Edited by Zdeněk P. Bažant, Northwestern University, Evanston, IL, and approved July 21, 2009 (received for review February 27, 2009)

Despite decades of studies of calcium-silicate-hydrate (C-S-H), the structurally complex binder phase of concrete, the interplay between chemical composition and density remains essentially unexplored. Together these characteristics of C-S-H define and modulate the physical and mechanical properties of this “liquid stone” gel phase. With the recent determination of the calcium/silicon (C/S = 1.7) ratio and the density of the C-S-H particle (2.6 g/cm<sup>3</sup>) by neutron scattering measurements, there is new urgency to the challenge of explaining these essential properties. Here we propose a molecular model of C-S-H based on a bottom-up atomistic simulation approach that considers only the chemical specificity of the system as the overriding constraint. By allowing for short silica chains distributed as monomers, dimers, and pentamers, this C-S-H archetype of a molecular description of interacting CaO, SiO<sub>2</sub>, and H<sub>2</sub>O units provides not only realistic values of the C/S ratio and the density computed by grand canonical Monte Carlo simulation of water adsorption at 300 K. The model, with a chemical composition of (CaO)<sub>1.65</sub>(SiO<sub>2</sub>)(H<sub>2</sub>O)<sub>1.75</sub>, also predicts other essential structural features and fundamental physical properties amenable to experimental validation, which suggest that the C-S-H gel structure includes both glass-like short-range order and crystalline features of the mineral tobermorite. Additionally, we probe the mechanical stiffness, strength, and hydrolytic shear response of our molecular model, as compared to experimentally measured properties of C-S-H. The latter results illustrate the prospect of treating cement on equal footing with metals and ceramics in the current application of mechanism-based models and multiscale simulations to study inelastic deformation and cracking.

atomistic simulation | mechanical properties | structural properties

By mixing water and cement, a complex hydrated oxide called calcium-silicate-hydrate (C-S-H) precipitates as nanoscale clusters of particles (1). Much of our knowledge of C-S-H has been obtained from structural comparisons with crystalline calcium silicate hydrates, based on HFW Taylor’s postulate that real C-S-H was a structurally imperfect layered hybrid of two natural mineral analogs (2): tobermorite of 14-Å interlayer spacing [Ca<sub>5</sub>Si<sub>6</sub>O<sub>16</sub>(OH)<sub>2</sub>·7H<sub>2</sub>O, (3)] and jennite [Ca<sub>9</sub>(Si<sub>6</sub>O<sub>18</sub>)(OH)<sub>6</sub>·8H<sub>2</sub>O (4)]. While this suggestion is plausible in morphological terms, this model is incompatible with two basic characteristics of real C-S-H; specifically the calcium-to-silicon ratio (C/S) and the density. Recently, small-angle neutron scattering measurements have fixed the C/S ratio at 1.7 and the density at 2.6 g/cm<sup>3</sup> (1), values that clearly cannot be obtained from either tobermorite (C/S = 0.83, 2.18 g/cm<sup>3</sup>) or jennite (C/S = 1.5 and 2.27 g/cm<sup>3</sup>). From the standpoint of constructing a molecular model of C-S-H, this means that these crystalline minerals are not strict structural analogs. Here we adopt the perspective that the chemical composition of C-S-H is the most essential property in formulating a realistic molecular description. We show that once the C/S ratio is described correctly, a number of characteristic structural features and physical properties follow naturally in atomistic simulations. We view the present model and its subsequent refinements as enabling a bottom-up perspective on the broad science of cementitious materials and the innovative engineering of concrete. Manipu-

lation of such a testable model should ultimately allow the establishment of the critical links between nanoscale microstructure and macroscale behavior, which requires fundamental understanding of the effects of confined water in the context of creep and durability.

**Model Construction.** One of the key issues in designing a realistic C-S-H molecular model is the calcium-to-silicon ratio (C/S). Indeed, confirming earlier measurements by Groves et al. (6) and Richardson and Groves (7), energy dispersive X-ray analyses of C-S-H in hardened Portland cement pastes aged 1 day to 3.5 years reveal a composition variation spanning C/S from approximately 1.2 to 2.3 with a mean value of 1.7; this variation also depends on the water-to-cement (W/C) mass ratio at which cement is hydrated (5). Given the shortfalls of the natural analogs, tobermorite and jennite, to meet this compositional constraint, Richardson proposed a two-fold classification to clarify C-S-H chemistry (5). This classification references so-called tobermorite/jennite (T/J) models on one hand and tobermorite-calcium hydroxyle (T/CH) models on the other hand. The T/CH class considers models that are solid solutions of tobermorite layers sandwiching calcium hydroxide, hence providing a means to achieve a higher C/S ratio than the one of tobermorite. The T/J class considers C-S-H as an assembly of tobermorite regions followed by jennite domains. While the T/CH class was found to be relevant for hydrated KOH-activated metakaolin Portland cement, more common water activated Portland cement pastes can be only partly described by the T/J or the T/CH approaches. A realistic model for C-S-H that predicts a realistic C/S ratio thus remains a center piece of any model construction. Furthermore, quantitative information on the fractions of Si present in silicate tetrahedra with different connectivities is provided by <sup>29</sup>Si nuclear magnetic resonance (NMR) (8, 9). Such studies have established that the dimer is the most predominant of all silicate species, with the linear pentamer as the second most abundant. Tetrahedral coordination measured by NMR is expressed in terms of the Q<sub>n</sub> factor, denoting the fractional chemical shift of a silicon atom bound to n bridging oxygens. Thus Q<sub>0</sub> is the fraction of a single tetrahedron (a silicate monomer), Q<sub>1</sub> the fraction of tetrahedra at the end of a chain (a silicate dimer would have two Q<sub>1</sub>), Q<sub>2</sub> the fraction of tetrahedra in the middle of a chain (a silicate pentamer would have three Q<sub>2</sub>).

To construct a molecular model of C-S-H that has a C/S ratio consistent with small-angle neutron scattering measurements, we begin with a monoclinic periodic computational cell of dry

tobermorite of interlayer spacing of approximately 11 Å, with 4, 2, and 1 units along axes *a*, *b*, and *c* with a unit cell chemical formula of  $\text{Ca}_6\text{Si}_6\text{O}_{16}$ . The cell contains two CaO layers lying in the *ab* plane, and eight silicate chains (2 chains each on top and bottom side of each layer). In this initial configuration the C/S ratio is 1.0; note that with this value of C/S, the layers are not electroneutral and there are interlayer calcium ions to maintain electroneutrality. We then remove  $\text{SiO}_2$  (neutral) groups in silica tetrahedra guided by the NMR results,  $Q_0 \sim 10\%$ ,  $Q_1 \sim 67\%$ , and  $Q_2 \sim 23\%$  (10), obtaining a defective C-S-H structure that has a distribution of  $Q_0 = 13\%$ ,  $Q_1 = 67\%$ , and  $Q_2 = 20\%$ , with a C/S ratio of 1.65. There are likely other ways to produce defected silicate chains that are consistent with the NMR constraints; we are currently investigating a combinatorial approach. Our procedure was carried out without the presence of any OH groups, so that a reasonable C/S ratio could be obtained under the electroneutrality constraint (11). After the silicate chain modification, we relax the dry cell using the core-shell potential model at 0 K to find a density of 2.12 g/cm<sup>3</sup>, the interlayer distance having shifted slightly to 11.3 Å (see *Methods*). At this stage, one can observe significant distortion of the layer structure. We next performed Grand Canonical Monte Carlo simulation of water adsorption in the above defected unit cell, coupling the system to an external reservoir at a chemical potential corresponding to liquid water at 300 K (see *Methods*). At equilibrium, the adsorbed water increases the density to 2.56 g/cm<sup>3</sup>, which is close to the experimental value provided by neutron scattering of 2.6 g/cm<sup>3</sup> (1). We regard this agreement, which was an outcome rather than an input or constraint to this model, to be a significant consistency check on our model development procedure. Further relaxation at 0 K of this hydrated C-S-H model yields a slight increase of the interlayer spacing from 11.3 Å to 11.9 Å, reducing the density by 4% to 2.45 g/cm<sup>3</sup>; molecular dynamics simulations under constant pressure and temperature (NPT-MD) give the same result (see *Methods*). In the final model, one can observe water molecules adsorbed in cavities inside the calcium oxide layers as a result of relaxation. While the amount of water is similar to that present in the interlayer region of 14-Å tobermorite, the water in our model is adsorbed not only in the interlayer regions, but also in the distorted intralayer regions around the silica monomers. As a consequence of water adsorption the density increases to 2.56 g/cm<sup>3</sup>, with the adsorbed water molecules being in an ultra-high confining environment. This water may be regarded as part of the structure, reminiscent of structural water or bound water in cement chemistry terminology. The overall chemical composition of the computational model of the hydrated C-S-H is thus found to be  $(\text{CaO})_{1.65}(\text{SiO}_2)(\text{H}_2\text{O})_{1.75}$ , which is in reasonable agreement with the neutron scattering experiments  $(\text{CaO})_{1.7}(\text{SiO}_2)(\text{H}_2\text{O})_{1.8}$  (1). The molecular configuration of this model is shown in Fig. 1; and all cell parameters and atomic positions of our model are provided in the SI (see also *Methods*).

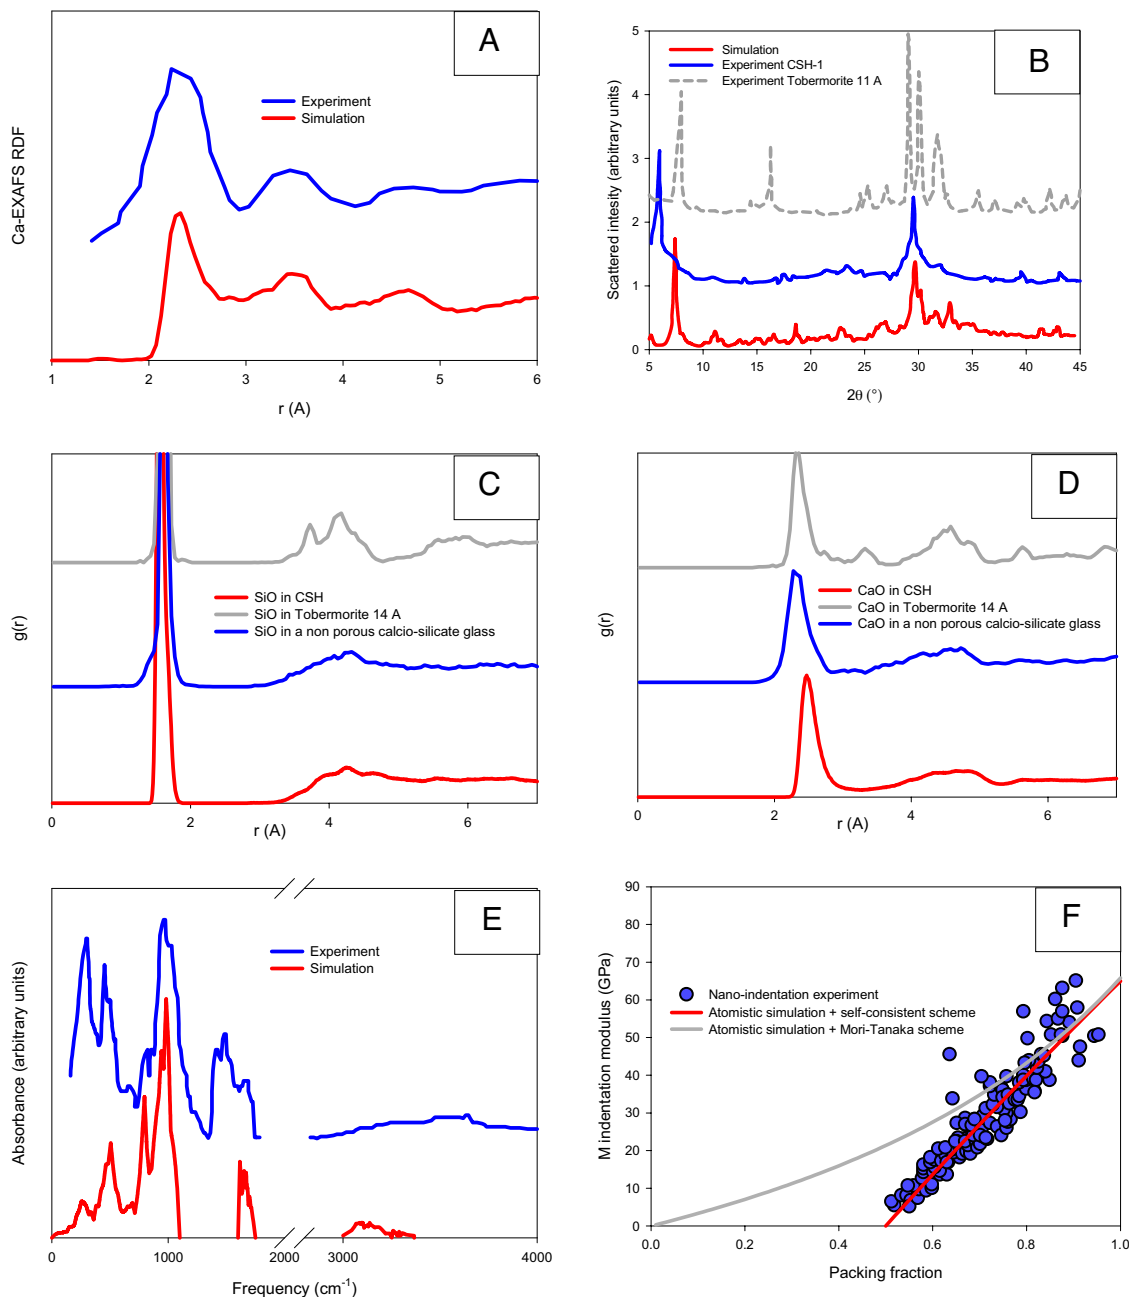

**Model Validation Against Experiments.** We validated the structure of our model by calculating several experimentally accessible properties. The results, summarized in Fig. 2, consist of extended X-ray absorption fine structure (EXAFS) spectroscopy signals measuring short-range order around Ca atoms (Fig. 2*A*), longer range correlations revealed in X-ray diffraction intensity (Fig. 2*B*), vibrational density of states measured by infrared spectroscopy (Fig. 2*E*), and nanoindentation measurements of elastic properties (Fig. 2*F*). The various tests provide strong evidence of a short-range structural disorder, the hallmark of a glassy phase. For instance, the simulated and experimental Ca total pair distribution functions as measured in EXAFS (Fig. 2*A*), agree well, showing peaks at the same inter-atomic distances with same relative intensities that allow discriminating C-S-H against all other calcio-silicate crystalline solids (12). The fact

**Fig. 1.** (A) TEM image of clusters of C-S-H (courtesy of A. Baronnet, CINaM, CNRS and Marseille Université, France), the inset is a TEM image of tobermorite 14 Å from (45). (B) the molecular model of C-S-H: the blue and white spheres are oxygen and hydrogen atoms of water molecules, respectively; the green and gray spheres are inter and intra-layer calcium ions, respectively; yellow and red sticks are silicon and oxygen atoms in silica tetrahedra.

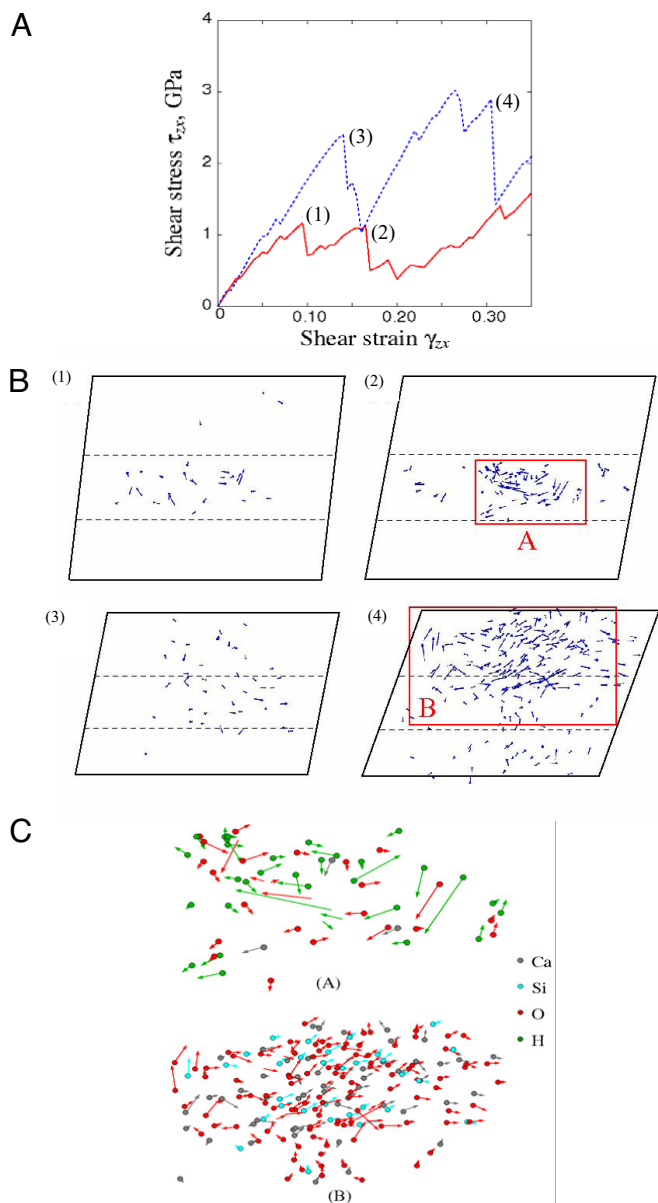

that the first peak in the experimental EXAFS signal is broader than that obtained in simulation suggests that real C-S-H may exhibit an even larger volume fraction of short-range structural disorder. The x-ray diffractogram of our C-S-H model (Fig. 2*B*) clearly indicates the reduced degree of crystallinity as compared with tobermorite. The suggestion that our C-S-H model can be seen as a glassy phase at short length scales is confirmed by a comparison of the partial pair distribution functions  $g(r)$  of our C-S-H model with that of a true non-porous calcio-silicate glass at room temperature with the same C/S ratio and a density of 2.34 g/cm<sup>3</sup> (Fig. 2*C* and *D*): the structure of the second peaks in the  $g(r)$  for Si-O and Ca-O pairs in tobermorite show characteristic structural features that are absent for both the calcium-silicate glass and our C-S-H model. For the sake of consistency, the Ca-glass and crystalline tobermorite simulations were carried out with the same empirical potential model (see *Methods*), with the Ca-glass potential obtained by following the method given in (13). We may interpret this comparison to indicate that C-S-H should be considered as a glass on the short range of distances associated with the distorted intralayer structure, while retaining some layered crystal features at longer range of distances associated with the interlayer spacing.

The comparison between simulation and experimental infrared spectra (Fig. 2*E*), allows further characterization of our model. Note that calculated infrared intensities were obtained from the relaxed model C-S-H structure by performing a numerical integration over the sampled phonon modes (14). All of the experimental bands are present in the calculated spectrum

**Fig. 3.** (A) Relationships between the shear stress  $\tau_{zx}$  and the strain  $\gamma_{zx}$  for the C-5-H model with (solid line) and without (dashed line) water molecules. (B) Atom displacements at the stress drops (1)–(4) in panel (A). Only atoms with displacement larger than 0.5 Å are shown, and the arrows indicate the displacements. pressive strength of  $\alpha$ -quartz (28). Simulations of water-silica interactions have identified three distinct competing mechanisms in the water attack on the siloxane bridging bond, Si-O-Si (29). Since we do not allow dissociation in our interatomic potential description, further considerations of this mechanism will be facilitated by first-principles MD studies of this C-S-H model.

In summary, our study provides an atomistic-level structural model for C-S-H, developed from a bottom-up perspective and validated against several experimental analyses of structure and properties. This model could enable many opportunities for future developments focused on understanding fundamental deformation mechanisms, diffusive properties, electrical properties and many other characteristic material parameters. C-S-H

is the primary hydration product and binding phase of concrete, the synthetic material currently produced in volumes larger than any other material on Earth. The insight gained by deformation simulations based on our C-S-H model (Fig. 3) illustrates the prospect of treating cementitious composites on equal footing with less structurally complex materials. The knowledge of unit deformation mechanisms (in analogy to dislocations, shear bands, etc.) in concrete could enable the development of mechanism-based models and multiscale simulation methods to study inelastic deformation, flow, and fracture to complement and improve current empirical strength models of this complex yet ubiquitous material. The existence of an atomistic level model of the C-S-H nanostructure is crucial to enable advances in our understanding of how specific structural arrangements at the nanoscale relate to resulting material properties. In a broader context, the approach illustrated here to carry out an experimentally validated structural prediction of a complex heteronanocomposite could be applied to many other systems such as colloids, hydrated polymer or protein gels, as well as polymer nanocomposites.

## Methods

**From Energy Minimization to Elastic Properties Using Empirical Interatomic Potentials.** All calculations were carried out with the GULP code (28–30). These calculations were performed using a set of empirical but transferable interatomic potentials calibrated on quartz and CaO compounds. Anions (here oxygens in tobermorite layers and in water molecules) were modeled as polarizable species using the core-shell model. These transferable empirical interatomic potentials based on the use of the formal electric charge for each interacting species, have successfully reproduced the structure and properties of many oxides (33) including silicates (34–36) and phyllosilicates (37, 38) [see reference (39) for liquid water]. The set of potentials used include two-body and three-body analytical functions that allow calculating the energy between pairs and triplets of atoms. They depend on the choice of some parameters that can be advantageously calibrated using ab initio calculations in some simple cases. Note that the calculation of electrostatic interactions between pairs of ions is carried out using the Ewald summation scheme. The advantage of such an approach compared to ab initio quantum mechanical methods is that one can compute for large systems with low symmetry, not only structural but also thermodynamic and elastic properties [from the elastic tensor using both Voigt and Reuss equations for bulk, shear, Young's, plane stress (or indentation) modulus and Poisson's ratio]. Periodic boundary conditions were used for all directions of space. Reference (40) gives all details and equations on such calculations in the case of lizardite, a layered magnesium silicate of central importance in tectonophysics. Energy minimization for finding an equilibrium structure consists in tracking stationary points that correspond to a minimum energy gradient with positive energy curvature (i.e., finding a set of atomic positions that minimizes system energy and give a Hessian operator with positive eigenvalues only). A phonon spectrum calculation at the center of the Brillouin zone is then used as a final validation from which one obtains the list of lattice vibration frequencies that should be all positive except the first three that should be zero (unit cell translational invariance). Such minimization procedure gives a zero temperature solution. In this work, all degrees of freedom were considered including atomic positions, unit cell dimensions and angles. All potential mathematical form and parameters are given in the SI. The same approach but at fixed volume was used to perform deformation and shear calculations: all atomic degrees of freedom were allowed to relax for a given cell volume modifying one cell parameter at a time. The derivative of the system energy versus the incremental modified cell parameter (the interlayer distance) is used to calculate the cohesive pressure that can be compared with experimental nanoindentation data (17, 18). Numerical shear experiments were carried out with the same strategy by modifying at each step a cell angle parameter, then followed by molecular dynamics simulation in the Canonical Ensemble (i.e., at constant volume, see below).

**The Grand Canonical Monte Carlo Technique for Water Adsorption.** In this work, we first produced an anhydrous version of the C-S-H substrate and subsequently calculated the maximum amount of water that can be accommodated in its pore voids. For this purpose, we used the Grand Canonical Monte Carlo (GCMC) simulation technique that is well-suited to study adsorption/desorption processes. GCMC simulations involve the determination of the properties of a system at constant volume  $V$  (the pore with the adsorbed phase) in equilibrium with a

fictitious infinite reservoir of particles imposing its chemical potential  $\mu$  and its temperature  $T$  (41, 42). For different values of  $\mu$ , the absolute adsorption isotherm can be determined as an ensemble average of the adsorbed atom numbers in the system versus the pressure of the gas reservoir  $P$  (the latter can be obtained from the chemical potential according to the equation of state for the bulk gas). The adsorption and desorption processes can be respectively simulated by increasing or decreasing the chemical potential of the reservoir; the final configuration of a simulation is the initial state for the next point. Periodic boundary condition was used in all directions of space as for the energy minimization procedure. An equal number of attempts for translation, rotation, creation or destruction of molecules was chosen. The isotherm was calculated for 300 K. Acknowledging the very restricted available space in between tobermorite layers, one should not expect capillary condensation to occur in contrast to larger pore systems such as vycor (43). In our case, the adsorption/desorption process is expected to be close to that observed for microporous zeolite as far as water adsorption is concerned (44). We did not calculate the entire water adsorption/desorption isotherm, but performed a single GCMC simulation with the water chemical potential fixed to a value that corresponds to the bulk liquid phase with a density of 1 g/cm<sup>3</sup> at room temperature ( $\mu = 0$  eV for the used water potential model); note that the water-oxygen atomic shells were switched-off and water molecules and substrate were treated as rigid bodies during the GCMC procedure. A complete study of the state of water confined in our realistic model of C-S-H including thermodynamics and dynamics properties will be presented in a separate publication.

**NVT and NPT Molecular Dynamics.** Room temperature relaxation and deformation were carried out using molecular dynamics simulation in the NPT and NVT statistical ensembles integrating motion equations with the leapfrog Verlet algorithm with Nosé-Hoover thermostat and pressostat (with the default GULP parameters for each of these constraints). When relaxing in NPT conditions (with zero external pressure) the resulting system from energy minimization, the simulation considers finite temperature entropic effects.

**X-Ray Diffraction.** X-ray diffraction patterns were calculated with the CRYSTAL-DIFFRACT code as part of the CRYSTAL-MAKER package [www.crystallmaker.com/crystaldiffract/](http://www.crystallmaker.com/crystaldiffract/) at a wave length of 1.54 Å and an apparatus aperture broadening of 0.4 Å<sup>-1</sup>.

**Reproducibility of Results.** Details for the calculation including the interatomic potential functions and related parameters, as well as details on the numerical strategy and simulation techniques used, and the final atomistic model (and relevant coordinates) are provided in the SI to this manuscript. A file containing all of the atomic coordinates is available upon request to RJM Pellenq ([pellenq@mit.edu](mailto:pellenq@mit.edu)) or FJ Ulm ([ulm@mit.edu](mailto:ulm@mit.edu)).

**ACKNOWLEDGMENTS.** We thank Cimpor Corporation, Portugal, for support of the "Liquid Stone" project, enabled through the MIT-Portugal program. We thank Dr. P. Ganster and Prof. A. Baronnet (CINaM, CNRS-Marseille Université, France) for making available to us respectively the calcio-silicate glass atomistic model and the transmission electron microscopic image of C-S-H.
