari are given in figure 6-9⁶. The simplified rules only check the mutabilities of the types because we assume the program being converted type checks under Java. An array element's type, T , is said to be contained by another array element's type, S , written $T \subset S$, if the set of types denoted by T is a subset of the types denoted by S .

We modify the constraint generation rules to use types as constraint variables and to enforce the subtyping relationship across assignments including the implicit assignments that occur during method invocation. The extended rules are shown in figure 6-10.

⁶In Java, arrays are covariant; however, in Javari, array are invariant in respect to mutability (see section 3.7), therefore, we use the contains relationship as Java's parametric types do.

Type well-formedness constraints

In addition to the constraints generated for each line of code, our algorithm adds constraints to the constraint set to ensure that every array type is well formed. Array well-formedness constraints enforce the fact that an array element's lower bound must be a subtype of the element's upper bound.

Constraint simplification

Before the constraint set can be simplified as before, subtyping and contains constraints must be reduced to guarded constraints. To do so, each subtyping or contains constraint is replaced by the corresponding rule's predicates (see figure 6-9). This step is repeated until only guarded and unguarded constraints remain in the constraint set. For example, the statement $x = y$, where x and y has the types $T[]$ and $S[]$, respectively, would generate and reduce constraints as follows:

$$\begin{aligned} x = y & : \{type(y) < type(x)\} \\ & : \{S[] < T[]\} \\ & : \{T[] \rightarrow S[], S \subset T\} \\ & : \{T[] \rightarrow S[], S_d < T_d, T_b < S_b\} \\ & : \{T[] \rightarrow S[], T_d \rightarrow S_d, S_b \rightarrow T_b\} \end{aligned}$$

In the final results, the first guarded constraint enforces that y must be a mutable array if x is a mutable array, while second and third constraints constrain the bounds on the arrays' elements types. $T_d \rightarrow S_d$ requires the upper bound of y 's elements to be mutable if the upper bound x 's elements is mutable. This rule is due to covariant subtyping between upper bounds. $S_b \rightarrow T_b$ requires the lower bound of x 's elements to be mutable if the lower bound y 's elements is mutable. This rule is due to contravariant subtyping between lower bounds.

After eliminating all subtyping or contains constraints, the remaining guarded and unguarded constraint set is simplified as before.

T, S	::=	C<T> X	<i>types</i>
C, D			<i>class names</i>
X, Y			<i>type variables</i>

Figure 6-11: Type meta-variables.

Applying results

Finally, we must apply the results back to the initial Java program. The results are applied to top-level types, the same way they were before. However, for element types, we must map the constraints on the upper bound and type lower bound to a single Javari type. If the upper bound and lower bound are both present in the constraint set, the element's type is annotated as mutable. If the upper bound and lower bound are both not present, then the element's type is annotated as read-only. If the lower bound is present, but the upper bound is not, then the element's type is annotated as `? readonly`. Finally, the case that the upper bound is present and the lower bound is not, cannot occur due to the well-formedness constraints.

6.1.6 Parametric types

Parametric types are handled in a similar fashion as arrays. For a parametric type, constraint variables must be made for the upper and lower bound of each type argument to a parametric class. As with arrays, we will use type parts as constraint variables.

We will use the following meta-syntax to represent parametric types. As in section 4.1, T and S will range over types, X and Y over type variables, and C and D over class names. We do not model wildcard types other than `? readonly`; however, they are a simple extension. The type meta-variable definitions are shown in figure 6-11.

As with arrays, we will use \triangleleft to denote type argument's upper bounds and \triangleright to denote their lower bounds.

$$\frac{D \rightarrow C \quad \overline{T'} \subset \overline{S'}}{T \triangleleft S \text{ where } bound_{\Delta}(T) = C \langle \overline{T'} \rangle \text{ and } bound_{\Delta}(S) = D \langle \overline{S'} \rangle}$$

$$\frac{T_{\triangleleft} \triangleleft S_{\triangleleft} \quad S_{\triangleright} \triangleleft T_{\triangleright}}{T \subset S}$$

Figure 6-12: Simplified subtyping rules for mutability in the presence of parametric types.

$$x = y : \{type(y) \triangleleft type(x)\} \text{ (ASSIGN)}$$

$$\frac{this(m) = this_m \quad params(m) = \overline{p} \quad retVal(m) = ret_m}{x = y.m(\overline{y}) : \{type(y) \triangleleft type(this_m), type(\overline{y}) \triangleleft type(\overline{p}), type(ret_m) \triangleleft type(x)\}} \text{ (INVK)}$$

$$\frac{retVal(m) = ret_m}{return x : \{type(x) \triangleleft type(ret_m)\}} \text{ (RET)}$$

$$x = y.f : \{type(f) \triangleleft type(x), type(x) \rightarrow type(y)\} \text{ (REF)}$$

$$x.f = y : \{type(x), type(y) \triangleleft type(f)\} \text{ (SET)}$$

Figure 6-13: Constraint generation rules in presence of parametric types.

Auxiliary functions

Our type generation rules uses the auxiliary function, $bound_{\Delta}$, as previously presented in section 4.1. $bound_{\Delta}(T)$ returns the declared upper bound of T if T is a type variable; if T is not a type variable, T is returned unchanged. In our formulation, we assume access to a global type environment, Δ , that maps type variables to their declared bounds. $bound$ ignores any upper bound or lower bound subscripts present on the type.

As with arrays, our type constraint generation rules use the auxiliary function $type$, which returns the declared type of a reference.

Constraint generation

As with arrays, the constraint generation rules (shown in figure 6-13) use subtyping

```

class Week<X extends /*mutable*/ Date> {
    X f;
    void startWeek() {
        f.setDay(Day.SUNDAY);
    }
}

```

Figure 6-14: The results of applying our type inference to a program containing a mutable type variable bound. Since the field `f` is mutated, `X`'s upper bound is inferred to be `/*mutable*/ Date`. Note that one may not apply the mutable annotation directly to the `f`'s type because a type parameter cannot be annotated as `mutable` (section 3.6.4).

constraints. However, the subtyping rules (shown in figure 6-12) are extended to deal with type variables. A type variable is not allowed to be annotated as mutable (see section 3.6.3); therefore, type variables can not occur in the constraint set. In the case of a type variable appearing in a subtyping constraint, *bound* is used to calculate the upper bound of the type variable and the mutability constraints are applied to the type variable's bound. Therefore, the mutation of a reference whose declared type is a type variable results in the type variable's bound being constrained to be mutable. An example of this behavior is shown in figure 6-14.

Type well-formedness constraints

As with arrays, in addition to the constraints from the constraint generation rules, well-formedness constraints are added to the constraint set. As before, a constraint is added that a type argument's lower bound must be a subtype of the type argument's upper bound. Parametric types, additionally, introduce the well-formedness constraint that a type argument's upper bound is a subtype of the corresponding type variable's declared bound.

Constraint simplification and applying results

As with arrays, subtyping (and contains) constraints are simplified into guarded constraints by removing subtyping constraint from the constraint set and replacing it with the subtyping rule's predicate.

The results of the solved constraint set are applied in the same manner as with arrays.

Limitations

Firstly, Javari does not allow raw types, and, therefore, our analysis is incapable of operating on code that contains raw types.

Secondly, in the case of poorly parameterized code, this approach is not guaranteed to always provide the most general methods⁷, or, therefore, the maximum number of read-only annotations. We are unable to always infer the most general method because in some cases one does not exist. For example, take the Java method below:

```
void addDate(List<Date> l, Date d) {
    l.add(d);
}
```

Three type-correct Javari methods can be inferred (our algorithm as stated above infers the first):

```
addDate(/*mutable*/ List<readonly Date> l, readonly Date d)
addDate(/*mutable*/ List<? readonly Date> l, /*mutable*/ Date d)
addDate(/*mutable*/ List</*mutable*/ Date> l, /*mutable*/ Date d)
```

The last method is strictly less general than the second because the second can be applied to list of read-only elements in addition to lists of mutable elements. However, the first and second methods are incomparable. The first method allows a more general type for `d` because could be applied to `readonly` or `mutable` `Dates`. The second method, on the other hand, allows a more general type for `l` because it can be applied to lists with `readonly`, `mutable`, or `? readonly` type arguments. Thus, neither the first or second method is the most general and, therefore, there does not exist a most general method signature to be inferred.

⁷The most general method is the method that accepts the most types of arguments. For example `foo(readonly Date)` is a more general method than `foo(/*mutable*/ Date)`, because it can take read-only `Dates` in addition to mutable `Date`'s.

However, parameterizing the method would make the method more general than all three of the previous methods:

```
<T extends readonly Date> void addDate(/*mutable*/ List<T> l, T d) {  
    l.add(d);  
}
```

Thus, in the case that programmers follow good method parameterization practices, our algorithm is capable of always providing the most general methods.

6.2 Inferring `readonly`

Our core read-only inference algorithm can be extended to infer the `readonly` keyword. Doing so allows more precise immutability annotations to be inferred.

`readonly` is used to create two versions of a method: a read-only version, which takes a read-only parameter and returns a read-only type, and a mutable version, which takes mutable parameter and returns a mutable type (see section 3). For example, in figure 6-15, the `getSeat` method could be declared to have a `readonly` parameter and return type. Declaring `getSeat` to be `readonly` allows the mutable version to be used by `lowerSeat`, which mutates the returned `Seat` object, and the read-only version to be used by `printSeat`, which does not mutate the returned `Seat` object. Providing both versions of the method is beneficial because it allows a more precise type to be inferred for `printSeat`'s parameter. By using the read-only version of the `getSeat` method, `printSeat`'s parameter may be declared `readonly`, as one would expect, since `printSeat` does not modify its argument. The results of the our analysis when `getSeat` is declared to be `readonly` are shown in figure 6-16.

Without the ability to infer `readonly`, our algorithm would infer that `getSeat` has a mutable return type and a mutable formal parameter. In this case, methods such as `printSeat` will be forced to supply `getSeat` with a mutable argument even though `printSeat` does not mutate the object returned by `getSeat`. The results of this type-safe, but imprecise analysis is shown in figure 6-17.

```

class Bicycle {
    private Seat seat;

    Seat getSeat() {
        return seat;
    }
}

static void lowerSeat(Bicycle b) {
    Seat s = b.getSeat();
    seat.height = 0;
}

static void printSeat(Bicycle b) {
    Seat s = b.getSeat();
    System.out.println(s);
}

```

Figure 6-15: For the above Java code, our analysis should declare the `getSeat` method to have an `romaybe` receiver and return type.

```

class Bicycle {
    private Seat seat;

    romaybe Seat getSeat() romaybe {
        return seat;
    }
}

static void lowerSeat(/*mutable*/ Bicycle b) {
    /*mutable*/ Seat s = b.getSeat();
    seat.height = 0;
}

static void printSeat(readonly Bicycle b) {
    readonly Seat s = b.getSeat();
    System.out.println(s);
}

```

Figure 6-16: Sound and precise Javari code which gives `getSeat` `romaybe` type. `lowerSeat` uses the mutable version of the method while `printSeat` uses the read-only version.

```

class Bicycle {
    private Seat seat;

    /*mutable*/ Seat getSeat() /*mutable*/ {
        return seat;
    }
}

static void lowerSeat(/*mutable*/ Bicycle b) {
    /*mutable*/ Seat s = b.getSeat();
    seat.height = 0;
}

static void printSeat(/*mutable*/ Bicycle b) {
    /*mutable*/ Seat s = b.getSeat();
    System.out.println(s);
}

```

Figure 6-17: Sound but imprecise Javari code, which does not use `romaybe`. `getSeat` is given the imprecise mutable type instead of the precise `romaybe` type.

6.2.1 Approach

We extend our read-only inference algorithm to infer `romaybe` by recognizing that `romaybe` methods have two contexts. In the first context, the `romaybe` return type and `romaybe` parameters are mutable. In the second context, the `romaybe` return type and `romaybe` parameters are read-only. Since our analysis does not know which methods are `romaybe` before executing, it creates both contexts for every method. In the case of a method that should not have `romaybe` parameters, the two contexts are redundant: the mutabilities of parameters from each context will be identical. However, in the case of a method that should have `romaybe` parameters, the parameters will be mutable in the mutable context and read-only in the read-only context.

To create two contexts for a method, we create two constraint variables for every method-local reference (parameters, local variables, and return value). To distinguish each context's constraint variables, we superscript the constraint variables from the read-only context with `ro` and those from the mutable context with `mut`. Constraint variables for fields are not duplicated as `romaybe` may not be applied to fields and, thus, only a single context exists.

$$\frac{\text{this}(m) = \text{this}_m \quad \text{params}(m) = \bar{p} \quad \text{retVal}(m) = \text{ret}_m}{x = y.m(\bar{y}) : \{x^? \rightarrow \text{this}_m^{\text{mut}} \rightarrow y^?, x^? \rightarrow \bar{p}^{\text{mut}} \rightarrow y^?, x \rightarrow \text{ret}_m\}} \text{ (INVK-ROMAYBE)}$$

Figure 6-18: The core algorithm’s INVK rule is replaced by INVK-ROMAYBE, which is used for method invocation in the presence of `romaybe` references.

Constraint generation rules

With the exception of INVK, all the constraint generation rules are the same as before, except now they generate (identical) constraints for constraint variables from both the read-only and mutable versions of the methods. For example, `x = y` now generates the constraints:

$$\{x^{\text{ro}} \rightarrow y^{\text{ro}}, x^{\text{mut}} \rightarrow y^{\text{mut}}\}$$

For shorthand, we write constraints that are identical with the exception of constraint variables’ contexts by superscripting the constraint variables with “?”. For example, the constraints generated by `x = y` can be written as:

$$\{x^? \rightarrow y^?\}$$

The method invocation rule (shown in figure 6-18) must be modified to invoke the mutable version of a method when a mutable return type is needed and to invoke the read-only version otherwise. That is, for the method invocation, `x = y.m(\bar{y})`, the mutable version of the method is used when `x` is mutable. Otherwise, the read-only version of the method is used. The invocation rule checks whether `x` is mutable, and in the case that it is, adds constraints that the actual arguments must be mutable if the formal parameters of the mutable context of the method are mutable. The rule also, without checking the mutability of `x`, adds the constraints that the the actual arguments must be mutable if the formal parameters of the read-only context of the method are mutable. The check can be skipped because it is guaranteed that the parameters of the mutable version of the method are mutable if the parameters of the read-only version of the method are mutable.

The constraints are solved as before.

Interpreting the results of the solved constraint set

Once the constraint set is solved, the results are applied to the program. For method-local references, the two constraint variables from the read-only and mutable method contexts must be mapped to a single method-local Javari type: `read-only`, `mutable`, or `romaybe`.

A reference is declared `mutable`, if both the mutable and read-only context of the reference's constraint variable are found to be in the simplified, unguarded constraint set. A reference is declared `read-only`, if both mutable and read-only contexts of the reference's constraint variable is absent from the constraint set. Finally, a reference is declared `read-only`, if the mutable context's constraint variable is in the constraint set but the read-only constraint variable is not in the constraint set, because the mutability of the reference depends on which version of the method is called.⁸

It is possible for a method to contain `romaybe` references but no `romaybe` parameters. For example, below, `x` and the return value of `getNewDate` could be declared `romaybe`.

```
Date getNewDate() {
    Date x = new Date();
    return x;
}
```

However, `romaybe` references are only allowed, or useful, if the method has a `romaybe` parameter. Thus, if none of a method's parameters are `romaybe`, all the method's `romaybe` references are converted to `mutable` references.

⁸The case that read-only constraint variable is not found in the constraint set but the mutable context's constraint variable is not cannot occur by the design of the `INVK-ROMAYBE` constraint generation rule.

	read-only	mutable	this-mutable	romaybe	? readonly	Total
field	2	0	19	2	0	23
receiver	18	30	N/A	6	0	54
parameter	32	13	N/A	0	0	45
return	4	13	N/A	12	0	29
local	4	48	N/A	2	0	54
Total	60	104	19	22	0	205

Figure 6-19: For each kind of reference in Java (fields, method receivers, parameters, and return values, and local variables), the table shows number of those references declared with a given Javari modifier. In the case of parametric types, each type argument is treated as a separate reference from the top-level type. Thus, `List<Date>` is counted as two references. Note that `romaybe` occurs on two fields. Although not discussed in this paper, `romaybe` can occur on fields of method-local classes.

6.3 Implementation

We have implemented the read-only and `romaybe` inference algorithms as described in this paper as the Javarifier tool. To enable the annotation of library class-files in the absence of source code, Javarifier takes classfiles as input. Javarifier can either output its results to text files or applied the results directly to class files in the form of classfile attributes.

6.4 Evaluation

To evaluate Javarifier we compared Javarifier’s output against hand-annotating the Barnes-Hut (BH) benchmark from the JOlden benchmark suite [11]. The BH benchmark contains 1130 (non-comment, non-whitespace) lines of code among 7 classes. The BH benchmark is written using raw types, therefore, before we hand-annotated or ran Javarifier, we converted the BH source code to use generics.

To evaluate the results of hand-annotation and Javarifier, we produced a set of “ideal” annotations. These annotations were created by comparing the hand annotations against Javarifier’s annotations. Wherever a difference occurred, we further examined the code to determine which annotation was correct. Although it is possible that the hand annotations and Javarifier erred in the same way, we have a high

degree of confidence that the ideal annotations are correct. Figure 6-19 summarizes the ideal results.

Hand annotation of the BH benchmark took 30 minutes and contained 22 (11%) errors. Five of the errors were due to the tedium of the task: the annotater forgot to annotate obviously read-only methods such as `toString`. The remainder of the errors were due not investigating the program sufficiently.

Javarifier was able to annotate the BH benchmark in under three minutes (3.6GHz Pentium 4, 3GB of RAM). Javari's erred in 35 (17%) of cases. The majority of cases (21) were due to Javarifier inferring a field or method's return type to be read-only when it would be reasonable to mutate the reference. In these cases, Javarifier executed as expected: those references were not mutated in the program. However, an inspection of the code shows that it would be reasonable for an unseen client to mutate the references. This is a problem with the closed-world assumption is discussed in section 6.1.2.

The remaining errors were due to our implementation being incomplete.

Chapter 7

Related Work

This paper is an extended version of a previous paper by same author [48]. The main changes from [48] are:

1. Introduction of the `? readonly` keyword for handling this-mutable type arguments (section 3.6.2).
2. An improved core language which handles the `? readonly` keyword (section 4).
3. A type inference to convert Java programs to Javari, including a discussion of a prototype implementation of the analysis (section 6).
4. A discussion of how Javari could be implemented using annotations (section B).

7.1 Javari2004

The Javari language presented in this paper and [48] is an evolutionary improvement of an earlier dialect [5], which we call “Javari2004”.

Experience with 160,000 lines of Javari2004 code indicated that Javari2004 is an easy-to-use language that retains the flavor and style of Java while providing substantial benefits, including improved documentation, extended ability to reason about code, and detecting errors in well-tested code. However, the Javari2004 design is deficient in a number of ways.

1. Conflates notions of assignability and mutability
2. Incompatible with generic types
3. Inflexible multi-dimensional arrays
4. Extra-linguistic macro-expansion templates
5. No support for reflection
6. No formal type rules

The current Javari language corrects these problems. The changes are significant but are relatively small from the point of view of a user: most uses of the language, and its overall character, remain the same.

Distinguishing assignability from mutability

Javari2004's `mutable` keyword declares that a field is both assignable and mutable: there is no way to declare that a field is only assignable or only mutable. Javari's `assignable` and `mutable` keywords (section 3.5.3) highlight the orthogonality of assignability and mutability, and increase the expressiveness of the language. See appendix A for examples of the use of `assignable` and `mutable`.

Generic types

This paper provides a detailed treatment of generic classes that smoothly integrates reference immutability into them. Javari2004 does not support generic classes, though the OOPSLA 2004 paper speculates about a macro expansion mechanism that is syntactically, but not semantically, similar to the way that Java 5 treats type parameters. Java 5 compiles type parameters via type erasure, but Javari2004 treated the mutability parameters (which appeared in the same list as the type parameters) via code duplication; this distinction complicates implementation, understanding, and use.

Javari2004 also proposed that a generic class could declare whether a field whose type is a type parameter is a part of the object's abstract state. We have discovered that such a declaration makes no sense. For a field whose type is a type parameter

to be a part of the object's abstract state, it must be `this-mutable`; however, such a field cannot be `this-mutable` (section 3.2). Javari also disallows type parameters be modified with the `mutable` keyword (section 3.6).

Arrays

As with generic classes, Javari permits programmers to independently specify the mutability of each level of an array (section 3.7). By contrast, Javari2004's specification states: "`readonly int[][]` and `readonly (readonly int[])` are equivalent," forbidding creation of a read-only array of mutable items.

Method templates

Javari2004 integrated the syntax for templating a method over mutability with the syntax for Java 5's generic types. Whether a parameter is intended to be a normal type parameter or a mutability type parameter must be inferred from its usage, greatly complicating a compiler (and the prototype Javari2004 implementation required distinct syntax to ease the compiler's task [4, 5]).

Furthermore, Javari2004 allows declaring a multiple mutability type parameters. As noted in section 5.1, only a single mutability type parameter is sufficient, so Javari uses a much simpler mechanism (`romaybe`) for indicating a variable mutability. This new approach highlights the orthogonality of the Java 5's generic types and Javari's mutability polymorphism for methods. Furthermore, it does not require any run-time representation of the polymorphism.

Reflection

Reflection create objects whose types are not known to the static type checker. In Javari2004 (as in many other proposed type systems for Java), reflection create loopholes in the type system. The current Javari language is sound with respect to reflection by introducing quick, local checks that can be performed at run time. See section 5.2.

Formal type rules

Javari2004's type-checking rules [5, 4] are stated, for the full Javari2004 language (including inner classes and other Java idiosyncrasies) in the semi-formal style of the Java Language Specification [21]. This formulation is natural for many Java programmers, but it unsatisfying to others. This paper formalizes a core calculus for the Javari language. It builds on Wild FJ (WFJ) [22], adding side effects and assignability and mutability type modifiers. By presenting the typing rules for a language that is stripped to the bare essentials, we have made it easier to grasp the key features of Javari. Equally importantly, the formalization can enable a type soundness proof for the Javari type system.

7.2 Other immutability proposals

Many other researchers have noticed the need for a mechanism for specifying and checking immutability. This section discusses other proposals and how ours differs from them.

Similarly to Javari, JAC [23] has a `readonly` keyword indicating transitive immutability, an implicit type `readonly T` for every class and interface `T` defined in the program, and a `mutable` keyword. However, the other aspects of the two languages' syntax and semantics are quite different. For example, JAC provides a number of additional features, such as a larger access right hierarchy (`readnothing < readimmutable < readonly < writeable`) and additional keywords (such as `nontransferrable`) that address other concerns than immutability. The JAC authors propose implementing JAC by source rewriting, creating a new type `readonly T` that has as methods all methods of `T` that are declared with the keyword `readonly` following the parameter list (and then compiling the result with an ordinary Java compiler). However, the return type of any such method is `readonly`. For example, if class `Person` has a method `public Address getAddress() readonly`, then `readonly Person` has method `public readonly Address getAddress() readonly`. In other words, the return type of a method call depends on the type of the receiver expression and may

be a supertype of the declared type, which violates Java's typing rules. Additionally, JAC is either unsound for, or does not address, arrays of `readonly` objects, casts, exceptions, inner classes, and subtyping. JAC `readonly` methods may not change any static field of any class. The JAC paper suggests that `readonly` types can be supplied as type variables for generic classes without change to the GJ proposal, but provides no details. By contrast to JAC, in Javari the return type of a method does not depend on whether it is called through a read-only reference or a non-read-only one. Javari obeys the Java type rules, uses a type checker rather than a preprocessor, and integrates immutability with type parameterization. Additionally, we have implemented Javari and evaluated its usability [5].

The above comments also explain why use of read-only interfaces in Java is not satisfactory for enforcing reference immutability. A programmer could define, for every class `C`, an interface `RO_C` that declares the `readonly` methods and that achieves transitivity through changing methods that returned (say) `B` to return `RO_B`. Use of `RO_C` could then replace uses of Javari's `readonly C`. This is similar to JAC's approach and shares similar problems. For instance, to permit casting, `C` would need to implement `RO_C`, but some method return and argument types are incompatible. Furthermore, this approach does not allow `readonly` versions of arrays or even `Object`, since `RO_Object` would need to be implemented by `Object`. It also forces information about a class to be maintained in two separate files, and it does not address run-time checking of potentially unsafe operations or how to handle various other Java constructs. Javari sidesteps these fundamental problems by extending the Java type system rather than attempting to work within it.

Skoglund and Wrigstad [43] take a different attitude toward immutability than other work: "In our point of [view], a read-only method should only protect its enclosing object's transitive state when invoked on a read reference but not necessarily when invoked on a write reference." A `read` (read-only) method may behave as a `write` (non-read-only) method when invoked via a `write` reference; a `caseModeOf` construct permits run-time checking of reference writeability, and arbitrary code may appear on the two branches. This suggests that while it can be proved that read

references are never modified, it is not possible to prove whether a method may modify its argument. In addition to read and write references, the system provides `context` and `any` references that behave differently depending on whether a method is invoked on a read or write context. Compared to this work and JAC, Javari’s type parameterization gives a less ad hoc and more disciplined way to specify families of declarations.

The functional methods of Universes [31] are pure methods that are not allowed to modify anything (as opposed to merely not being allowed to modify the receiver object).

Pechtchanski and Sarkar [36] provide a framework for immutability specification along three dimensions: lifetime, reachability, and context. The lifetime is always the full scope of a reference, which is either the complete dynamic lifetime of an object or, for parameter annotations, the duration of a method call. The reachability is either shallow or deep. The context is whether immutability applies in just one method or in all methods. The authors provide 5 instantiations of the framework, and they show that immutability constraints enable optimizations that can speed up some benchmarks by 5–10%. Javari permits both of the lifetimes and supplies deep reachability, which complements the shallow reachability provided by Java’s `final` keyword.

Capabilities for sharing [10] are intended to generalize various other proposals for immutability and uniqueness. When a new object is allocated, the initial pointer has 7 access rights: read, write, identity (permitting address comparisons), exclusive read, exclusive write, exclusive identity, and ownership (giving the capability to assert rights). Each (pointer) variable has some subset of the rights. These capabilities give an approximation and simplification of many other annotation-based approaches.

Porat et al. [37] provide a type inference that determines (deep) immutability of fields and classes. (Foster et al. [18] provide a type inference for C’s (non-transitive) `const`.) A field is defined to be immutable if its value never changes after initialization and the object it refers to, if any, is immutable. An object is defined to be immutable if all of its fields are immutable. A class is immutable if all its instances are. The analysis

is context-insensitive in that if a type is mutable, then all the objects that contain elements of that type are mutable. Libraries are neither annotated nor analyzed: every virtual method invocation (even `equals`) is assumed to be able to modify any field. The paper discusses only class (static) variables, not member variables. The technique does not apply to method parameters or local variables, and it focuses on object rather than reference immutability, as in Javari. An experiment indicated that 60% of static fields in the Java 2 JDK runtime library are immutable. This is the only other implemented tool for immutability in Java besides ours, but the tool is not publicly available for comparison.

Effect systems [25, 46, 33] specify what state (in terms of regions or of individual variables) can be read and modified by a procedure; they can be viewed as labeling (procedure) types with additional information, which the type rules then manipulate. Type systems for immutability can be viewed as a form of effect system. Our system is finer-grained than typical effect systems, operates over references rather than values, and considers all state reachable from a reference.

Our focus in this paper is on imperative object-oriented languages. In such languages, fields are mutable by default. In our type system, when a type is read-only, the default is for each field to be immutable unless the user explicitly marks it as mutable. Functional languages such as ML [28] use a different policy: they default all fields to being immutable. OCaml [24] combines object-orientation with a `mutable` annotation on fields (for example, references are implemented as a one-field mutable record). However, without a notion of read-only types, users are forced to hide mutability via use of interfaces and subtyping, which is less flexible and expressive than our proposal.

A programming language automatically provides a sort of immutability constraint for parameters that are passed, or results that are returned, by value. Since the value is copied at the procedure call or return, the original copy cannot be modified by the implementation or client, respectively. Pass- and return-by-value is typically used for values that are small. Some programming languages, such as Pascal and Ada, permit variables to be explicitly annotated as in, out, or in/out parameters; this is an early

and primitive form of compiler-enforced immutability annotation.

7.3 C++ `const`

C++'s `const` keyword is intended to aid in interfaces, not symbolic constants [45]. Our motivation is similar, but our notion of immutability, and our type system, differ from those of C++, thus avoiding the pitfalls that led Java's designers to omit `const`.

Because of numerous loopholes, the `const` notation in C++ does not provide a guarantee of immutability even for accesses through the `const` reference. An unchecked cast can remove `const` from a variable, as can (mis)use of type system weaknesses such as unions and varargs (unchecked variable-length procedure arguments).

C++ permits the contents of a read-only pointer to be modified: read-only methods protect only the local state of the enclosing object. To guarantee transitive non-mutability, an object must be held directly in a variable rather than in a pointer. However, this precludes sharing, which is a serious disadvantage. Additionally, whereas C++ permits specification of `const` at each level of pointer dereference, it does not permit doing so at each level of a multi-dimensional array. Finally, C++ does not permit parameterization of code based on the immutability of a variable.

By contrast to C++, Javari is safe: its type system contains no loopholes, and its downcast is dynamically checked. Furthermore, it differs in providing guarantees of transitive immutability, and in not distinguishing references from objects themselves; these differences make Javari's type system more uniform and usable. Unlike C++, Javari permits mutability of any level of an array to be specified, and permits parameterization based on mutability of a variable. Javari also supports Java features that do not appear in C++, such as nested classes.

Most C++ experts advocate the use of `const` (for example, Meyers advises using `const` wherever possible [26]). However, as with many other type systems (including those of C++ and Java), some programmers feel that the need to specify types outweighs the benefits of type checking. At least three studies have found that static

type checking reduces development time or errors [30, 20, 38]. We are not aware of any empirical (or other) evaluations regarding the costs and benefits of immutability annotations. Java programmers seem eager for compiler-checked immutability constraints: as of March 2005, support for `const` is the second most popular Java request for enhancement. (See http://bugs.sun.com/bugdatabase/top25_rfes.do. The most popular request is “Provide documentation in Chinese.”)

A common criticism of `const` is that transforming a large existing codebase to achieve `const` correctness is difficult, because `const` pervades the code: typically, all (or none) of a codebase must be annotated. This propagation effect is unavoidable when types or externally visible representations are changed. Inference of `const` annotations (such as that implemented by Foster et al. [18]) eliminates such manual effort. Even without a type inference, we found the work of annotation to be greatly eased by fully annotating each part of the code in turn while thinking about its contract or specification, rather than inserting partial annotations and attempting to address type checker errors one at a time. The proper solution, of course, is to write `const` annotations in the code from the beginning, which takes little or no extra work.

Another criticism of C++’s `const` is that it can occasionally lead to code duplication, such as the two versions of `strchr` in the C++ standard library. Mutability templates (section 5.1) make the need for such duplication rare in Javari. Finally, the use of type casts (section 5.3.5) permits a programmer to soundly work around problems with annotating a large codebase or with code duplication.

7.4 Related analyses

Reference immutability can help to prevent an important class of problems, in a simple and intuitive way. However, it is no panacea. Other techniques can address some of these issues, and there are many software engineering challenges that reference immutability does not address. We mention just a sample of other techniques.

Boyland [9] observes that mutational representation exposure (in which external code can corrupt a data structure) and observational exposure (in which external

code can observe an internal representation changing) are duals: in each case, modifications on one side of an abstraction boundary are observable on the other. Reference immutability does not address observational exposure. Boyland argues that a language extension should not solve one of these problems without also solving the other. However, the problems are arguably different, since the latter is a result of a client improperly retaining a reference “too long,” and even a value returned from `size()` may become out of date if it is retained too long (though it will never become an invalid integer). Mechanisms for solving all representation exposure problems are less mature, and it may be valuable to solve some important problems without solving them all.

Ownership types [12, 3, 7] provide a compiler-checked mechanism for preventing aliasing to the internal state of an object. As noted previously, alias, escape, and ownership analyses can enhance reference immutability. However, they do not directly address issues of immutability, including those not associated with abstraction boundaries. Ownership type annotations such as `rep` describe whether a reference is part of the object’s state, whereas mutability annotations such as `readonly` indicate whether it can be modified; each approach has its advantages, and it would be interesting to combine them. Fractional permissions [8] are another mechanism for helping to avoid representation exposure. Finally, a type system based on linear logic [50, 16] can prevent multiple uses of a value, which may be useful, for example, when preventing representation exposure through constructor arguments.

Effect analyses for Java and in general [13, 41, 39, 40, 32, 27] have been widely studied. An effect analysis returns the set of references that initially refer to objects that are not mutated in a given scope such as a particular method invocation. Similar to our algorithm’s read-only parameters, effect analysis can be used to determine which method parameters are “safe”[42]. A method parameter is safe if the method never modifies the object passed to the parameter during method invocation. Unlike read-only references, a parameter is not safe if the method mutates the object to which the parameter refers through a different aliasing reference. An example of this difference is shown in figure 7-1. On the other hand, if a safe parameter is reassigned

```

/** Copies of the day of d1 into d2. */
void copyDay(readonly /*unsafe*/ Date d1, /*mutable, unsafe*/ Date d2) {
    d2.setDay(d1.getDay());
}

Date d = new Date();
copyDate(d, d);

```

Figure 7-1: In the presence of the method invocation shown, `copyDay`'s `d1` parameter is read-only but not safe. Effect analysis determines `d1` to be unsafe because of the method invocation shown passes the same `Date` object to both parameters; thus, the object referred to by `d1` is mutated through the alias `d2`. The read-only-ness of method parameters, as expected for type system, can not be affected by the particular manner in which the method is invoked.

```

/** Returns a copy of d with the month set to m */
Date copy(/*mutable*/ /*safe*/ Date d, readonly /*safe*/ Month m) {
    d = new Date(d); // Assume copy-constructor's parameter is read-only and safe.
    d.setMonth(m);
    return d;
}

```

Figure 7-2: `d` is safe because any object passed to `d` will not be modified; however, `d` is not read-only because it is used to modify a different object—the newly created `Date` returned by the method.

with a different object, the parameter remains safe even if it mutates that object. A read-only parameter, on the other hand, may not be used to mutate any object. This difference is shown in figure 7-2 Safety and read-only-ness are orthogonal: safety is a property over objects while read-only-ness is a property over references.

Additionally, our algorithm has a much lower complexity than effect-analyses, which must be context-sensitive to achieve reasonable precision.

Chapter 8

Conclusion

We have presented a type system that is capable of expression, compile-time verification, and run-time checking of reference immutability constraints. Reference immutability guarantees that the reference cannot be used to perform any modification of a (transitively) referred-to object. The type system should be generally applicable to object-oriented languages, but for concreteness we have presented it in the context of Javari, an extension to the full Java 5 language, including generic types, arrays, reflection, serialization, inner classes, exceptions, and other idiosyncrasies. Immutability polymorphism (templates) for methods are smoothly integrated into the language, reducing code duplication. We have provided a set of formal type rules for a core calculus that models the Javari language.

Javari provides a practical and effective combination of language features. For instance, we describe a type system for reference rather than object immutability. Reference immutability is useful in more circumstances, such as specifying interfaces, or objects that are only sometimes immutable. Furthermore, type-based analyses can run after type checking in order to make stronger guarantees (such as object immutability) or to enable verification or transformation. The system is statically type-safe, but optionally permits downcasts that transform compile-time checks into run-time checks for specific references, in the event that a programmer finds the type system too constraining. The language is backward compatible with Java and the Java Virtual Machine, and is interoperable with Java. Together with substantial

experience with a prototype for a closely related dialect [5], these design features provide evidence that the language design is effective and useful.

Additionally we have designed and implemented an analysis to convert Java programs to Javari. This analysis is necessary for converting legacy programs and libraries such as the JDK to Javari. Experience with the analysis indicates that Javari is practical type system is practice.

Appendix A

Assignability and Mutability

Examples

As shown in figure 3-6, each instance field can be declared with one of three assignabilities (assignable, unassignable, or this-assignable) and also with one of three mutabilities (mutable, read-only, and this-mutable). This appendix illustrates the use of Javari's reference immutability system through examples of all nine possibilities. As with the rest of this paper, we omit most visibility modifiers (`public`, `private`, ...) for brevity. Furthermore, for brevity this appendix does not explicitly address uses of type parameters.

A.1 this-assignable, this-mutable

This is the standard type for a field in a possibly-mutable class. All fields not declared `final` in Java code are interpreted as this type.

Suppose there is a class `Wheel` that is mutable (its pressure can change) and a class `Bicycle` that contains two `Wheels` that may be changed (different wheels for different terrains).

```
class Wheel {
    int pressure;
}
```

```
class Bicycle {
    Wheel frontWheel;
    ...
}
```

A read-only reference to a `Bicycle` cannot be used to modify the `Bicycle` by reassigning `frontWheel` or mutating `frontWheel` by reassigning `pressure`. A mutable reference can modify `Bicycle` by reassigning `frontWheel` or changing its `pressure`.

A.2 `final`, `this-mutable`

Consider a file abstraction that contains a `StringBuffer` holding the contents of the file.

```
class MyFile {
    final StringBuffer contents;
}
```

The contents of a read-only file cannot be changed. `contents` should not be reassigned, and `StringBuffer` operations can be used to alter mutable files' contents as needed.

A.3 `assignable`, `this-mutable`

`assignable` fields can be used for caching. In the case of an `assignable this-mutable` field, it is caching an object that is `this-mutable`. For example, recall the `Bicycle` example from above. Suppose one wished to provide a method that returned the wheel with the greatest aerodynamic drag. If this method was costly to execute, one would wish to cache the result until one of the `wheels` changed.

```
class Bicycle {
    Wheel frontWheel;
    Wheel backWheel;
```

```

private assignable Wheel mostDrag;
romaybe Wheel mostDrag() romaybe {
    if (mostDrag == null || /*wheels have changed*/) {
        mostDrag = ...;
    }
    return mostDrag;
}
}

```

Even when the reference to the `Bicycle` is read-only, `mostDrag` can be assigned with the result of the method. The cache and what it is caching—one of the `Wheels`—are `this-mutable`.

A.4 `this-assignable`, `readonly`

Consider a class, `ChessPiece`, that represents a chess piece including the piece’s position on a board. The position field, `pos`, should be modifiable for mutable references but not for read-only references. If the programmer wishes to reassign `pos`, instead of mutating the object assigned to the field, each time the piece is moved, then the field should be declared to be `this-assignable` and `read-only`.

```

class ChessPiece {
    readonly Position pos;

    readonly Position getPosition() readonly {
        return pos;
    }

    void setPosition(readonly Position pos) {
        this.pos = pos;
    }
}

```

A.5 `final`, `readonly`

`final` `readonly` fields are useful for state that should never change, including constants. A `ChessPiece`’s color should never change.

```

class ChessPiece {
    final readonly Color color;
}

```

A.6 assignable, readonly

Suppose that `ChessPiece` has a costly method, `bestMove`, that returns the best possible move for that piece. Since the method is costly, one would like the method to cache its result in case it is called again (before anything on the board has altered). Calling the `bestMove` method does not change the abstract state of the class, so it should be a `readonly` method. However, to allow the `bestMove` method to assign to the field that caches its result, the field must be declared `assignable`. Furthermore, since there is never a reason to mutate the position calculated, the field should be declared `readonly` to avoid programmer error.

```

class ChessPiece {
    private assignable readonly Position bestMove;
    readonly Position bestMove() readonly {
        if ((bestMove == null) || /* board changed */) {
            bestMove = ...;
        }
        return bestMove;
    }
}

```

A.7 this-assignable, mutable

Suppose one wishes to represent a set by an array and, for efficiency, move the last successfully queried item to the beginning of the array. The author must declare the array to be `mutable` to allow moving the last successfully queried item to the beginning of the array even when the set is read-only. The array must be declared `this-assignable` to allow reassigning the array when it reaches its capacity due to calls to `addElem`.

```

class MoveToFrontSet {
    private mutable Object[] elms;
    private int size;
    boolean contains(Object obj) readonly {
        for (int i = 0; i < size; i++) {
            if (elms[i].equals(obj)) {
                // should also check for null
                moveToFront(elms, i);
                return true;
            }
        }
        return false;
    }

    // Be sure to not declare method readonly
    void add(Object elm) {
        if (elms.length == size) {
            Object[] tmp = new Object[2*elms.length];
            for (int i = 0; i < elms.length; i++) {
                tmp[i] = elms[i];
            }
            elms = tmp;
        }
        elms[size] = elm;
        size++;
    }

    // Be sure to return readonly Object[]
    readonly Object[] toArray() readonly {
        return elms;
    }
}

```

The order that the elements appear in `elms` is not a part of the abstract state of the `Set` object; however, the fact that they are contained by the array assigned to `elms` is a part of the abstract state. This relationship is too complicated for the type system to capture, so the field must be declared `mutable`.

`elms` must be `mutable` so that the elements can be rearranged even when the instance of `Set` is read-only. Unfortunately, methods that add or delete elements could be declared `readonly` and still type check. Therefore, when writing code such as this, the programmer must be careful not to declare those methods read-only and to ensure that a mutable reference to `elms` does not escape.

A.8 final, mutable

Suppose one wishes to monitor the users who access a file. A simple way to do this is to require a user ID to be passed as an argument to the file's accessors and then record the ID in a set.

```
class File {
    final mutable Set<UserID> accessedFile;
    StringBuffer contents;

    readonly StringBuffer
    getContents(UserID id) readonly {
        accessed.add(id);
        return contents;
    }
}
```

The set `accessedFile` must be mutable so that a users ID may be added to it within the read-only method `getContents`.

A.9 assignable, mutable

Consider an implementation of a splay tree [44]:

```
class SplayTree<T extends readonly Comparable> {

    // The internal representation of a splay tree
    assignable mutable BinarySearchTreeNode<T> root;

    // Adjusts the tree so that newRoot becomes the root.
    splay(BinarySearchTreeNode newRoot) { ... }

    void insert(T val) { root.insert(val); }
    void delete(T val) { root.delete(val); }

    boolean find(T val) readonly {
        BinarySearchTreeNode node = root.find(val);
        if (node == null) {
            return false;
        } else {
```

```
        splay(node);
        return true;
    }
}
```

In this example `assignable` and `mutable` are used because the type system is unable to capture how the abstract state of the class relates to its data structure at the field `root`. Without the `assignable` keyword, the `root` of the tree could not be reassigned by the `splay` method. The `mutable` keyword is also needed because the `splay` method needs to mutate the nodes rooted at `root` while rearranging the nodes within the tree.

Appendix B

Annotations

It is impractical to implement reference immutability using Java's current annotation system. Alternatively, Javari can be implemented using new keywords (as assumed in the description of the language up to this point) or through an extended annotation system. This section discusses the issues involved. We believe that Javari should either use all keywords or all annotations; it would be confusing, and would offer little benefit, to mix the two.

Use of annotations is attractive. It ensures that Javari code is valid Java code. This guarantees interoperability with existing tools: Javari code can be compiled using any Java compiler, then run either by a JVM whose byte code verifier checks the immutability types encoded in the annotations, or by any JVM (losing the benefits of immutability checking). The Javari system could additionally work as a stand-alone type-checker. There would be no worries about breaking existing code that uses Javari keywords as identifiers. Avoiding changes to the programming language could encourage programmers to adopt Javari.

Unfortunately, the current Java annotation system is too weak to use to implement a reference immutability system. There are two main problems.

1. Annotations can only be applied to type declarations, not to other uses of types.
 - (a) Annotations cannot be applied to a cast.
 - (b) Annotations cannot be applied to the receiver (`this`) of a method. This

could be worked around with a new annotation such as `@rothis`, which is syntactically applied to the method return type but semantically applies to the receiver type.

(c) Annotations cannot be inserted at arbitrary locations within arrays. To express “`(readonly Date[]) [] []`”, one would need to write something like the (unintuitive) annotation `@readonly(2) Date[] [] []` where the integer argument to the annotation indicates at what level the read-only modifier should be applied.

(d) Annotations are not permitted on type parameters, so expressing this type would be difficult:

```
Map<List<readonly Date>, readonly Set<Number>>.
```

2. Annotations on local variables are not recorded within the classfile by the `javac` compiler. Therefore, if we wish to use annotations and perform type checking on classfiles, we would be required to extend the annotation system. This would require changing the compiler, possibly by recording local variables’ annotations within the local variable symbol table. A compiler change eliminates one of the benefits of using annotations: not requiring people to use a new compiler to check reference immutability constraints. (But the Javari code would remain backward-compatible with other Java compilers.)

Currently, there is work on extending Java’s annotation system to overcome the limitations discussed above [35]. If such an extended annotation system was adopted, it would be practical to implement Javari in terms of annotations.

A language change could still achieve backward compatibility with standard Java compilers by providing a special comment syntax where any comment that begins with “`/*=`” is considered as part of the code by the Javari compiler. (This approach was taken in `LCLint` [15], for example.) This feature allows the programmer to annotate an existing Java program with Javari’s keywords without losing the ability to compile that program with a normal Java compiler. That comment mechanism could be supported by external tools, but should not be part of Javari proper.
