ABSTRACT

Deep Structure and Geophysical Processes
Beneath Island Arcs

by

Norman Harvey Sleep

Submitted to the Department of Earth and
Planetary Sciences on January 17, 1973
in partial fulfillment of the
requirements for the degree of
Doctor of Philosophy

The deep structure and geophysical processes associated with island arcs were examined as a problem in heat and mass transfer. Particular attention was given to the thermal behavior of lithosphere as it descends into mantle, seismic transmission through descending slabs, the origin of the magmas which erupt on island arcs, and the cause of crustal spreading in intra-arc basins.

The factors affecting the thermal behavior of a lithosphere slab descending into the mantle are so complicated and numerous that only numerical methods can accurately account for them. A series of finite-difference calculations of the temperature field were made to test the effect of phase changes, the dip of the slab, the thermal conductivity, and the initial geotherm. Reasonable variations

in those parameters and geologically permissible variations in radioactive heating and adiabatic compression did not greatly effect the gross thermal structure calculated for the slab. Irregularities in slab movement on a time scale of less than 2 million years do not significantly effect the thermal field. Possible factors limiting the maximum depth of seismic zones include thermal assimilation of the slab due to latent heat from phase changes and thermal conduction, mechanical disruption of the slab, and the lack of stress at great depths due to lower density contrast between the slab and the mantle.

Theoretical ray paths through the numerically calculated thermal models of slabs were computed. The results were in good agreement with observed travel times. First motion amplitudes of P-waves at teleseismic distances were measured from long and short period WWSSN records of intermediate focus earthquakes in the Tonga, Kermadec, and Kurile regions and of nuclear explosions and shallow earthquakes in the Aleutian region. These amplitudes were corrected for source mechanism. The Aleutian data were sufficient to show that intermediate focus earthquakes in that region occur in the colder regions of the slab. At short periods shadowing effects which could be associated with the slab were not very marked, less than a factor of 2 reduction for epicentral distances greater than 50 degrees and possibly

more reduction for epicentral distances between 30 and 50 degrees. No systematic effects due to plates were found in the long period data. Some stations in the predicted shadow zone of a Tonga earthquake recorded low amplitude precursors which probably were greatly defocused waves which ran the full length of the slab. Simple diffraction is incapable of explaining the short period results.

Numerical and analytic models were constructed to examine four hypotheses for the origin of island arc volcanics: (1) melting at temperature lowered by inclusion of subducted material; (2) frictional heating related to the descent of the slab; (3) upwelling of material from the asthenosphere into the lithosphere of the island arc; (4) concentration of pre-existing melt in the asthenosphere. Presently available geochemical data is insufficient to resolve whether a significant portion of subducted material erupts on island arcs. This does not create a difficulty in evaluating the other hypotheses, as the observed eruption temperature of island arc volcanics is similar to that of basalt. The viscosity of the melt and the geometry of the asthenosphere are not conducive to segregation of melt. At low concentrations of melt, the regions with the highest concentration of melt contribute disproportionately to the magma which segregates. About 4 kb of shear stress is needed to cause melting above the slab. Frictional heating is not

likely to cause the widespread high crustal temperature observed beneath island arcs. Hypothesis 3 involves no obvious thermal or mechanical difficulties although the uncertain rheological properties of the region near the base of the lithosphere preclude the computation of a realistic, detailed model. However, it is both mechanically and thermally reasonable that the slab could entrain intermediate viscosity material near the base of the lithosphere. An influx of material from the asthenosphere to replace the entrained material could produce high crustal temperatures and provide a source region for island arc volcanics.

The hypotheses and models studied in relation to island arc volcanism are also relevant to spreading in intra-arc basins. Frictional heating above the slab is probably insufficient to cause this spreading. A numerical study was made to see if the extension could be related to viscous flow of material entrained with the slab. This calculated flow had the correct geometry to cause tension behind the island arc. Intra-arc spreading would be most likely to occur if the flow was induced in the intermediate viscosity region between the lithosphere and the asthenosphere.

ACKNOWLEDGEMENTS

This work might have proved intractable without the help of others. Especial thanks goes to my adviser, M. Nafi Toksöz, who endured my midwestern conservatism and suggested the topic of study and whose ideas and comments both clarified my thinking and improved this manuscript. I would also like to thank: Drs. John Minear and Bruce Julian for supplying computer programs which were subsequently modified; Drs. Jorge Mendiguren, Don Weidner and Professor Sean Solomon for helpful hints on reading seismograms; Dr. D. Joe Andrews for much advice on numerical and mathematical matters; Al Smith, Professors Richard Naylor, Seiya Uyeda and Sean Solomon for critical comments on various parts of the draft of this manuscript; and the above named people, Kei Aki, Patrick Hurley, Dai Davies, and William Bryan for useful discussions. Al Taylor provided assistance with using the seismic library. Ms. Sara Brydges typed the manuscript, translating it into standard English.

This work was supported by the Advanced Research Projects Agency and monitored by the Air Force Office of Scientific Research under Contract No. F44620-71-C-0049. The author was supported in part by a National Science Foundation graduate fellowship.

BIOGRAPHICAL NOTE273

CHAPTER 1. INTRODUCTION

The downwarping and descent of lithospheric plates into the mantle, as implied by the plate tectonic hypothesis has been widely accepted. Increasing amounts of geological, geochemical, and geophysical data are being explained in terms of descending slabs. In this thesis, the results of a series of analytical and numerical calculations on the evolution and properties of downgoing lithosphere and adjacent regions are described and compared with relevant observations. Rather than attempting to solve the convection problem for the entire earth, attention was given to problems which could be considered using observed plate motions as data. In particular, four areas were covered in detail:

1. Thermal evolution of a slab as it descends into the lithosphere (Chapter 2)
2. Teleseismic P-wave transmission through slabs (Chapter 3)
3. Origin of magmas which erupt on island arcs (Chapter 4)
4. Origin of intra-arc basins (Chapter 5).

The results of the thermal calculations were relevant to the subsequently considered problems. The seismic studies were concerned mainly with testing the implication of the thermal models to the gross structure of the slab

and with determining the spatial relationship between slabs and intermediate focus earthquakes. Physical models of several hypotheses on the origin of island arc volcanism and intra-arc basins involve the consideration of processes secondary to subduction.

The method of approach was well suited to the problems studied as the heat flow equation could be solved once the kinematics of subduction were known and since the mass transfer equation is most easily solved in regions directly influenced by the descent of the slab. As the kinematics of plate motion are used as input in the mathematics in this study, little information will be gained on the ultimate cause of this motion or on the flow and temperature at great depths far from slabs.

All protracted calculations were relegated to Appendix A. The physical models were kept simple using only the amount of detail warranted by knowledge of the physical parameters are by quality of the data to which the model was relevant. A better insight into the effect of various parameters was therefore obtained. Thermal and seismic calculations were generally more detailed; calculations involving viscosity were less detailed.

CHAPTER 2. TEMPERATURE IN A DOWNGOING SLAB

Deep earthquake zones beneath island arcs are believed to be related to slabs of subducted oceanic lithosphere (e.g., Isacks et al., 1968). The relatively simple pattern of motion in these areas makes calculation of the temperature field practical without solving the full convection problem for the earth. Several solutions for the temperature in a slab have been obtained. McKenzie (1969) used a two-dimensional analytic solution which assumed the top and the bottom of the slab were isotherms. Griggs (1972) included the effect of phase changes in a numerical solution with similar boundary conditions. Turcotte and Oxburgh (1969) obtained a solution using boundary layer theory. Langseth et al. (1966), Minear and Toksöz (1970a,b), Hasebe et al. (1970), and Toksöz et al. (1971) used two dimensional numerical models in which the mantle surrounding the slab was explicitly included so energy was conserved.

The purpose of this chapter is to use improved numerical calculations similar to those used by Toksöz et al. (1971) to test the effect of various physical parameters on the evolution of the slab. Questions unanswered by previous studies include: the effect of slab geometry on slab evolution; the factors which limit the length of the slab; the sensitivity of the slab to thermal conductivity, phase changes, and the initial geotherm, and the effect of

constant slab motion. The numerical methods used in this chapter are described in Appendix A.

2.1 Physical parameters

Certain physical constants such as mantle radioactivity, adiabatic gradient, density, and specific heat, can be shown to be well enough constrained from a knowledge of observational geophysics, solid state physics, and geochemistry that they can be considered known for purposes of constructing a model. The uncertainty in the value of other parameters, such as thermal conductivity and phase change relations, are large enough that these effects should be modeled. In addition, systematic parameters which themselves depend on the local physical constants, such as the unperturbed mantle geotherm, must be determined. The effect of frictional heating and its relation to volcanism are considered in Chapter 4.

The average density profile of oceanic crust (Press, 1970) and a specific heat of 1.3×10^7 erg/g-°C are sufficiently accurate for purposes of modeling the thermal structure of the slab (Minear and Toksöz, 1970a,b).

2.1.1 Radioactivity

The average radioactivity of the oceanic lithosphere is probably about equal to the radioactivity of the upper mantle, because differentiation at mid-oceanic ridges occurs

mainly above 30 km depth (Kay et al., 1970). Some radioactivity is added to a plate by sediments and mid-plate volcanism. It is not known to what extent this material is subducted.

Radioactive heating in the upper mantle of the earth is too low to effect the evolution of the slab. Estimates of the quantity include 2.3×10^{-7} erg/gm-sec (MacDonald, 1959, 1963), 5.4×10^{-8} erg/gm-sec (Armstrong, 1968), and 1.5×10^{-8} erg/gm-sec (Hurley, 1968a,b). The larger radioactivity of MacDonald would increase the temperature only 6°C in the 10 my descent of the slab. A more important effect of radioactive heating is on the unperturbed geotherm of the upper mantle.

The amount of radioactive heating in the upper mantle is constrained by the abundance of Ar^{40} in the atmosphere and the abundances of radiogenic and radioactive elements in sampled rocks to the low values of Hurley (1968a,b) and Armstrong (1968). The MacDonald radioactivity is based on chondritic element abundances and calculated by distributing the radioactivity to obtain conductive equilibrium.

2.1.2 Adiabatic heating

The amount of heating due to adiabatic compression in a downgoing slab can be calculated by $\rho g \alpha T v_z$ (Hanks and Whitcomb, 1971). Other than α , all the parameters are known at the start of any time step. As in Toksöz et al. (1971),

α (in units of $10^{-6} \text{ }^\circ\text{C}^{-1}$) was calculated by $\exp(3.58 - 0.0072z)$, where z is depth in kilometers. The increase in slab temperature due to adiabatic heating is about $0.3 \text{ }^\circ\text{C}/\text{km}$. Considering that the uncertainty in the unperturbed mantle geotherm is greater than this amount, adiabatic heat generation is known well enough for purposes of this chapter.

2.1.3 Thermal conductivity

Two possible schemes for calculating thermal conductivity in the interior of the earth were used in constructing models. The MacDonald (1959) formulation was used for most of the models calculated. Some models were calculated using an empirical formulation (Schatz, 1971). These formulae are given in Appendix A. The MacDonald conductivity is generally larger than the Schatz conductivity.

The conductivity change associated with the phase change at 400 km is probably not very large since ferrous iron, which increases opacity and reduces radiative conductivity, enters the common phases on both sides of the transition zone (Ringwood, 1970). If iron-free oxides such as MgO , Al_2O_3 or SiO_2 exist as minerals below the 600 km discontinuity, the radiative conductivity would be extremely high. Without direct experimental evidence at the phase relations of mantle materials at these pressures, no further speculation is warranted.

2.1.4 Phase changes

Several phase changes may occur in the upper mantle. Some such as slight partial melting in the low velocity zone do not effect bulk properties because only a minor portion of the material is involved. Other phase changes involving most of the material in the slab must be considered explicitly in a thermal model. If the vertical velocity through a phase change is fast enough, a few tenths of a centimeter per year for mantle material, the phase boundary will be moved from its normal position (Schubert and Turcotte, 1971). Except in a very rapidly convecting fluid the thermal gradient is locally sub-adiabatic near a major phase change (Verhoogen, 1965; Schubert and Turcotte, 1971; Ringwood, 1972). This inhibits small scale flow in this region, although large scale flow is enhanced by the density difference associated with the phase change.

An improved method was used to calculate the effects of phase changes in this paper. All points in the model, rather than just those points in the slab, were examined for phase changes at the end of each translation step and the change in the amount of each phase from the previous step recorded. Latent heat was calculated from this change and included as a heat source in the model. The translation routine for translating temperature was also used to translate the amount of each phase with the slab.

This calculation scheme works for phase changes going both ways whether or not the slab is assumed to move (Appendix A).

Three phase changes were considered in the models. Many of the models include a basalt-eclogite or equivalently a plagioclase peridotite-garnet peridotite reaction. The heating from this reaction was insignificant. Heat generation from the phase changes at 400 and 600 km is probably quite large. The 400 km transition has been studied experimentally (Ringwood, 1970). The slope of both phase changes is likely to be 20 to 30 bar/°C (Ringwood, 1972). For the models in which these changes were considered the phase diagram used by Toksöz et al. (1971) was used. One model was run with a seismically constrained phase diagram for the 400 km phase change; the effect was not greatly different.

2.1.5 Unperturbed mantle geotherm

In earlier papers the unperturbed geotherm of the mantle was either assumed to be adiabatic (McKenzie, 1969), the conductivity geotherm (Minear and Toksöz, 1970a,b; Toksöz et al., 1971), or to be controlled by the solidus temperature of peridotite (Griggs, 1972). In this study a crude approximation to the average geotherm in a convecting earth was obtained so that the importance of the unperturbed geotherm on the final results could be tested. For purposes of

calculation it is assumed that the downwelling parts of the flow do not interact thermally with a significant volume of the mantle, and that the upwelling flow can be approximated with a uniform, steady-state upward flow necessary to conserve mass. The latter assumption is reasonable since the migration of ridges with respect to trenches precludes a steady-state cell with a trapped flow in its core. At some depth heat must be added to the convection pattern to heat material which has sunk from the surface. In this region, which could conceivably include the lower part of the upper mantle, a conductive geotherm would exist.

Once these assumptions have been made, a "convective" geotherm can be calculated in a straightforward manner (Appendix A), if the surface heat flux, the average age of oceanic crust, and the dependence of conductivity on temperature and pressure are known. The results of the calculations are shown in Figure 2.1. Below 160 km the average thermal gradient is adiabatic. The gradient is increased in the region of the phase change due to the increased amount of heat generation there. Within the phase change region, the gradient is locally subadiabatic since the latent heat of the phase change is conducted to the surrounding regions. The choice of conductivity does not greatly effect the geotherm. The conductive geotherm did not grossly differ from the convective geotherm as the effects of ignoring convection and placing all the heat sources in the upper

mantle have opposite signs.

2.2 Computational results

Due to the increased efficiency of the improved numerical scheme, it was possible to calculate several models with small time and space increments (Table 2.1). Adiabatic heat generation, density, pressure, and specific heat were not varied between models. To facilitate comparison with earlier calculations, most of the models used the MacDonald (1959) radioactivity and temperature distribution and the phase boundaries by Minear and Toksöz (1970a, b). Models were calculated to test the importance of the depth of the slab, the unperturbed geotherm, and the conductivity. Frictional heating and its relevance to intra-arc basins and island arc volcanism is considered in Chapters 4 and 5.

A model similar to those calculated by Toksöz et al. (1971) is used as a base model with which to appraise the effects of changes in the parameters (Figures 2.2 and 2.3). The temperature field in this model is in good agreement with the most similar earlier model (Toksöz et al., 1971, Figure 8). Upward migration of the phase boundaries into the coldest part of the slab should be noted. The second phase change produced a kink in the isotherms, but did not cause the slab to assimilate. Latent heat from the lower phase change heated the slab to the ambient mantle temperature.

Below the depth of the lower phase change this slab would no longer be detectable by geophysical means.

The temperature field of a slab dipping 29 degrees was computed using the physical parameters of the base model (Figures 2.4 and 2.5). Although 16 my, as opposed to 11 my for the base model, was required for this slab to penetrate to 650 km, the maximum depth of penetration of both slabs is controlled by the lower phase change. The maximum penetration of isotherms into the mantle is about 30 to 100 km less in the shallower dipping model.

The modeled slab remains cooler to a greater depth if the Schatz conductivity formulation is used (Figures 2.6 and 2.7). The thermal gradients are steep along the boundaries of this slab, since the minimum conductivity is at intermediate temperatures. This slab persists to some extent below the lower phase change.

Use of the "convective" geotherm does not greatly alter the temperature field (Figure 2.8). The lower phase change was not included in constructing the geotherm of the model. Unlike the models using the strongly superadiabatic MacDonald (1959) geotherm, the temperature field is not greatly influenced by the kinematics assumed for the slab, since motions in the nearly adiabatic regions of the mantle effect temperatures only slightly. It should also be noted that the effect of 400 km phase change is evident, although this reaction was explicitly included when constructing the geotherm.

It is conceivable that for a period of time a slab may become hung up at a trench such that no subduction occurs. Contraction of the lithosphere would presumably occur elsewhere. The numerical method used in this chapter corresponds to such a periodic stop-start case. In some of the less detailed models the translation distance was about 80 km and the translation time-step about 1 my. The effect on the temperature contours is barely noticeable (Figure 2.9). The geological record might contain evidence relating to irregularities in subduction rate. The observed irregularities in the seismic zone are thus more likely due to disruption of the slab than non-uniform descent rate.

Once subduction ceases it is most likely that the slab will detach and sink as it did in South America or the New Hebrides. Tension near the top of the slab would permit fracture and separation. Detachment would occur if new material was being subducted more slowly than the separation rate. The maximum amount of time a slab may remain beneath a locked subduction zone may be calculated by assuming that no motion of the slab occurs. Several such numerical models were calculated. It was found that after 3.6 my the slab was not greatly effected (Figures 2.8 and 2.10). After 16 my, the slab was still evident but the temperature anomaly was spread over a larger region. After 50 my only a very broad temperature anomaly remained (Figure 2.11). It is not likely that a seismic zone will remain active for much

more than 10 my after subduction ceases. Once the slab is partially heated, detachment would be easier. The velocities of plate motions are great enough that the former site of a subduction zone could be rapidly separated from the material produced by the assimilation of the slab.

2.3 Geophysical implications

The models computed by varying thermal conductivity, ambient geothermal gradient, and dip differed only in fine structure which would not be resolved by most geophysical methods. This gives some confidence in the earlier conclusions drawn from earlier calculations (Toksöz et al., 1971).

1. Significant contributions to heating the interior of the slab are in order of importance: (a) Conductive and radiative transfer of heat from the surrounding mantle; (b) Adiabatic compression of the slab material, including the latent heat of phase changes; (c) Frictional heating. Heating from radioactive decay is insignificant on a 10 my time scale.
2. The slab penetrates to at least the level of the 600 km transition zone in the mantle. The 400 km transition causes only fine structure.
3. Conductive heat transfer cannot explain high heat flow behind island arcs.

4. The slab models may be used as a basis from which to compute the gravity, seismic velocity, and stress fields.

Conversely, the insensitivity of the models to reasonable variations in physical parameters makes the use of data on slabs an inefficient way to determine these parameters.

Further discussion of the relevance of the models to the maximum depth of earthquakes, the gravity anomalies associated with island arcs, and of subducted continental material is in order. Seismic transmission through slabs is discussed in Chapter 3 and the island arc volcanism in Chapter 4.

2.3.1 Maximum depth of earthquakes

No earthquakes have ever been observed below a depth of 650 to 700 km, although several seismic zones terminate at shallower depth (Isacks et al., 1968). The absence of well defined travel time anomalies for deep focus earthquakes indicates that a well defined slab does not exist for a significant distance below the earthquakes (Toksöz et al., 1971; Mitronovas and Isacks, 1971; Sen Gupta and Julian, in preparation). A broad region of somewhat reduced temperature or a weak continuation of the slab below the depth of maximum earthquakes cannot be excluded by the data.

This limited depth of earthquakes may be explained by either the absence of stresses necessary to produce earthquakes

or by the absence of material which would undergo brittle failure. Hypotheses postulating the absence of brittle material below 650 km include:

1. Subduction has been active for only 10 my and the slabs have not had time to penetrate deeper (Isacks et al., 1968).
2. Thermal conductivity is high enough that the slab assimilates with the adjacent mantle (McKenzie, 1969).
3. A local subadiabatic gradient related to the latent heat of the phase change precludes convection below 650 km or adds heat to the slab. (Verhoogen, 1965; Toksöz et al., 1971).
4. Metastable minerals are necessary for deep earthquakes to occur and do not exist below 650 km (Ringwood, 1972).
5. High viscosity or iron content precludes convection below 650 km (McKenzie, 1966).

Possible causes of the absence of stress below 650 km include:

6. The 650 km phase change occurs at shallower depths in the slab and produces the stress for deep focus earthquakes; below 650 km there is less density contrast and, therefore, less stress (Smith and Toksöz, 1972).
7. The slab below 650 km is sufficiently fragmented to not act as a stress guide.

These hypotheses are not mutually exclusive, as several factors may contribute to the absence of deep earthquakes below 650 km. The models calculated above, except for 1, 4, and 5, have some relevance to these hypotheses. Hypothesis 4 is difficult to test; hypothesis 5 can be excluded since glacial rebound studies indicate that a major barrier to convection such as a subadiabatic gradient or an increase in iron content with depth does not exist around 650 km (Cathles, 1971). Hypothesis 1 is unlikely since there is little evidence for a major start-up of sea-floor spreading 10 my ago. Magnetic lineation correlation (e.g., Heirtzler et al., 1968), deep sea drilling (e.g., Menard, 1972) and the relationship between topographic elevation and the age of the sea floor (Sclater et al., 1971) tend to preclude this hypothesis.

To accurately model the assimilation of the slab as in hypotheses 2 and 3 it is necessary to have a geotherm consistent with the physical parameters and motion assumed for the mantle. For example, a conductive geotherm must exist below the depth where convection ceases since much of the heat which flows at the surface must originate in the deep interior of the earth (Hurley, 1968a,b). A lower geothermal gradient may exist since convection could continue into the lower mantle after the thermal deficiency in the slab has spread out over a broad region.

Equilibration through thermal conduction is not likely

to be the sole cause of a maximum depth for earthquakes as earthquakes in some seismic zone, such as Tonga, do not become progressively rarer with depth (Isacks et al., 1968). The age differs by a factor of 2, from the nearly vertical Mariana slab to the 30 degree dipping Japanese slab. Thermal conductivity would have to increase with temperature as in the models for the slab to heat up in 10 my since the thermal time constant for oceanic lithosphere is about 35 to 50 my (Sleep, 1969; Sclater and Francheteau, 1970).

Several modeled slabs were heated to above the normal mantle temperature after penetrating the 600 km phase change (Figures 2.3, 2.5, and 2.9). These higher than normal temperatures are a result of the artificial nature of the assumed motion. In the physical situation the material would move away laterally as soon as it became buoyant with respect to the mantle. However, the excess temperature at the base of the slab is not large and not found in all the models including the 600 km phase change (Figure 2.7). Whether a broad cool region can exist where the slab penetrates into the lower mantle depends sensitively on the geothermal gradient and on the latent heat of the 600 km phase change. The geothermal gradient, however, depends whether mantle-wide convection occurs. Models which assume the kinematics of the motion and the geotherm are, therefore, unlikely to resolve this problem.

The density contrast due to the 600 km phase change,

about 10%, is much larger than the 2% or 3% density contrast due to ordinary thermal contraction. If the phase transition occurred at shallower depths in the slab, considerable stress would be generated in the lower part of the slab. This probably explains the high seismicity of small detached segments of slab in Tonga and the New Hebrides (Smith and Toksöz, 1972). Below the depth of the phase transition in the mantle, where this density could not exist, the stress might be insufficient to cause earthquakes.

A small detached fragment of a slab is not likely to have enough stress for earthquakes although it may be sufficiently cool for faulting. Sufficiently low subduction rates cannot supply material to the slab as fast as a detached block would sink on its own. Successive blocks would not interact and no seismic zone would form. If the empirical relation between dip and subduction rate (Luyendyk, 1970) gives the minimum sinking rate, no slabs should form from subduction below 2 or 3 cm/yr. This is consistent with the observed absence of seismic zones near poles of plate rotation.

A mechanical condition, such as a moderate increase in viscosity around 650 km, might disrupt the slab without interfering with mantle-wide convection or the response to glacial rebound. The process of disruption is probably active in the deeper part of the Tonga slab. Locally vertical and horizontal dips are present in the highly

contorted region (Isacks et al., 1969). The stress patterns of deep earthquakes are compressional along the dip of the slab, indicating that the descent is being resisted from below (Isacks and Molnar, 1971; Smith and Toksöz, 1972). The horizontal dip of detached slabs in the New Hebrides and South America and the horizontal portion of the Tonga slab also indicate that the slab has mechanical difficulty penetrating below 650 km. Once the slab is disrupted the smaller fragments are easily thermally assimilated and unlikely to accumulate enough stress to cause earthquakes.

2.3.2 Gravity anomalies

The gravity anomaly due to the slab can be calculated in a straightforward manner if the coefficient of thermal expansion is approximately known (Appendix A). The gravity anomaly is relatively independent of the detailed structure of the slab. Thermal conductivity can redistribute heat over short distances, but the total amount of heat and therefore the density anomaly is conserved. Thermal models which consider the slab alone (McKenzie, 1969; Griggs, 1972) cannot be used to calculate gravity, because heat is not conserved at the artificial boundary with the surrounding mantle.

Gravity anomalies which were calculated for six slabs (Figures 2.12 and 2.13) are much larger than observed, although conservative values of physical parameters were used.

The effects of the slab on the free surface of the earth and perhaps the region near 650 km may compensate the gravity anomaly. Hydrodynamic pressure will move a stably stratified boundary in a slowly moving viscous fluid relative to the pressure creating a density anomaly. Oceanic trenches are a feature of this type (Elsasser, 1967; Morgan, 1965). Stress equilibrium requires that the excess weight of the slab be balanced by either hydrodynamic forces or rigid support. The viscosity of the lower mantle determined from glacial rebound is too low for that region to rigidly support the slab (Cathles, 1971). The lithosphere is too thin to have any great effect over regions larger than its thickness.

Consideration of the dynamics as well as the kinematics of convection is necessary to understand the small observed amplitude of gravity anomalies near island arcs. Any complete convection model must satisfy this data. Without additional, more difficult calculations, all that can be concluded is that the weight of the slab is supported by hydrodynamic forces rather than the static strength of the mantle.

2.3.3 Continent-continent collisions

Continents connected to oceanic plates may drift into a trench causing a continent-continent collision. An orogeny caused by that event is likely to be brief and abrupt,

since less dense continental crust cannot penetrate the mantle. Numerical slabs of an intra-continental subduction zone were constructed to obtain predictions on their behavior.

The large scale structure in the region of a continent-continent collision is in part inherited from the pre-existing active continental margin and in part due to the subducted continental crust. The qualitative effect of most subduction parameters can be easily determined. At normal subduction rates, the material in the slab cools the surrounding region. High geothermal gradients above the slab could result from frictional heating on the fault plane (e.g., McKenzie and Sclater, 1968) or from mass transfer with material from below. At subduction rates of a few centimeters per year frictional heating in the seismic zone cannot cause high geothermal gradients near the surface without convective heat transfer (Hasebe et al., 1970). For continental crust to have much effect on temperature during its subduction, the subduction rate would have to be low since the average radioactive heat production of continental crust, 4.1×10^{-6} erg/gm-sec (Hurley, 1968a,b; Armstrong, 1968), can cause a maximum temperature increase of $10^{\circ}\text{C}/\text{my}$.

A numerical model using extreme value of parameters was constructed showing that frictional heating along the fault plane, alone, could not produce extremely high geothermal gradients above a subducted continent (Figure 2.14).

After about 50 my the temperature returns to steady state (Figure 2.15). We may conclude that orogeny is most likely to occur during the collision or after about 50 my when the subducted continental material has become heated. In the former case the heat of the orogeny would be related to volcanic activity along the active margin prior to the collision. In the latter it would be radioactive decay in the subducted material.

Mass transport of heat, probably necessary if high geothermal gradients occur in the crust above the slab, can be caused by igneous intrusions from the mantle, folding of deep strata upward during the collision, and partial melting and intrusion of continental crust. To determine the extent to which these processes operated during a continent-continent collision, the duration of igneous activity and folding associated with the orogeny and the relative temporal order of folding, metamorphism, and igneous activity must be deduced from observed geology.

2.4 Conclusions

Numerical models of the temperature regime in a downgoing slab were constructed using a more flexible version of the numerical scheme used by Toksöz et al. (1971). The results were not greatly dependent upon the reasonable changes in the thermal conductivity, the unperturbed geotherm, and the dip of the slab. This gives more confidence in the

results of the calculation.

The observed maximum depth of earthquakes is probably related to lack of cool brittle material due to increased thermal conductivity at high temperatures and the latent heat of the 600 km phase change; and to the lack of stress due to mechanical disruption of the slab and a smaller density contrast below the phase transition. A kinematic model which assumes the ambient mantle temperature cannot be expected to give a reliable answer on the maximum depth of convection in the mantle. Gravity anomalies are effected by hydrodynamic forces in the mantle and can be calculated only from a model which considers the response of the mantle to the slab. The ambient state of the mantle, which depends on the extent of convection, is needed to determine this response.

Models were also constructed which showed that: short term irregularities in slab motion would not significantly perturb the thermal state of the slab; once a slab has halted, it is not likely to remain seismically active for much greater than 10 my; and, about 50 my is needed for subducted continental crust to heat up due to its radioactivity.

TABLE 2.1: A summary of parameters used for temperature field calculations for different models. Phase changes are listed in Appendix A. "M" refers to MacDonald (1959) conductivity; "S" to Schatz (1970) conductivity; and "ML" to MacDonald conductivity below 30 km and lattice conductivity above 30 km. "A35" refers to value of parameter above 35 km; "B35" refers to value below 35 km. Geotherms 1 and 3 are shown in Figure 2.1. Geotherm 4 is in conductive equilibrium with a flux of $45 \text{ erg/cm}^2\text{-sec}$ at 200 km.

Table 2.1

FIGURE CAPTIONS

- Figure 2.1 Possible geotherms for the earth were calculated using different assumptions. Geotherm 1 is in conductive equilibrium assuming the MacDonald (1959) conductivity formulation and MacDonald's distribution of radioactivity. Geotherms 2 and 3 were calculated using a radioactive heat production of 1.5×10^{-8} erg/cm³-sec by assuming convective equilibrium. Geotherm 2 uses the Schatz (1970) conductivity formulation and Geotherm 3 the MacDonald (1959) formulation. The convective geotherms are nearly adiabatic below 200 km except for the effects of the phase change near 400 km. The surface heat flux for all the geotherms was 70 erg/cm²-sec.
- Figure 2.2 The base slab model after 3.6 my and 7.1 my was calculated using the parameters given in Table 2.1. Note that the second phase change produces a sharp kink in the geotherms.
- Figure 2.3 The base slab after 10.7 my was calculated using the parameters given in Table 2.1. This slab was assimilated by the latent heat of the 600 km phase transition.
- Figure 2.4 This slab was calculated using the same

parameters as in Figure 2.3 except for a dip of 29 degrees.

- Figure 2.5 The slab in Figure 2.4 after 16 my was assimilated by the 600 km phase change. The penetration of isotherms into the mantle is slightly less than for the base slab in Figure 2.3.
- Figure 2.6 Temperature field of slab was calculated using the parameters of the slab in Figure 2.3 except that the Schatz (1970) conductivity formulation was used. Steeper thermal gradients occur at the boundaries of this slab.
- Figure 2.7 The slab in Figure 2.6 after 10.7 my. Due to the lower Schatz conductivity, this slab penetrated the 600 km phase change.
- Figure 2.8 Temperature field in a slab penetrating into a mantle having Geotherm 3 (Figure 2.1). The parameters used for this slab and given in Table 2.1 are self-consistent with the geotherm. Penetration of the slab was stopped at 10.7 my, and the lower right slab was allowed to equilibrate with the mantle for 3.6 my.
- Figure 2.9 The temperature field of this slab after 10.7 my was calculated with identical parameters to the slab in Figure 2.3, except that each translation was 6 grid points rather than 2. The difference

between the two slabs is barely noticeable. This confirms that the numerical scheme used to translate the slab is a small source of error in the calculations and that irregularities in slab motion on a time scale of a million years would have little effect on the thermal regime.

Figure 2.10 The thermal field of the lower slab in Figure 2.2 after the slab was left at rest for an additional 3.6 my. Note that equilibration is retarded in the vicinity of the phase boundary on the bottom part of the slab.

Figure 2.11 The thermal field of the slab in Figure 2.5 was left at rest for an additional period of 48 my. The temperature anomaly becomes progressively broader with time. It is unlikely that the upper slab would be seismically active.

Figure 2.12 Gravity field calculated for the base slab model in Figure 2.3 (1), and the upper (3) and lower (2) parts of Figure 2.2. This gravity anomaly is much larger than observed. The horizontal zero point in Figures 2.2 and 2.3 is at 770 km.

Figure 2.13 The gravity field calculated for the slab in Figure 2.8, upper left (1), upper right (2),

and lower left (3). The horizontal zero point in Figure 2.8 is at 770 km. These anomalies are also much larger than observed.

Figure 2.14 The temperature in a subducted continent is shown after 7.7 my (above). The base of the crust is indicated by M. After remaining stationary for an additional 47 my, a thermal maximum has formed in the subducted crust (below).

Figure 2.15 Temperature field in subducted continent after 10 my was effected by extreme frictional heating along the fault plane. The highly radioactive continent crust is indicated by hatching.

CHAPTER 3. SEISMIC WAVE TRANSMISSION THROUGH SLABS

Slabs of oceanic lithosphere subducted beneath island arcs at oceanic trenches are now believed to be the site of intermediate deep focus earthquakes and anomalous seismic transmission (e.g., Isacks et al., 1968; Utsu, 1971). Velocity and amplitude anomalies have been used to demonstrate the existence of the slab (Davies and McKenzie, 1969; Sorrells et al., 1971; Mitronovas and Isacks, 1971; Toksöz et al., 1971; Jacob, 1970, 1972; Abe, 1972a,b; Davies and Julian, 1972). Ray theory calculations have been made for only ad hoc, grossly simplified, or analytic models. Davies and Julian's model is probably the most realistic so far used. The purpose of this chapter is to use the thermal models of slabs calculated in the previous chapter to construct seismic models and to use ray theory to predict effects which can be compared with observations of P-waves at teleseismic distances. Local observations are too difficult to interpret since the upper mantle may vary regionally. Travel times and amplitudes of teleseismic phases other than P are too poorly known to confidently look for slab effects. Modeling of the attenuation of high frequency P and S-waves is beyond the scope of this chapter.

A numerical approach is necessary to model the transmission of P-waves through slabs, as analytic solutions cannot give sufficient resolution. A ray tracing method

(Julian, 1970) was used in preference to more complete solution. Even this simplified calculation proved so protracted that an exhaustive development of models would have been uneconomical. Although direct calculation of amplitude was not practical by the numerical method used, the amplitude could be quantitatively estimated from the spacing of emerged rays. Models were constructed mainly to test the sensitivity of travel time and amplitude to the location of a source with respect to the slab. The velocity distribution through which rays were traced was obtained from numerically calculated thermal models (Chapter 2).

3.1 Geology of source regions

The Tonga and Aleutian slabs were selected for study, since data from suitable seismic events are available and since the geometric parameters relevant for constructing a thermal model are reasonably known. An event from the Kurile area was also used for data. A short review of the geology and geometry used in constructing the thermal and velocity models is in order.

The activities of the nuclear testing range on Amchitka island (Figure 3.1) have included the passive location of earthquakes by a local network of seismometers (Engdahl, 1971). Reliable epicentral locations also exist for a region near Adak island (Murdock, 1969a,b). The seismic zone dips

about 60 degrees to the north and extends to about 200 km depth in those regions. Geological evidence indicates that the short length of the Aleutian slab is due to recently commenced subduction. The initiation of island arc volcanism in the Aleutians has been dated at 1.8 my from studies of the distribution of volcanic ash in deep-sea cores (Hays and Ninkovich, 1970). This upper Pliocene age is consistent with the geology on land (Burk, 1965). Several deep-sea sedimentary fans were beheaded from their source region when subduction began in the Pliocene (Mammerickx, 1970).

A thermal model was calculated using the subduction rate normal to the arc at Amchitka island, 4.5 cm/yr (Figure 3.2) (Morgan, 1968; LePichon, 1968). The arc in this region has a radius of curvature of 12 degrees and extends sufficiently far from Amchitka that no teleseismic rays would emerge from the ends of the slab.

Deep earthquakes occur down to about 650 km depth in the Tonga-Kermadec region (Sykes, 1966). As the date of initiation of subduction has not been determined from geology, the thermal model for the Tonga slab was calculated to obtain the observed length of the slab. A subduction rate of 8 cm/yr and a dip of 45 degrees were assumed in the model. The actual subduction rate decreases southward from 9 cm/yr to 5 cm/yr (Morgan, 1968; LePichon, 1968). The subduction rate of the Kurile slab is about 8 cm/yr (Morgan, 1968; LePichon, 1968). The dip and length of this slab are similar

to the Tonga slab. One thermal model (Figure 2.3) was used to model both long slabs.

3.2 Computations of velocity models

These velocity models were constructed from numerical thermal models calculated for parameters relevant to the Aleutian, Tonga, and Kurile slabs using a linear relation, including phase changes, as given by

$$v(x,z) = v_0(z) + \frac{\partial v}{\partial T}(T_0(z) - T(x,z)) + \sum_m \frac{\partial v}{\partial m}(m_0(z) - m(x,z)) \quad (3.1)$$

where

v = seismic velocity

T = calculated temperature

0 (subscript) = unperturbed quantity

x, z = horizontal and vertical coordinates

m = amount of phase present

Model CIT 204 (Julian and Anderson, 1968) was used as a base from which to calculate anomalous velocities and delays.

The low velocity zone below 80 km and the rapid velocity gradients at 400 and 600 km are probably caused by phase changes (e.g., Anderson and Sammis, 1970; Ringwood, 1970, 1972). The amount of seismic velocity increase and the position of the phase change were adjusted such that the phase diagram was consistent with the unperturbed temperature

and seismic velocity profiles (Figure 3.3). A linear slope of the 400 km phase transition curve of $9^{\circ}\text{C}/\text{km}$ was used (Ringwood, 1970), and the width of the phase change adjusted to give self-consistency. Partial melting was assumed to cause a variation of 0.5 km/sec over a temperature range of 300°C . The solidus curve, adjusted to give self-consistency, was in reasonable agreement with high pressure experiments (Lambert and Wyllie, 1970). The 600 km phase change was not included in the calculations.

A trade off exists between the thermal coefficient of velocity ($\partial v/\partial T$) and the assumed unperturbed geotherm in the mantle. It is also not clear that the laboratory value of the parameter is relevant to the mantle. A coefficient of $-0.5 \times 10^{-3} \text{ km/sec}^{\circ}\text{C}$ has been measured in short term experiments on several possible materials (Anderson et al., 1968). However, several strongly multivariant phase transitions which cannot be calibrated directly from the dependence of seismic velocity on depth may occur in the mantle. Possible reactions include the formation of garnet, olivine, and jadeite at the expense of aluminous pyroxene, spinel, and plagioclase (Green and Ringwood, 1967b; O'Hara et al., 1971). There is insufficient experimental data to correct directly for these reactions and for partial melting in a velocity model. The gross geometry of the slab is well enough determined from the location of deep earthquakes that it is better to calibrate the coefficient of velocity with

observed travel time anomalies to a predetermined slab geometry than it is to adjust the slab shape to use a preconceived velocity coefficient.

Travel times from the LONGSHOT event and the Aleutian slab model were used to obtain the value of the thermal coefficient of seismic velocity used to calculate theoretical ray paths. The observed advance for rays down dip of the slab is slightly over 2 sec (Jacob, 1972; Abe, 1972a). This value, relatively independent of shot location, was given by a coefficient, which does not include the effect of partial melting, of -9×10^{-4} km/sec°C (Figure 3.4). In agreement with Jacob (1972) a velocity contrast of about 10% is required. The resulting velocity models are shown in Figure 3.5 and Figure 3.6.

3.3 Theoretical ray paths

Theoretical travel times and ray paths were calculated for 6 surface locations on the Aleutian velocity model, 4 surface locations on the long slab model, and 7 intermediate depth locations on the long slab model. The computed travel times and assumed take-off parameters are plotted as a function of the emergence point of the rays on Figures 3.7, 3.8, and 3.9. The models are symmetric with respect to the dip of the slab.

The Aleutian locations were spaced at 0.1 degree [11 km] intervals (Figure 3.2). The travel time anomalies were found

to be slowly varying functions of terrestrial coordinates (Figure 3.7). The size of the travel time anomaly is greatest for locations C and D and smaller on either side.

The shadow zones for locations A, B, and C are similar. South of location C the size of the shadow zone decreases, becoming insignificant at location F. Two branches of teleseismic rays travel north from location A. At distances less than 35° the arrival consists of a small precursor which traversed the slab and a normal arrival which missed the slab. For locations north of A the normal arrival emerges at increasingly larger distances. No multiple arrivals were found for more southerly shot locations. For location C the amount of defocusing in the shadow reduces amplitude by a factor of about 8. The defocusing reduces the amplitude more at locations A and B. The effects of defocusing are somewhat canceled by the effect of attenuation since the defocused rays going through the slab miss the high attenuation of the low velocity zone.

For the long slab model a pronounced shadow zone existed for all sources (Figure 3.8). The results for surface positions A and B are nearly identical as the shadow zone results from rays being critically refracted off the slab (Figure 3.6). The edge of the shadow is a complex region of multiple arrivals. The predicted amplitudes in the shadow were so low that rays entering some areas could not be obtained although the take-off angle of the rays was

incremented by 0.001 degrees. The shadow zone is smaller for surface positions C and D. The maximum travel time anomaly for a ray running the full length of the slab from position C is 7.8 sec early. Again it was numerically difficult to obtain rays entering the shadow.

Amplitudes and delays for intermediate earthquake locations A through E are not significantly different, since the shadow zone is caused by critical refraction (Figure 3.9). The maximum time anomalies are about 6 sec early. The size of the shadow zone decreases for locations near the base of the slab. At position G the shadow zone does not extend out to the core shadow and the delays are somewhat smaller. The amplitudes in the shadow zone are reduced to one one-hundredth of normal. The edge of the shadow zone is again a region of complex multiple arrivals.

3.4 Travel time anomalies

Although the arrival time of P-waves can often be measured to 0.1 sec, care is required to resolve anomalous effects due to slabs, since errors on the order of a second may exist in published travel time tables and station corrections. If earthquakes rather than controlled explosions are used as sources, lack of knowledge of the origin time and location of the event further complicates the analysis. Discussion is confined to travel time anomalies

which vary as a function of station location. World-wide constant advances and delays are difficult to interpret and mostly unresolvable from systematic errors in the tables.

Three nuclear explosions, LONGSHOT, MILROW, and CANNIKIN were used as sources for the Aleutian region (Figure 3.1). LONGSHOT data is primarily considered, as the explosions were in close proximity and as the LONGSHOT data was more carefully analyzed (Lambert et al., 1970). A check of the PDE reports showed no systematic differences among the travel times from these events. It was necessary to station correct the LONGSHOT data since the station effects were of the same order as the source effects and correlated with broad geographic regions (Jacob, 1972). After station corrections were made, there was so much scatter that it was necessary to average the data from geographical areas (Jacob, 1972; Abe, 1972a). Averaging over 10 x 10 degree quadrangles in a polar epicentral project left over a second of scatter in the travel time residuals (Jacob, 1972).

The station corrected data averaged over all tele-seismic distances and 15 degree intervals of azimuth (Abe, 1972a) were used as data with which to test the theoretical model (Figure 3.10). A good fit resulted. The location of LONGSHOT with respect to the slab cannot be accurately constrained from the travel time data since the data were insufficient to resolve the anomaly as a function of epicentral distance and since theoretical travel time

anomalies were insensitive to shot point location.

Abe (1972a) noted that arrivals were later at stations between 10 and 30 degrees azimuth than at adjacent azimuth intervals and postulated a gap in the slab. Errors in either the travel time table or the station corrections are alternative explanations, however, since only 4 different stations were involved.

No controlled events are located suitably with respect to long slabs such as Tonga. Travel time residuals were calculated relative to locations obtained from a network of local stations for numerous earthquakes near Tonga (Mitronovas and Isacks, 1971). After spatially averaging these residuals for teleseismic stations, the effect of the slab is clearly evident (Figure 3.11). The theoretical travel time anomaly fits the observed data reasonably well. Although the data were insufficient to give a clear-cut relationship between epicentral distance and delay, the largest advances were observed around $\Delta = 60^\circ$ in agreement with the theoretical model. Again, little resolution could be obtained on the spatial relationship between the slab and the earthquakes.

3.5 Amplitude anomalies

The amplitudes of 3 nuclear explosions and 15 shallow and intermediate focus earthquakes were measured to obtain improved information on the location and structure of the slab (Table 3.1). Amplitudes observed only on World Wide

Standard Seismographs (WWSS) were used in this study to avoid error due to faulty correction for instrument response. Thirty-five millimeter films were generally used; comparison with full scale reproductions, where available, showed that the films were adequate for the purpose of this chapter. High quality copies of the LONGSHOT event were used (Lambert et al., 1970).

The normal definition of magnitude is unsuitable, since different parts of the coda may be measured at different stations. It was most convenient to measure the amplitude of the first peak-to-peak motion. Following Cleary (1967) and Nuttli (1972) the frequency of the first arrival was assumed to be constant at all stations. This made it unnecessary to know the period of the arrival at each station, which would be nearly undeterminable on the short period record. No variation of frequency between stations was evident for any of the events studied.

In order to look for amplitude anomalies, it is necessary to have a wide distribution of stations. All stations were used where it was possible to find the first arrival. Rejection of weak arrivals would have biased the results against finding any shadow zones.

In order to interpret amplitude data, it is necessary to correct for variations in amplitude as the result of heterogeneities in the radiation pattern at the source and as a result of systematic variations with epicentral distance. Unlike travel time corrections, the uncertainty in amplitude

corrections is the same order as the amplitude itself.

The amplitudes of earthquakes were corrected for source mechanism (to the value at the axis of maximum compression) using double couple solutions (Stauder, 1968; Isacks et al., 1969; Isacks and Molnar, 1971).

$$F(x,y) = |\sin(2\theta) \cos(\phi)| \quad (3.2a)$$

$$A_f(x,y) = A(x,y)/F(x,y) \quad (3.2b)$$

where

F = focal plane correction

x = location of station

y = location of earthquake

ϕ = co-latitude of ray on focal sphere measured
about null axis

θ = longitude of ray on focal sphere measured
about null axis and from the nodal plane

A_f = source corrected amplitude

A = measured amplitude

Source corrections were restricted to a maximum value of a factor of 10 since it was felt that the nodal planes were not accurate to more than 3 degrees. Poor location of a nodal plane that does not emerge at teleseismic distances does not effect the results significantly, since the source correction is large only if a station is near a nodal plane and only a weak function of the location of the more distant nodal plane. Errors in the location of the earthquake only weakly effect the position of a station on the focal

sphere, since all earthquakes studied were in the upper mantle where the angle of emergence is a slowly varying function of depth and distance for teleseismic rays. If the slab should strongly refract a ray emerging near a nodal plane, the angle of emergence given in the table might give a spurious value of source correction. No source correction is necessary for nuclear explosions.

The source corrected amplitudes must also be corrected for epicentral distance

$$A_{\Delta}(x,y) = A_f(x,y)/G(\Delta) \quad (3.3)$$

where

A_{Δ} = distance and source corrected amplitude

Δ = epicentral distance

G = distance correction.

Although the amplitude-distance relationship is poorly known for P-waves, the choice of this function is not critical if a good distribution of stations can be obtained. The amplitude-distance curves were used to divide the observed data for each event into interval classes differing by factors of two. A simple continuous curve consisting of four line segments was used in this chapter to correct short period amplitudes for epicentral distance (Figure 3.12). Previously published amplitude curves are neither simple nor in agreement with each other nor with the Gutenberg and Richter (1956) curve. Curves derived from nuclear explosion

data (Carpenter et al., 1967; Kaila, 1970) are biased since most of the arrivals at some distances are in the shadow zone of LONGSHOT, and are discontinuous. The various curves differ most strongly between 30 and 40 degrees. Errors of a factor of two could easily be introduced by faulty correction of amplitude for epicentral distance. A systematic biasing is much less likely.

An amplitude distance curve measured at a period of about 2.5 sec on the long period WWSS (Nuttli, 1972) was used to correct the long period results for distance. This curve is more accurate than the short period curve as the scatter due to local station effects is much larger at short periods.

A combined station and distance correction can be obtained if an event whose rays, unaffected by the slab, is located suitably close to the event being studied. The station corrected amplitudes of the slab event (A_s) can be obtained by

$$A_s(x, y_1) = A_\Delta(x, y_1) / A_\Delta(x, y_2) \quad (3.4)$$

where

y_1 = event studied

y_2 = reference event.

This formula is independent of $G(\Delta)$ to the first order since the epicentral distance corrections of y_1 and y_2 are similar and cancel out on the right hand side of equation (3.4). These station corrections should not be interpreted

as being invariant properties of the local geology of the stations, since they include the amplitude distance curve and are determined for only one event.

3.5.1 Aleutian amplitude results

The amplitudes of 3 nuclear explosions and 6 earthquakes around Amchitka island were measured. The nuclear explosions and two normal faulting earthquakes in the Aleutian trench generated the best data.

Short period amplitudes measured for LONGSHOT and MILROW are plotted in Figure 3.13. Arrivals from CANNIKIN were generally off-scale on short period records, except at stations in the shadow zone or those with unusually small magnification. Long period amplitudes for MILROW and CANNIKIN are plotted in Figures 3.14, 3.15, and 3.16. Although there is considerable scatter in the data, it is evident that the shadow zone extends from about 310° to 50° azimuth for distances between 70° and the core shadow. The shadow zone observed for LONGSHOT with Canadian stations extends to 70° azimuth at distances between 30° and 40° (Davies and Julian, 1972). The shadow zones for MILROW and CANNIKIN are similar at long periods and slightly larger than the short period shadow for LONGSHOT. The difference between LONGSHOT and MILROW may not be real since the best data for each event were measured on instruments with different frequency response (SPZ for LONGSHOT, LPZ for MILROW).

The amplitudes of two normal faulting earthquakes in the trench near Amchitka were measured to obtain station corrections for LONGSHOT and MILROW. These earthquakes occurred seaward enough that teleseismic rays would not be effected by the slab. The path through the deep mantle and up to the station for rays emerging from LONGSHOT is nearly identical to this portion of the path from the earthquakes. The data for the June 2, 1966 earthquakes were of superior quality since the nodal planes emerge away from teleseismic stations. There were no interfering events. No shadow zone was observed at either long or short period for either event (Figures 3.17 and 3.18).

Long and short period amplitudes of four underthrusting earthquakes belonging to the Rat island sequence of Feb. 1965 were measured from WWSSN records. The long period record from three other earthquakes proved too difficult to untangle. Contamination of the measured amplitudes with pP could have occurred on the noisier long period records. It was difficult to consistently pick the first motion on the short period records since the amplitude did not usually peak by the third half cycle. The first arrival was frequently missed at stations near the nodal plane. These stations showed considerable scatter with the high-noise, low-magnification stations giving higher measured amplitudes. It is possible that some of the earthquakes were true multiple events. The number of reliable measurements of rays

which probably missed the slab is limited, since one of the nodal planes generally emerged near the western United States and Australia.

The data for these earthquakes, plotted in Appendix B, precludes the possibility of a large shadow zone with an average reduction factor greater than 10 at short periods, but the scatter is sufficiently large that a shadow zone comparable to the LONGSHOT shadow would not be detectable. No attempt was made to use station corrections: No long period shadow was evident for any of the events.

The observed short period amplitudes for LONGSHOT and MILROW were station corrected using the June 2, 1966 event (Figure 3.13). An insufficient number of station corrected amplitudes were obtained for MILROW. The amplitudes after station correction in the shadow zone between -50° and 50° azimuth are about a factor of 2.5 below the other amplitudes (geometric average). The scatter in the data is greatly reduced by the station correction and there is little overlap between shadow zone and non-shadow zone amplitudes. Note that the stations at northern azimuths and small epicentral distances have low station corrected amplitudes. The slab location preferred in this paper places this region in the shadow zone.

The amplitude data for LONGSHOT are sufficient to locate the shot between locations C and D (Figure 3.2). Considerable scatter in the edge of the shadow is expected

to result from crustal structure and minor irregularities in the slab. This location of LONGSHOT with respect to the slab is significantly south of the position suggested by Davies and Julian (1972) and not grossly different from the position proposed by Jacob (1972). The position suggested herein can be shown to be more likely by considering multiple arrivals which were observed at teleseismic distances. A normal ray which misses the slab may be preceded by a low amplitude precursor which travelled the length of the slab. Rays which miss the top of the slab will appear at small distances and northern azimuths. Rays which miss the bottom of the slab will emerge south of the shadow zone out to large azimuths. Unless the slab is extremely thin, both types of multiple arrival cannot occur for one shot. For LONGSHOT, multiple arrivals were observed south of the shadow zone at large azimuths at western Canadian stations (Davies and Julian, 1972). A multiple arrival north of LONGSHOT at Point Barrow, Alaska, may be a refraction off the 600 km discontinuity (Jacob, 1972).

The slab location deduced from LONGSHOT is such that intermediate depth earthquake epicenters fall in the coldest region of the slab model (Figure 3.19). This is expected since intermediate earthquake mechanisms can be attributed to tension (or compression in other regions) along the dip of the slab (Isacks et al., 1969; Isacks and Molnar, 1971; Smith and Toksöz, 1972) but not to shearing on the boundary

of the slab. For mechanical reasons brittle fracture should occur in the coldest part of the slab (McKenzie, 1969).

3.5.2 Long slab amplitude results

Long and short period amplitudes were measured for six intermediate focus earthquakes in the Tonga-Kermadec region (Figures 3.20 and 3.21). The use of intermediate depth earthquakes eliminates problems resulting from contamination with pP and from attenuation of normal rays in the low velocity zone. The measured amplitudes were corrected for source mechanism using earthquake solutions by Isacks et al. (1969) and Isacks and Molnar (1971). A nodal plane often emerged moderately near the western United States. The results of the measurements are plotted in Figures 3.22 through 3.27.

Low short period amplitudes were observed only within 45 degrees to the west of the epicenters. Although this is the location of the predicted shadow zone, it is possible that errors in the distance correction effected the results. Short period amplitudes at stations beyond 50 degrees from the source were independent of azimuth for all the earthquakes studied. Distance and source corrected long period amplitudes were independent of azimuth for all the earthquakes in the Tongan region. Slight variations in the long period amplitudes are probably due to measurement errors and errors in the distance and source corrections and to station differences.

Reasonable quality amplitude data were obtained from one intermediate event near the center of the Kurile arc (Figure 3.28). Although there is some scatter in the data, an average of a factor of 2 reduction in short period amplitude in the predicted shadow zone between 255 and 15 degrees azimuth is observed (3.29). The data reduction was fairly insensitive to errors in the amplitude distance curve since the stations in and out of the predicted shadow zone are distributed over a similar range of distances. The source corrections for data in both regions are similar. There were no suitable events to use for making station corrections for the Tonga and Kurile earthquakes. An attempt to use a nearby earthquake, which occurred 80 km deep beneath the Kurile trench, for station corrections failed since few reliable amplitudes could be obtained. The nodal planes for this event passed near many stations. Away from the nodal plane it was difficult to pick the first arrival. The error in the location of this earthquake may be abnormally large since many stations picked later parts of the coda as the first arrival. The long period signal from this event was often too small to measure reliably.

Low amplitude precursors occurring 1 to 3 sec before the main arrival were observed in the predicted shadow zone for the earthquake of 21 July 1964 near Tonga. The amplitude of these precursors was small enough that they would have been missed on noisy records. Tracings of

relevant seismograms are plotted in Figure 3.30. Possible precursors were observed for some of the other events but the shape of the wave form away from the shadow zone was such that these arrivals could not be confidently identified as precursors. Some of the scatter in the amplitudes measured inside of 45 degrees from the source may be due to inconsistent picking of the main arrival or the precursor.

The small precursors to the 21 July 1964 arrival were considered to be strongly defocused waves which ran the full length of the slab rather than evidence of a foreshock, since the time delay between the precursor and the main arrival was variable, since the amplitude ratio of the main signal was variable, and since no precursors were observed outside the predicted shadow zone. The multiple P-wave arrival corresponds to no known seismic phase (Jeffries and Bullen, 1958; Herrin, 1968). It is very unlikely that local station effects would cause precursors only at stations in the predicted shadow zone. Although it was not possible to compute the spectra, it is evident from the records that the frequency content of the precursor and main arrival is similar. There is some interference between the two arrivals at CTA and PMG.

The observed precursors can be easily explained as defocused waves which have run the full length of the slab. The more difficult problem is explaining why the amplitudes in the shadow zone for the Tonga and Kurile slabs are not

smaller than for the shadow zone for the much shorter Aleutian slab. Although the data is better for the Aleutians, the Tonga and Kurile data can support, at most, amplitude reduction of a factor two for epicentral distances greater than 45 degrees and a factor of eight between 30 and 40 degrees. These amplitudes observed in the shadow zone were much larger than the amplitudes predicted from the ray theory. This is unlikely to be the result of too high a theoretical slab velocity, since the velocity model was calibrated to give observed travel time anomalies. Possible explanations for the larger observed than predicted amplitudes include: diffraction, gaps in the slab, large fault length, occurrence of the earthquake near the base of the slab, and guided or converted phases. The implications of these possibilities are discussed below.

The long period observations can be explained by diffraction (Ward, 1971; Davies and Julian, 1972) since the wavelengths were comparable to the width of the slab. The source determinations used in this paper are unlikely to be in error due to refraction, since long period data were used in the determination. Simple diffraction, however, cannot explain the short period results, since normal or slightly reduced amplitudes were observed for rays which would emerge over 10 degrees into the shadow zone. An analytical solution for wave propagation in a one-dimensional slab indicates that ray theory will work with respect to diffraction for the

1 to 3 second waves measured in this paper (Ward, 1971).

Irregularities, tortuosities, or gaps in the slab may cause the shadow zone to be absent. A local dip of 30 degrees in the slab is sufficient to let normal rays emerge at distances beyond 60 degrees. The Tonga slab when viewed in detail varies significantly from the average dip of 45 degrees, being overhanging in some places and nearly flat in others. Significant advances relative to normal mantle velocity could still be expected for rays which escape from the slab since rays emerging from an earthquake near the center of the slab remain in the slab for a considerable distance. For a slab dipping 45 degrees, large variations from the average dip would be necessary to let rays emerging at epicentral distances between 30 and 45 degrees escape, since these rays take off at close to the dip of the slab. These rays could escape at locally vertical sections on the top of the slab as well as locally flat sections on the bottom.

Large true gaps in the slab are unlikely since high frequency waves efficiently propagate to the surface from deep earthquakes (Barazangi et al., 1972). Small gaps in the slab such as suggested by Abe (1972a) for the Aleutian slab might be sufficient to let normal amplitude rays escape without effecting high frequency transmission.

The fault length of intermediate focus earthquakes in the magnitude range used in this study is probably

insufficient to account for the arrivals in the shadow zone. Although the fault for the largest earthquakes extends through the slab (Kanamori, 1971b; Fukao, 1972), the fault length of moderate size intermediate earthquakes has been determined to be 10 to 20 km by seismic moment studies (Wyss and Molnar, 1972; Brune, 1970). Unless the rupture started in the lower part of the slab, the shadow zone for P-waves would still exist.

Intermediate focus earthquakes are not likely to occur in the high temperature region at the base of the slab, where no shadow zone would be present, since the stress drop for intermediate focus earthquakes is high (Wyss and Molnar, 1972) and since fracture would begin in the coldest and strongest area. The seismic plane in Tonga is as narrow as can be resolved by epicenter location, about 25 km (Sykes, 1966). If intermediate depth earthquakes occurred in the high temperature region beneath the slab, a greater spatial scatter would be expected since mechanical conditions in that region vary slowly with position.

The normal amplitude arrivals in the predicted shadow zone could be a phase not predicted by the simple ray theory calculation. The converted or guided phase must satisfy several restrictions. This phase must arrive within 1 to 3 seconds of a low amplitude precursor, the wave must have the correct polarity, and the arrival must have normal amplitude. Conversion of S to P-waves on the bottom of the

slab is unlikely since this wave would arrive too late unless the earthquake was near the bottom of the slab anyway. Reflections off the top of the slab are refracted with the same shadow zone as a source in that region. However, rays might be trapped in the slab by reflection off its boundaries at a low angle. A more sophisticated calculation would be required to evaluate the amplitude of any reflected or guided wave having the correct arrival time. The quality of the data presently available precludes any appraisal which requires detailed knowledge of the spectral characteristics of the signal.

3.6 Conclusions

Velocity models for downgoing slabs were constructed from theoretical temperature profiles and calibrated by considering travel time anomalies for nuclear tests on Amchitka island and intermediate focus earthquakes in Tonga. The LONGSHOT event was located with respect to the slab by using variations in P-wave amplitude observed at teleseismic distances. The locations of intermediate focus earthquakes correspond with the coldest region of the theoretical slab model. Normal faulting earthquakes in the Aleutian trench were used to obtain station corrections. It was determined that the shadow zone extends northward into Greenland and Northern Canada. The observed shadow for

LONGSHOT is definitely not a network bias.

Although some low amplitude precursors were observed for Tonga earthquakes, the amount of amplitude reduction in the part of the predicted shadow zone beyond 45 degrees epicentral distance, was less than a factor of 2 for short period measurements of intermediate Tonga and Kurile events. The short period amplitude may be more reduced at epicentral distances between 30 and 45 degrees. Any long period shadow zone could be at most a reduction of a factor of 2. The precursors can be explained as defocused waves which have run the full length of the slab, and the lack of reduction at long periods can be attributed to diffraction. The explanation, however, for the observed lack of reduction in amplitude in the predicted shadow zone is not clear-cut; possible hypotheses include irregularities in the slab, earthquakes at the base of the slab, and guided or converted seismic phases.

The data used in this chapter were the highest quality data available which had good spatial distribution. An improvement in the quality of travel time data would increase its utility as the resolution was lost by the need to spatially average. This improvement is unlikely in the near future since a major difficulty is systematic errors rather than poor measurements. The amplitude interpretations would be greatly improved by digital records with good spatial distribution, by the wide-spread installation of

arrays which could detect low amplitude precursors, and by improved knowledge of distance and station corrections.

Until these improvements are made, additional knowledge of seismic transmission through slabs is most likely to come from the study of phases other than teleseismic P-waves.

TABLE 3.1: The source parameters of earthquakes for which the amplitudes were measured. The number refers to the source of the focal plane correction (S, Stauder, 1968; ISO, Isacks et al., 1969; IM, Isacks and Molnar, 1971). Quality refers to the difficulty of recognizing the first arrival (1, no difficulty at most stations; 2, serious difficulty at many stations; 3, records too difficult to untangle).

FIGURE CAPTIONS

- Figure 3.1 Index map of southern Amchitka island showing the locations of LONGSHOT (L), MILROW (M), and CANNIKIN (C). The relation of Amchitka to neighboring islands is shown in the inset. The islands immediately north of Amchitka are volcanic, while Amchitka is part of the frontal arc.
- Figure 3.2 Theoretical temperature contours at 250°C interval were calculated for a slab dipping at 57 degrees. The subduction rate is 4.5 cm/yr. Ray theory travel times and amplitudes were calculated for surface explosions at locations A through F. Point C is 12 degrees from the center of curvature of the arc.
- Figure 3.3 The CIT-204 velocity profile was used for unperturbed regions of the mantle. The straight lines were used to determine the change of seismic velocity with respect to phase changes in a way consistent with the unperturbed velocity model.
- Figure 3.4 Calculated delays for rays going parallel to the dip of the slab were calculated for various velocity coefficients and shot locations. The number indicates for velocity coefficient in

10^{-4} km/sec-°C; the letter indicates the shot site in Figure 3.2. A coefficient of 9×10^{-4} km/sec-°C was needed to fit observed delays.

Figure 3.5 Theoretical velocities determined from the temperature profile in Figure 3.2 are contoured at 0.25 km/sec intervals. The velocities outside of a cone about 38 degrees wide from the shot site are of no significance to this paper since only teleseismic data was used in this paper. No attempt was made to include a detailed crustal model of Amchitka island.

Figure 3.6 Calculated ray paths for a model of the Tonga slab are plotted above the theoretical velocity used to model that region. Letters indicate source locations. Rays were stopped near their source and darkened for clarity. The rays are refracted away from the slab creating a shadow zone. The contour interval for velocity is 0.25 km/sec.

Figure 3.7 Calculated travel time residuals (advances positive) are plotted on the left of an equidistant azimuthal projection about the shot point. Calculated initial ray parameters for rays emerging on the projection are plotted on the right. Initial take off angles in degrees

are contoured at 3 degree intervals, with 1 degree intervals indicated by thin lines and 0.5 degree intervals by dashed lines. Initial take off azimuths are contoured at 40 degree intervals by dashed lines. The stippling indicates the area of significantly reduced amplitudes. The letters refer to shot locations in Figure 3.2. The northward limit of normal rays which miss the top of the slab at location A is indicated by the dashed line L.

Figure 3.8 The results for ray tracing from surface sources above the Tonga slab are plotted as in Figure 3.7. Rays running the full length of the slab were difficult to obtain for numerical reasons. Later multiple arrivals at the edge of the shadow zone are not plotted. Letters refer to surface locations in Figure 3.6.

Figure 3.9 The results of ray tracing from 200 km deep sources, indicated by letters in Figure 3.6, are plotted as in Figure 3.7.

Figure 3.10 Calculated delays at site C (Figure 3.2) are compared with observed station corrected delays averaged over interval of azimuth and over delta (Abe, 1972a). The fit is obtained by assuming the strike of the arc is N82W.

Figure 3.11 The theoretical delays for intermediate earthquake location C (Figure 3.6) at a distance of 60 degrees are compared with averaged observed delays computed with respect to locations computed from local stations (Mitronovas and Isacks, 1971).

Figure 3.12 Amplitude distance relations of various authors show little similarity. Curve 1 (Gutenberg and Richter, 1956), curve 2 (Kaila, 1970), and curve 3 (Carpenter, et al., 1967) were not used in this paper. Curve 4 is this smoothed curve assumed in this paper for short period waves. Curve 5 (Nuttli, 1972) was used for long period data.

Figure 3.13 Observed short period amplitudes for the LONGSHOT (above) and MILROW (below) events are plotted on equi-distance azimuthal projections about the shot points. The amplitudes given on a \log_2 scale are given in Appendix B. The raw amplitudes for both events (right) are generally low between about 310 and 50 degrees azimuth. The station corrected amplitudes on the left show that the shadow zone is real.

Figure 3.14 Long period amplitudes for the MILROW event (Nuttli, 1972) are plotted on an equi-distant

azimuthal projection about the shot point. Circles indicate normal amplitudes and triangles reduced amplitudes. A shadow zone to the north is indicated although it is somewhat undefined.

Figure 3.15 The observed long period amplitudes of CANNIKIN are plotted as a function of epicentral distance, δ . Amplitudes at stations between 310 and 50 degrees azimuth, indicated by triangles, have somewhat lower amplitudes than other stations, indicated by circles. Nuttli's (1972) curve is used to divide the data into two groups. Stations used in order of increasing δ include: MAT, COR, SHK, GUA, DUG, GOL, TUC, KEV, KTG, DAL, FLO, HNR, NUR, SCP, PMG, BLA, SHA, CHG, COP, ESK, SNG, QUE, BEC, STU, TRI, LEM, PTO, PDA, RIV, SJG, JER, and WEL.

Figure 3.16 Long period amplitudes for CANNIKIN plotted as in Figure 3.10. Note the shadow zone.

Figure 3.17 The observed short (above) and long period amplitudes of the earthquake of 2h on 7 FEB 1965 are plotted on equi-distant azimuthal projection about the source. The amplitudes are expressed on an arbitrary \log_2 scale. The amplitudes on the right have been corrected

for the effect of a double couple source. The observed amplitudes are plotted as a function of delta in Appendix B. No shadow zone is evident on either instrument. This is earthquake number 7 (Stauder, 1968a).

Figure 3.18 Observed amplitudes for the 2 JUN 1966 event are plotted as in Figure 3.17. These amplitudes were used to source correct the LONGSHOT and MILROW amplitudes. This is earthquake number 14 (Stauder, 1968a).

Figure 3.19 The theoretical temperature anomaly associated with the best fitting seismic model of the Aleutians is plotted with respect to observed earthquake epicenters (Engdahl, 1971). Note that the epicenters of intermediate depth earthquakes fall in the calculated low temperature region of the slab.

Figure 3.20 Index map shows the location of intermediate earthquakes used in this paper to the Tonga seismic zone (modified after Isacks and Molnar, 1971). Numbers indicate: 1, 18 MAR 1965; 2, 10 AUG 1966; 3, 20 AUG 1965; 4, 12 AUG 1967; 5, 21 JUL 1964. The numbers assigned to these earthquakes in Isacks and Molnar's catalogue are 52, 51, 55, 56, and 57 respectively.

- Figure 3.21 Index map shows the relation of the earthquake of 5 AUG 1964 to the Kermadec seismic zone (modified after Isacks and Molnar, 1971, catalogue number 61).
- Figure 3.22 Amplitudes for the earthquake of 21 JUL 1964 are plotted as in Figure 3.17. The 'p' indicates the stations where low amplitude precursors were observed.
- Figure 3.23 The amplitudes of the earthquake of 5 AUG 1964 are plotted as in Figure 3.17.
- Figure 3.24 The amplitudes of the earthquake of 18 MAR 1965 are plotted as in Figure 3.17.
- Figure 3.25 The amplitudes of the earthquake of 20 AUG 1965 are plotted as in Figure 3.17.
- Figure 3.26 The amplitudes of the earthquake of 10 AUG 1966 are plotted as in Figure 3.17.
- Figure 3.27 The amplitudes of the earthquake of 12 AUG 1967 are plotted as in Figure 3.17.
- Figure 3.28 The location of the earthquake of 4 AUG 1964 is compared with the seismic zone of the Kurile arc (modified after Isacks and Molnar, 1971, catalogue number 118).
- Figure 3.29 The amplitudes of the earthquake of 4 AUG 1964 are plotted as in Figure 3.17.

Figure 3.30 Tracing of the short period P-wave arrivals from the earthquake of 21 JUL 1964 show precursors at PMG, CTA, BAG, and ANP. Normal appearing arrivals at TUC and SBA are shown for reference.

CHAPTER 4. ISLAND ARC VOLCANISM

Volcanoes, an obvious feature of island arcs, have been extensively studied by geologists and geochemists. Geophysical contributions to the understanding of the processes of generation of magma have been of a more general nature consisting of the gross understanding of the kinematics of plate tectonics (e.g., Isacks et al., 1968) and the delineation of the seismic zone (Benioff, 1955; Sykes, 1966). Numerical convection models (Turcotte and Oxburgh, 1968, 1969; Minear and Toksöz, 1970; Toksöz et al., 1971; Hasebe et al., 1970) do not have the resolution to give a definitive answer. The purpose of this chapter is to apply the laws of heat and mass transfer to the problem of the origin of the primary magmas for island arc volcanics. Numerical and analytical models will be constructed to test the feasibility of various hypotheses by comparison with observed data. Geochemical sampling of eruptives, the extent and duration of volcanism, and geophysical data relating to the stress and thermal structure beneath island arcs are relevant to the origin of island arc volcanics. The usefulness of geochemical data is enhanced by low and high pressure geochemical experiments. Geophysical experiments, however, are so generally intractable that numerical and mathematical modeling of the processes provides more lucid results.

There is little agreement on the ultimate origin of the magma which erupts on island arcs other than that a mantle process, rather than partial melting of the crust under the island arc, is involved. Possible origins suggested in current literature include (See Figure 4.1):

1. Partial melting of subducted material
 - a. Partial melting of the basaltic, oceanic crust at the top of the subducted plate (T. Green and Ringwood, 1968a, 1969; Taylor, 1969; Fitton, 1971).
 - b. Partial melting of the subducted oceanic crust with the addition of subducted ocean sediments (Coats, 1962; Hess, 1965; Rayleigh and Lee, 1969).
 - c. Upward migration of water from the downgoing slab thereby lowering the melting point of the mantle (McBirney, 1969).
2. Melting due to frictional heating related to earthquakes on the fault plane which separates the downgoing slab from adjacent mantle (McKenzie and Sclater, 1968; Turcotte and Oxburgh, 1969; Oxburgh and Turcotte, 1971; Minear and Toksöz, 1970; Hasebe et al., 1970).
3. Upwelling of material from the asthenosphere related to tectonic stresses (Gorshkov, 1969a,b, 1970; Isacks et al., 1968).

4. Concentration of pre-existing magma in the asthenosphere by inhomogeneities or hydrodynamic forces (Scheinmann, 1968, 1971).

These hypotheses are by no means naturally exclusive. Direct geochemical evidence of subducted oceanic crust or sediments alone could be sufficient to appraise hypothesis 1. Hypotheses 2 and 3 imply melting at similar depths in the mantle. If the melting point of the volcanics is not greatly reduced as in hypothesis 1, geochemical evidence would be little help in choosing between hypotheses 2 and 3. Numerical modeling of the physics of frictional heating along the fault plane and of the nature of tectonic forces associated with the slab is more relevant. The physics governing the separation of a partial melt from an ultrabasic mush are relevant to all the hypotheses.

4.1 Data and constraints

Island arcs and their volcanics have been extensively studied for various purposes. Data which are useful for establishing constraints on the physical and chemical nature of the source region of the volcanics are most relevant to the purpose of this paper. Little attention will be given to work relating to near surface processes. Abundant geological and petrological data forms the framework within which the more sophisticated results of geochemistry and geophysics must be considered.

4.1.1 Geology and petrology of island arc volcanics

Unlike mid-oceanic and seamount lavas, which erupt with limited duration at one location of the crust within zones of tension, most island arc volcanics erupt on the same part of the crust for tens of millions of years in zones of compression (Matsuda and Uyeda, 1971). Extensive study and classification of magmas has indicated that several varieties erupt on island arcs, the more voluminous of which are not found elsewhere (e.g., Kuno, 1966).

A group of eruptives from a single volcano or a group of closely spaced volcanoes over a limited period of time is known as a petrographic series, whose variations are assumed to be caused by near surface differentiation. Although intermediate members of the series are most abundant, the parental magma is generally believed to be the most basic member of the series which is not a cumulate (Kuno, 1966, 1969). Four petrographic series are associated with island arcs.

The calcic, pigeonitic, or island arc tholeiitic series is low in potassium and shows iron enrichment during the middle states of differentiation (Peacock, 1931; Kuno, 1950, 1966; Jakes and Gill, 1970; Joplin, 1964). The differentiation sequence ranges from "tholeiitic" basalt through granophyre. When present, the pigeonitic rock province is the most seaward and has a sharply defined volcanic front (Kuno, 1966; Sugimura, 1967, 1968; Matsuda and Uyeda, 1971).

Approximately 85% of island arc volcanics are pigeonitic (Sugimura, 1968; Jakes and White, 1971). Pigeonitic provinces include the South Sandwich islands (Baker, 1968a), Tonga islands (Bryan et al., 1972), the central Kurile islands (Gorshkov, 1970), and the seaward belt in Japan (Kuno, 1950).

The calc-alkaline, or hyperthenic, or andesitic rock series has moderate amounts of potassium and shows little iron enrichment during the main part of differentiation (Peacock, 1931; Kuno, 1950, 1966; Joplin, 1964). This sequence includes high alumina basalts, *sensu-stricta* andesites, dacite, and rhyolites. About 12% of all island arc volcanics belong to this series (Sugimura, 1968; Jakes and White, 1971). Recent calc-alkaline rocks are found, for example, in the Aleutian islands (Coats, 1962; Forbes et al., 1969), the Cascade mountains (McBirney, 1968; Kuno, 1969), and Japan, where pigeonitic rocks occur in close proximity (Kuno, 1950, 1966). A continuous gradation may exist between the two series (Kuno, 1966). Pigeonitic rocks are commonly believed to be the first eruptive on young island arcs (Baker, 1968a; Jakes and Gill, 1970; Bryan et al., 1972). On the Aleutian islands, however, volcanic activity began 1.8 my ago (Hayes and Ninkovich, 1970), yet the volcanics are calc-alkaline, not pigeonitic.

Rocks of the nepheline normative alkaline series erupt far inland from the arc (Sugimura, 1968; Kuno, 1966).

The shosonitic series of Joplin (1964) is a subclass of this series. The alkaline series also occurs in non-orogenic areas with a similar mode of emplacement (Forbes and Kuno, 1965).

The other series sometimes found on island arcs is the Andean series (Joplin, 1964; Jakes and White, 1971) which includes voluminous rhyolitic ignimbrites. Strontium isotope studies indicate that these rocks originate from the melting of continental crust (McBirney and Weill, 1966).

Both pigeonic and calc-alkaline volcanics are sufficiently voluminous to build island arcs in oceanic areas. A significant portion of the continental crust may form these rocks (e.g., Dickinson and Luth, 1971; Taylor and White, 1966; Jakes and White, 1971). The mantle between the crust of the arc and the slab could only be a transient source of island arc volcanic, since only a small fraction (ca. 2%) yield of these volcanics is possible from average mantle composition (Armstrong, 1971). Either the more enriched elements in island arc volcanics are added from subducted material or the depleted residuum is somehow removed after differentiation.

The eruptives further inland appear to have fractionated at greater depths and constitute smaller fractions of the source material (e.g., Kuno, 1966; Jakes and White, 1970). "Incompatible" elements such as potassium are more abundant farther inland. These trends have been ascribed to partial

melting at progressively deeper levels along the seismic zone (e.g., Kuno, 1968; Jakes and White, 1970; Dickinson and Hatherton, 1967; Dickinson, 1968; Hatherton and Dickinson, 1969; Fitton, 1971; Green, 1972). Alternatively the material heated along the seismic zone may ascend for some distance as a diapir before melting occurs (Green and Ringwood, 1967a). It is expected that any direct evidence for melting on the fault plane would be subtle, since the eruption temperature of island arc volcanics including calc-alkaline andesites is not greatly reduced in comparison with basalts (Osborn, 1969b). Geochemical and isotopic evidence relevant to this problem is reviewed below. A brief review of relevant high pressure experiments and geophysical data also follows.

4.1.2 Geochemistry

Calc-alkaline magmas are most likely to show chemical evidence of subducted material since they are richer in "incompatible" elements. However, the effects of near-surface fractionation on these magmas are not thoroughly understood.

The differentiation of calc-alkaline magmas is influenced by high water content, and possibly by high alkali and silica content of the parent magma. The initial composition of the parent magma has been difficult to determine since the phenocrysts in an eruptive may have formed at

different water and oxygen fugacities than the bulk of the cumulate. Proposed parental magmas vary from high-alumina basalt to andesite itself. Direct evidence of the source region is lacking as peridotite xenoliths are not found in calc-alkaline rocks and high pressure, 10 to 20 kb, garnets are only found rarely (Green and Ringwood, 1969b). It is sometimes contended that a silica rich andesitic magma could not ascend through the mantle since it would react with olivine in the wall rock (Osborn, 1969b). However, once a reaction rim was established in the conduit the reaction rate would be very low.

Low pressure petrological experiments have been difficult to perform since it is necessary to control the oxygen fugacity as well as the partial pressure of water. Vapor transport, which may be important in nature (Anderson and Gottfried, 1971), is difficult to measure in the laboratory. Much confusion has resulted since it has not been considered that the observed eruption temperature and liquidus of andesite are close to those of basalt, about 1200°C (Osborn, 1969b).

Minerals commonly observed in ejected cumulate blocks and calc-alkaline gabbros include magnetite, titanous aluminous hornblende, calcic plagioclase, olivine, calcic clinopyroxene, apatite, biotite and sphene. If care is taken, it is possible to fit major element compositions of andesites to a differentiation model of the observed

phenocryst from high-alumina basalts (Baker, 1968b; Osborn, 1969b,c; Anderson and Gottfried, 1971). Petrological experiments have confirmed that plagioclase precipitating from a hydrous melt is calcic (Yoder, 1965, 1969; Osborn, 1969b). The association of plagioclase and olivine in cumulates limits the depth of fractionation to 20 km (Yoder, 1969).

Osborn (1969a) favors the country rock as the source of the water in calc-alkaline melts. This seems unlikely since recent calc-alkaline rocks are found only on island arcs, but intrude a variety of rock types which would have different porosities and permeabilities with respect to water and are found inland of and in close association with pigeonitic rocks intruding the same rock types.

Trace element compositions in calc-alkaline rocks are difficult to reconcile with the fractional crystallization of andesite from high-alumina basalt magma. Vanadium and scandium which would be depleted by magnetite precipitation, are not strongly depleted in andesites with respect to the associated high-alumina basalts. Other "normally" concentrated elements (K, Rb, Cs, Ba, rare earth elements, Th, U, Zr, Hf, and Li) are not greatly enriched in andesite with respect to the associated high-alumina basalts. Nickel contents of high-alumina basalts and andesites are low but similar (Taylor and White, 1966; Taylor, 1969; Taylor et al., 1969a,b; cf. Osborn, 1969c). On this evidence, Taylor

(1969) proposes a source region depleted in refractory elements with a composition of one part basalt to two parts peridotite.

4.1.2.1 Daughter isotopes

Relatively unambiguous evidence on the source region of volcanics can be obtained from isotopic ratios of heavy elements, which are not effected by chemical reactions. Most importantly remobilized continental crust (or subducted sediments) can be identified by measuring the ratios of stable daughter elements formed from the decay of long lived parents. Strontium (87) (from rubidium decay) and lead (206, 207, 208) (from thorium and uranium decay) are most useful. The daughter elements in the continental crust have more radiogenic isotopic ratios than in the mantle, since parent elements have been preferentially concentrated in the crust with respect to the mantle (Hurley, 1968a,b).

It is now evident that most island arc volcanics contain too few radiogenic isotopes to be formed only from remelted continental crust or by extensive mixing of continental material with basalt (Hedge, 1966; Ewart and Stipp, 1968; Lewis, 1968; Pushkar, 1968; Kurasawa, 1968; Yoder, 1969; Tatsumoto and Knight, 1969; Hedge and Knight, 1969; Tatsumoto, 1969; Gill, 1970; Hedge et al., 1970; Peterman et al., 1970b,c). The strontium Sr (87/86) ratios for island arc volcanics generally range between 0.7030 and 0.7045 (Hedge

et al., 1970; Peterman et al., 1970b,c; Gill, 1970; Yoder, 1969; Pushkar, 1968), although in some areas more radiogenic ratios of about 0.7060 have been observed (Pushkar, 1968; Ewart and Stipp, 1968). Abyssal tholeiites generally are less radiogenic than island arc volcanics having Sr (87/86) ratios of 0.7010 to 0.7030 (Hart, 1971; Ozima et al., 1971; Hedge and Peterman, 1970). Hawaiian basalts, seamount basalts, and certain continental basalts have the same range of strontium isotopic ratios as island arc volcanics (Laughlin et al., 1971; O'Neil et al., 1970; Peterman et al., 1970a, Powell and Delong, 1966; Ozima et al., 1971; Leggo and Hutchinson, 1968). Continental rocks generally have Sr (87/86) ratios greater than 0.7100.

Lead isotopes in island arc volcanics are generally more radiogenic than in abyssal tholeiites (Figure 4.2) (Tatsumoto, 1966a,b; Hedge and Knight, 1969; Tatsumoto and Knight, 1969; Armstrong, 1971). Tatsumoto (1969) stated that Japanese alkali basalts are less radiogenic than Japanese tholeiites; however, only three points were available for alkali basalts and the distributions of both rock types overlap.

Lead isotopic ratios have been used to show that island arc volcanics originate from a mixture of subducted oceanic sediments and abyssal basalts (Armstrong, 1971; Armstrong and Cooper, 1971; Tatsumoto, 1969). When Icelandic basalts and basalts from small oceanic islands are considered, the

case becomes much less convincing. In Figure 4.2 it is evident that the Pb (206/204) vs. Pb (208/204) co-ordinates of abyssal tholeiites and island arc volcanics overlap. The distribution of lead isotopes in island arc volcanics and Icelandic volcanics is similar. Some rocks from small Atlantic islands are much more radiogenic than island arc volcanics (Oversby and Gast, 1968, 1970).

The scatter in lead isotopic ratios is due to mantle inhomogeneities, possibly related to convection and previous episodes of differentiation (Oversby and Gast, 1970; Oversby et al., 1971; Armstrong and Cooper, 1971). Two-stage model ages for lead found on oceanic islands are about 2 by (Oversby and Gast, 1970; Oversby et al., 1971).

Isotope studies thus confirm the conclusion of trace element studies that the source region of island arc volcanics is enriched in non-refractory elements. This is compatible with but not necessitating the incorporation of subducted material into the volcanics.

Mid-ocean ridge basalts alone cannot be the parent or the source regions of island arc volcanics, since potassium, heavier alkalis, vanadium, and radiogenic lead and strontium are much more abundant in island arc volcanics than mid-oceanic basalts (Taylor et al., 1969a; Armstrong, 1971).

4.1.2.2 High pressure geochemistry of calc-alkaline rocks

High pressure petrological experiments have been

hampered by the lack of knowledge of the primary melt which forms the calc-alkaline series.

Some type of multistage process may be necessary to form calc-alkaline melts, since silica saturated magmas cannot form under dry conditions at pressures exceeding 5 kb (O'Hara, 1963a,b; Boyd and England, 1963). Under wet conditions both high-alumina basalts and andesites can form from mantle rocks in the lithosphere, 10 to 30 kb (O'Hara, 1965; Yoder, 1969). Andesitic melts can also form from the partial melting of a quartz eclogite at 80 to 150 km depth or from the fractional crystallization of a hydrous basalt between 15 and 80 km depth (Green and Ringwood, 1967, 1968a, 1969). The melting temperature of the hydrous andesites produced by Green and Ringwood (1968a, 1969) is probably too low when compared to the observed eruption temperature of calc-alkaline rocks.

The range in depth, 30 - 150 km, of differentiation for island arc volcanics implied by these experiments is so broad that no useful constraints on the genesis of these volcanics can be obtained.

4.1.3 Geophysical data

The distribution and focal mechanisms of earthquakes in the seismic zone beneath island arcs are too well known to need a review. Other geophysical data relevant to the problem of the origin of island arc volcanics and also of

intra-arc spreading includes studies of the seismic velocity and attenuation beneath island arcs, heat flow measurements, and electrical conductivity measurements. The mechanism and distribution of earthquakes located away from the seismic zone is more relevant to the origin of intra-arc basins (Chapter 5).

Geophysical data indicates that the upper most mantle beneath western Japan is exceptionally hot and possibly partially molten. Heat flow values often exceed $80 \text{ erg/cm}^2\text{-sec}$ (Uyeda and Horai, 1964; Matsuda and Uyeda, 1971). Low seismic velocity and high seismic attenuation exist in the upper most mantle of this region (see Utsu, 1971 for a review). The deep electrical conductivity is also high (Rikitake, 1969).

Metamorphic rocks from similar regions in the geologic record show the effects of metamorphism with a high geothermal gradient (Dewey and Bird, 1970; Oxburgh and Turcotte, 1970; Matsuda and Uyeda, 1971). Partial melting at the base of the lithosphere sometimes produces voluminous rhyolitic ignimbrite deposits (McBirney and Weill, 1966; Pushkar et al., 1972). It should be noted that the volcanics which actually erupt do not constitute a major part of the heat budgets of island arcs (Sugimura, 1968).

Compressive stress in the region of island arc volcanoes must impede the ascent of magma at least to some extent. (Alkaline volcanics ascend rapidly to the surface and

probably erupt in zones of tension as in non-orogenic environments.) It would therefore be expected that the magmas which eventually erupt are more differentiated than they would otherwise be. There is little evidence, however, relevant to the relationship between transient variations in local stress associated with the occurrence of great earthquakes and volcanism. Tokarev (1971) was unable to detect any correlation between earthquakes and volcanoes in the Kurile region other than a correlation for the entire arc. He believed that the correlation was not a simple cause and effect because the earthquakes and volcanoes occurred at opposite ends of the arc. Kanamori (1972) found a correlation between eruptions of a volcano near an arc-arc-arc triple junction and great earthquakes on the arcs not associated with the volcano. In this case the volcano was located immediately in front of a trench and was therefore subjected to tension after great earthquakes.

4.1.4 Geological, geochemical, and geophysical constraints

Any physical model of island arc volcanics must be compatible with the following data:

- A. Island arc volcanics erupt continually within zones of compression.
- B. The eruption temperature of island arc volcanics is similar to that of basalts.
- C. There is a sharp volcanic front on the seaward

side of island arcs. Inland the volcanics become more fractionated and less voluminous.

D. The source region of the volcanics is rich in incompatible or nonrefractory elements and radiogenic isotopes compared with the source region of mid-ocean basalts.

E. High heat flow and crustal temperatures sometimes are associated with island arcs.

The data are sufficient neither to prove nor to reject a fundamental role of subducted material in island arc volcanics. The association of these volcanics with the subduction process is well established, but available data appear to be insufficient to directly resolve the problem.

4.2 Theoretical modeling and testing of hypotheses

Physical models of the proposed mechanisms for the origin of island arc volcanics were constructed for comparison with observed data. Incorporation of subducted material in the volcanics, if any, is not sufficient to be of concern in a thermal model. The physics governing the segregation of melt from an ultrabasic mush is treated first as it has relevance to all of the mechanisms under consideration.

4.2.1 Segregation of melt from mush

For magma to erupt at the surface it is necessary for the partial melt to segregate from the crystal which formed

it. Once a substantial volume of melt is present, it can ascend by elastic crack propagation (Weertman, 1971). This process, however, is too slow for melts trapped between grain boundaries. A small fraction of partial melt can segregate if a hydraulic pressure gradient is present and if the geometry of the grains and the conduit are suitable.

4.2.1.1 Mathematical model of segregation

A model with an analytic solution is available to demonstrate the dimensional dependence of this effect (Figure 4.3). The equations governing the flow in a dike-like region bounded by rigid boundaries and containing two fluids with different viscosities are (Faizullaev, 1969):

$$f_1 \eta_1 \frac{\partial^2 u_1}{\partial y^2} + \chi(u_1 - u_2) = f_1 \frac{\partial p}{\partial x} \quad (4.1a)$$

$$f_2 \eta_2 \frac{\partial^2 u_2}{\partial y^2} + \chi(u_2 - u_1) = f_2 \frac{\partial p}{\partial x} \quad (4.1b)$$

where

u_1, u_2 - velocity

f_1, f_2 - fraction

η_1, η_2 - viscosity

1, 2 (subscripts) - fluid 1, fluid 2

y - direction normal to dike

x - direction of flow

χ - empirical coefficient

It is evident from the equations that two end member regimes are possible. Both fluids may move at the same rate and obey Poiseuille's law or the less viscous fluid may move rapidly with respect to the more viscous one and obey Darcy's law. The problem of flow induced segregation reduces to determining the transition between these two types of flow, since differential movement of the two fluids is a necessary condition for the less viscous fluid to become enriched downstream.

For an ultrabasic mush, $f_1 \ll f_2$ and $\eta_1 \ll \eta_2$. As Darcy's law must be obeyed at the limit of $\eta_2 \rightarrow \infty$, the empirical coefficient χ can be identified with the permeability k .

$$\chi = f_1^2 \eta_1 / k \quad (4.2)$$

The permeability, which depends only on the geometric arrangement of the two fluids can be calculated from a variety of assumptions and an expression of the form

$$k = C f_1^3 / S^2 \quad (4.3)$$

where

C - a constant

S - ratio of area to volume

The constant C must in practice be assumed ad hoc for each set of data. For materials having tortuous pores, C can be significantly smaller than the theoretical value of about 0.5. Fortunately, free energy requirements prohibit highly

tortuous grain boundaries in a chemically active system such as an ultrabasic mush. (See Scheidegger (1960) for a detailed review of how equation 4.3 is derived.) Assuming $C = 0.5$ and a-sided cubical grains, equation 4.3 becomes

$$k = f_1^3 a^2 / 72 \quad (4.4)$$

Equation 4.1 can be solved exactly (Faizullaev, 1969). The expression relating the difference in velocities at the center of the flow is sufficient for our purpose of determining in which flow regime an ultrabasic mush is:

$$U = \frac{u_{1\max} - u_{2\max}}{u_{1\max}} = \eta^{-1} \left[\eta - \frac{\eta}{(f_1 + f_2 \eta)} \right] \quad (4.5)$$

$$+ \frac{H}{2f_1 f_2} \left(\frac{\cosh \left\{ \left(\frac{f_1}{\eta} + \frac{f_2 H}{f_1 f_2} \right)^{1/2} \right\}}{\cosh \left\{ \left(\frac{f_1}{\eta} + \frac{f_2 (H-1)}{f_1 f_2} \right)^{1/2} \right\}} \right) \right]$$

where $\eta \equiv \frac{\eta_2}{\eta_1}$ $H \equiv \chi h^2 / 4\eta_1 = f_1^2 h^2 / 4k$

For large f_2 , η , and H (3) reduces to

$$U = \eta / (\eta + H/f_1) \quad (4.6)$$

A dimensionless constant $P = 2\eta f_1 / H$ thus determines whether there is Darcy flow ($P \gg 1$) or Poiseuille flow ($P \ll 1$). An

expression of the form of (4.6) also results from Faizullaev's (1969) solution for flow in a cylindrical conduit. Substituting the expression derived for permeability one obtains

$$P = a^2 f_1^2 \eta / 9h^2 \quad (4.7)$$

Note that segregation is most likely if the conduit is narrow, the viscosity of the grains large, or the fraction of melt large. Adjacent domains in the conduit with different fractions of melt could segregate independently.

4.2.1.2 Discussion of model

The relatively simple geometry of seamounts and mid-ocean ridges permits a test for gross validity of the mathematical model for segregation. It is believed on petrological grounds that magma segregation under mid-ocean ridges begins at about 5% partial melt (Kay et al., 1970; Ringwood, 1969; Green et al., 1967). In agreement with this observation a fraction of 3% melt at the beginning of differentiation can be obtained by using parameters applicable to mid-oceanic ridges. (The value of η is approximately the ratio of the viscosity below the asthenosphere (10^{22} to 10^{23} poise, e.g., Cathles, 1971) and basaltic melts (10^3 to 10^4 poise, e.g., Bottinga and Weill, 1972).)

$$\eta = 10^{19} \quad h = 30 \text{ km} \quad a = 0.1 \text{ cm}$$

The oceanic crust, if it is produced from segregated melt, should be somewhat thicker at low spreading rates where the conduit is narrower. However, this effect is not likely to be large since the increase due to adiabatic decompression of the fraction of melt from 5% to 30% in a small depth range above 30 km (Kay et al., 1970; Ringwood, 1969; Green et al., 1967) would dominate over the dependence of fractionation on conduit width. The observed relatively constant thickness and the composition of oceanic crust are thus compatible with the model.

Magma formed away from ridge axes at seamounts differentiates at greater depths and smaller fractions of melt than magma formed at ridge axes. From thermal considerations only a relatively narrow conduit can exist at depth for a minor source of magma. If only a small fraction of melt segregates, the regions with the highest concentrations of partial melt contribute disproportionately to the magma since the rate of segregation is a strong function of the fraction of melt present. At high concentrations, such as found at mid-ocean ridges, all regions contribute to the melt. The melt erupted on seamounts has more radiogenic isotopes than magma erupted on ridges. For geochemical reasons, radioactive isotopes and therefore their products are found with the lowest melting fraction. A reasonable cause for the postulated heterogeneities is segregation at ridge crests and island arcs during previous cycles of

mantle convection (Armstrong and Cooper, 1971). Viscous flow, such as that commonly observed in metamorphic rocks, deforms inhomogeneities but does not eliminate them. Considerable randomness in mantle composition on a local scale is probable since no fixed cores of convection cells can exist if ridges migrate with respect to trenches. Thus, virtually any mechanism for producing island arc volcanics is compatible with the apparent enrichment of the source region in radiogenic isotopes and nonrefractory elements, as long as segregation occurs at a small fraction of melt. There is no need to require that the radiogenic isotopes come directly from subducted sediments.

A very small conduit thickness is necessary for differentiation segregation of melt from the asthenosphere if the viscosity and fraction of this melt determined from seismic attenuation are not in gross error. For the 1% melt and 10^7 poise viscosity of the melt in this region (Solomon, 1972), a conduit less than a kilometer wide is needed for segregation to occur. (An analytic solution (McKenzie, 1969) indicated that flow through this constricted conduit occurs only within a few kilometers of the intersection of the fault zone and asthenosphere. Island arc volcanoes occur over a much larger region.) The permeability of such a material would be so low that little melt could diffuse through it. Assuming

grain size - $a = 0.3$ cm

specific weight of melt - $\mu = 3 \times 10^3$ dynes/cm³

viscosity of melt - $\eta = 10^7$ poise

hydraulic gradient - $\Delta \ell' = 0.1$

and calculating the permeability using equation (4.4), a flux of 1 cm/my of melt results. Unless there is a gross error in these parameters, no significant amount of melt could be directly concentrated in the asthenosphere. This calculation, however, says nothing about the possibility of non-differentiated material rising from the asthenosphere.

4.2.2 The fault zone and frictional heating

The details of the region near the trench where the slab turns down are probably exceedingly complicated. It is highly unlikely that the top of the slab remains the simply stratified section of oceanic sediments, extrusive basalts, intrusive crust, and mantle that is sometimes shown in schematic diagrams. The active fault plane between the island arc and the slab is likely to vary in location, sometimes entraining parts of the lithosphere of the arc in the slab, sometimes leaving behind ophiolite complexes. As with most large faults observed in the field and with ophiolites, extensive mixing of material can be expected.

The existence of a fault plane on top of the slab is relevant to the production of island arc volcanics and

intra-arc spreading since friction along the fault may provide a heat source, and in addition, the flow pattern in the mantle above the slab would be modified by the existence of any shear zones. A detailed numerical model is necessary to determine the amount of frictional heating needed to cause increased temperatures. The conditions for a shear zone to exist above the slab within the fluid regions of the mantle can be determined from a simple analytical model, as can the time necessary for a diapir of material heated in such a shear zone to ascend.

4.2.2.1 Frictional heating in the rigid mantle

Great earthquakes occur where the slab is thrust against the lithosphere of the island arc. The hypothesis that frictional heating along the fault plane associated with these earthquakes causes melting beneath island arcs can be tested mathematically, for the relevant parameters except for the amount of frictional heating are known reasonably well. It does not matter whether the melting occurs in subducted oceanic crust or in the mantle since the temperature needed to produce the observed volcanics is constrained by their observed high eruption temperatures. Two variants of the hypothesis are considered: each earthquake may melt its own batch of magma; or the heat may build up continually. The former case results in mechanical and geochemical difficulties; in the latter case, the mode

which frictional heating is usually assumed to take requires thorough modeling.

The possibility that each great earthquake produces its own batch of magma is very unlikely since the observed mode of volcanism would be difficult to explain. Great earthquakes occur on the order of every 50 years (Kanamori, 1971a). For the hypothesis to work, almost all the melt produced would have to escape from the fault zone before the next earthquake and, also, without losing significant heat to the walls of the fault zone. Almost total melting would be required for the material to flow out in a short time span, thus conflicting with the highly differentiated character of island-arc magmas with respect to the mantle and the lack of mantle derived ultra-basic xenoliths in these magmas.

The stress needed to rapidly raise even a thin sheet above its melting temperature is excessive. Assuming a latent heat of 8×10^9 ergs/cm³, 10 kb of stress are required to melt 5 m layer of rock every 50 years. Unless the flow of material from the fault zone is extraordinarily rapid, most of the heat from a thinner zone would be lost to the sides of the fault zone.

Partial melting near the fault zone may also result from the buildup of heat over long periods of time (Hasebe et al., 1970; Oxburgh and Turcotte, 1970, 1971; Minear and Toksöz, 1970a,b). Stress heating is likely to adjust

itself in such a way that the temperature is at most slightly above the solidus since appreciable melting reduces friction.

Extensive frictional heating on the uppermost 20 or 30 km of the fault plane is unlikely, since those melange sequences which are believed to form in that environment exhibit the effects of very low rather than high temperature metamorphism (e.g., Ernst et al., 1970). Frictional heating on a shear zone in the more fluid parts of the mantle is limited by a variation principle which requires that the frictional energy dissipation on the fault plane be less than the dissipation which would have resulted if a great proportion of shear had occurred in the fluid. There is also the requirement that energy dissipation not exceed the amount of work available from the convection process.

Two-dimension numerical models of descending slabs were calculated with different amounts of frictional heating near the fault plane (Figure 4.4). Approximately 6.4×10^{-4} ergs/cm³-sec of heating in a 14 km wide shear zone were needed to produce an 80 km deep region of slightly elevated temperature. Less than a million years are needed for the temperature to reach dynamic equilibrium. A detailed numerical model with a grid spacing of 2.5 km, a 3.5 km wide shear heating zone, and a translation distance of 5 km confirms that the amount of frictional

heat required for melting is relatively independent of the shear zone and that the less detailed numerical models were reasonably accurate (Figures 4.5 and 4.6). For normal subduction rates, the stress required to produce melting is independent of subduction rate; most of the heating goes into heating the moving slab and frictional heating is proportional to velocity at constant stress.

The frictional heating in both the more and the less detailed models is equivalent to a stress of 4 kb at the assumed subduction rate of 8 cm/yr, about the same as deduced by Minear and Toksöz (1970). There is no obvious violation of the conservation of energy or the variational principle for viscous flow, since frictional heating is necessary only next to the lithosphere of the island arc.

The calculated value of stress is high compared to the apparent stress drops of about 100 bars which define a lower limit of stress for thrusting earthquakes (Brune, 1968, 1970; Wyss, 1970). This value is, however, in agreement with the stress required to produce the observed uplift on the outer rise of the Japan trench (Hanks, 1971).

Great thrusting earthquakes are less frequent in regions where a low velocity zone has developed between the crust of the arc and the slab (Kanamori, 1971a). It is difficult to see how a shear zone could continue to produce significant amounts of frictional heat after such a large zone of heated mantle has developed above it. Once

a moderate viscosity region developed above the slab, forced convection would begin if the stress of the fault plane was high enough to cause melting. Widespread high temperatures in the uppermost mantle beneath island arcs indicated by geophysical measurements, by the eruption of voluminous products of crustal anatexis and by the emplacement of granite batholiths are too hot to be explained by frictional heating above the slab.

This does not preclude frictional heating along the fault plane providing the heat source of volcanism on young island arcs where the crustal temperatures are not high. Minor amounts of frictional heating may also be important in material which is already hot for some other reason. A mechanism other than or in addition to frictional heating is needed to explain the association of high lithospheric temperatures with island arc volcanism.

4.2.2.2 Shear zones in fluid mantle

A brief examination of the physics controlling a shear zone is in order as hypotheses under examination propose the existence of a shear zone above the slab in the fluid parts of the mantle. Equations for the velocity and temperature distribution in a shear zone have been solved by Turcotte and Oxburgh (1968). For the purpose of this paper the conditions necessary for the existence of the shear zone, itself, are more relevant.

The variational principle for viscous flow limits the amount of viscous heating in the shear zone. An attempt to increase the amount of viscous heat generation in a shear zone by decreasing its thickness or increasing its viscosity would cause a large amount of the flow to concentrate outside the shear zone. The total amount of heat generation with a low viscosity shear zone cannot exceed the amount with the shear zone absent.

An analytical solution is easily obtained to approximate this effect. Let the region above the slab be modeled by two fluids bounded by parallel planes, a shear zone with viscosity η_1 and thickness d_1 and the normal mesosphere with viscosity η_2 and thickness d_2 . Stress is conserved at the boundary between these fluids

$$\eta_1 v_1 / d_1 = \eta_2 v_2 / d_2 \quad (4.8)$$

where v_1 and v_2 are the velocity changes across each fluid. The total energy dissipation in each of the fluids is given by

$$\eta_1 v_1^2 / d_1 \quad (4.9)$$

Substituting for v_1 , the ratio of energy dissipation in the shear zone to the energy dissipation in the entire region is

$$E = \eta_2 d_1 / (\eta_1 d_2 + \eta_2 d_1) \quad (4.10)$$

Setting $E = 0.95$ and $d_1/d_2 = 0.05$, the ratio of the viscosities is 380. As this ratio is well within the range of

viscosities normally considered in earth models it is not unreasonable to presume that a shear zone is present above the slab in the asthenosphere. However, assuming a normal mesosphere viscosity of 10^{23} poise (e.g., McConnell, 1968; Cathles, 1971) and a distance from the slab to the lithosphere of the arc of 150 km, the maximum stress that could result would be 2 kb for 8 cm/yr spreading. If the shear zone in the example developed, the stress would drop to 100 bars. Frictional heating would then be too small to maintain any excess temperature in the shear zone. The shear zone however might be maintained by a strain rate dependent viscosity.

It is thus unlikely that a thermal maximum could result from shear heating adjacent to the slab in the mesosphere. Since the viscosity of the asthenosphere is about 10^{20} to 10^{21} poise, significant frictional heating in the asthenosphere is even less likely.

Even if a thermal maximum did result from frictional heating adjacent to the fluid part of the mantle, the time required for a thermal diapir to rise from the shear zone is geologically significant. This can be seen by modeling the diapir with a fluid sphere. The rate of ascent is then

$$u = R^2 \Delta \rho g / 3\eta_2 \quad (4.11)$$

R is the radius of the sphere. The density difference due to the maximum possible viscous heat generation is (setting

$d_1 = 2R$ and assuming no heat is lost)

$$\Delta\rho = \rho tv^2 \alpha \eta_2 / (C_p 2Rd_2) \quad (4.12)$$

where t is the time of heating. By assuming that heating and ascent are concurrent, one can set $u = d_2/t$ to obtain

$$t^2 = 6C_p d_2^2 / Rv^2 \rho g \alpha \quad (4.13)$$

Setting specific heat $C_p = 10^7$ erg/°C-gm
 thickness of mesosphere $d_2 = 100$ km
 radius of diapir $R = 50$ km
 velocity of subduction $v = 10$ cm/yr
 acceleration of gravity $g = 10^3$ dynes/gm
 coefficient of thermal expansion $\alpha = 4 \times 10^{-5} \text{ } ^\circ\text{C}^{-1}$
 density $\rho = 3$ gm/cm³

one obtains that 10 my are required for a diapir to form and rise. Note that the estimate is independent of viscosity and that the model and the parameters were chosen to minimize the ascent time and that any heat loss by conduction was ignored. It thus is both unlikely that significant frictional heating could occur adjacent to the slab below the lithosphere and that a thermal diapir could rise from that zone of heating in a reasonable time.

In partially molten regions below the island arc where the viscosity of the melt and the geometry of the flow are conducive to segregation, any additional heat due to friction would increase the fraction of melt, thereby contributing to the volcanism. As shown above, the asthenosphere

is not likely to be a region favorable for segregation. A large increase in the percentage of melt would, therefore, be required for any melt to ascend directly from the asthenosphere to the surface. Shear heating in the fluid part of the mantle, therefore, is even less likely to cause island arc volcanism, than heating in the shear zone between the lithosphere of the island arc and the slab. Even if some shear heating did occur, it is unlikely that the heated region would rise as a diapir or that the additional melt could segregate directly from it.

4.2.3 Intrusions from asthenosphere

Intrusions of the asthenosphere into the lithosphere of island arcs may be the source region for island arc volcanics (Gorshkov, 1969a,b, 1970). The feasibility of this hypothesis is somewhat hard to appraise since the lithosphere beneath the volcanic belt is the most difficult region to represent, since the stress pattern there is not constrained by abundant direct evidence and since continuous flow and brittle fracture are possible means of deformation in its lower portion. (A problem of semantics exists here since the lithosphere is commonly considered rigid. Clearly, lithosphere and asthenosphere are artificial divisions. Rather than create new terminology, high viscosity upper asthenosphere is used herein to refer to the region near the base of the lithosphere which is much more

viscous than the asthenosphere, yet subject to significant deformation.) Calculation of the shape and extent of the intrusion is difficult without some direct evidence since brittle fracture may cause intrusions to penetrate cooler parts of the lithosphere.

If flow is induced in the high viscosity upper asthenosphere, hotter, less viscous material rising from the asthenosphere would replace the material entrained with the slab. This process would be somewhat self-generating, since new intrusions would raise the temperature of the lithosphere beneath the arc, increasing the area subject to coupling with the slab. An adequate source of magma could result this way since depleted residuum would be later entrained with the slab and carried away. The entrained material probably continues down to a considerable depth since the forced convection cell would become depleted in magma and heat if it were too tightly closed.

The problem of determining whether the asthenosphere intrudes the lithosphere of island arcs thus reduces to determining whether the high viscosity upper asthenosphere can deform at a rate such that the intruding asthenosphere can supply the observed magma and excess surface heat flux. Analytical models giving the rate of flow induced by coupling of the high viscosity upper asthenosphere and the slab and the rate of flow needed to maintain high crustal temperatures were constructed. A numerical calculation was made to

obtain the general geometry of the flow.

4.2.3.1 Mechanical model for flow in high viscosity upper asthenosphere

Models of flow in the high viscosity upper asthenosphere are difficult to construct since relevant mechanical properties and boundary conditions are not evident. It may be reasonably expected, however, that viscosity would vary continuously with depth and that a region having a viscosity 2 or 3 orders of magnitude higher than the asthenosphere exists near the base of the lithosphere. Theoretical viscosity calculations assuming solid state creep indicate that this region would be 10 or 20 km thick (Weertman, 1970). It is easy to show that the amount of friction, calculated to cause melting on the fault between the lithosphere of the island arc and the slab, would induce significant flow in such a region. For example, assuming that

stress on the fault = 3 kb

viscosity = 10^{23} poise

thickness of high viscosity upper asthenosphere = 10 km

a flow of 1 cm/yr results directly from the definition of viscosity. Stresses of this magnitude might also cause faulting in the lithosphere adjacent to the slab.

A numerical model was computed to simulate flow caused by coupling of the slab to the high viscosity upper

asthenosphere (Figure 4.7). A no-slip boundary was assumed to exist between the asthenosphere and the slab and the lower lithosphere was assumed to be partially coupled to the slab. An approximately equidimensional eddy resulted in the upper more viscous region probably due to the different boundary conditions in the two layers. Calculations in Chapter 5 indicated that viscosity stratification alone was insufficient to cause a separate eddy in the higher viscosity region. Other models calculated using different boundary conditions along the slab in the upper layer gave geometrically similar flow patterns as long as some coupling along the boundary was assumed.

If the gross shape of the flow pattern calculated above is correct, that fraction of melt in the flow would increase seaward since melting curves being steeper than adiabats cause the fraction of melt to increase upward in an ascending material (Figure 4.8). The volume of magma erupted would thus increase seaward. The fraction of incompatible elements in the erupted magma, such as potassium, would increase landward since these elements are most enriched if a small fraction of melt is formed. A sharp volcanic front could form at the turning point of the flow as it would be difficult for differentiation to occur in the descending part of the flow where the material is cooler and the fraction of melt is decreasing.

The flow pattern actually present is probably more

complicated, since brittle fracture in the lithosphere of the island arc may permit irregular and intermittent flow into cooler regions. These intrusions would be favorable regions for magma segregation due to the smaller dimensions of their conduits. Heat lost by conduction during the cooling of an intrusion into a cooler part of the lithosphere would increase the regional temperature, the surface heat flux, and the region below the island arc capable of viscous flow.

4.2.3.2 Thermal considerations on flow in high viscosity upper asthenosphere

If material which intrudes from the asthenosphere to replace the material in the high viscosity upper asthenosphere that was entrained with the slab is the source region for island arc volcanism, the velocity of upwelling must be great enough for the material to remain hot. An analytic solution is easily obtained to show that flow at a small fraction of observed subduction rates can remain hot if it upwells beneath island arcs. Heat lost to the surface from this flow, an obvious source for the observed high flow on island arcs, is a limiting factor on the depth of the top of the upwelling.

$$q = K \left(\frac{T}{z} - \frac{T}{l} \right) \quad (4.14)$$

q = heat flux at surface

T = temperature of asthenosphere

K = thermal conductivity

z = depth of top of upwelling

l = thickness of asthenosphere

This heat must be balanced by heat brought up by convection.

$$q = \rho c v T r \quad (4.15)$$

ρc = volume specific heat

v = vertical velocity in upwelling

r = fraction of cooling of convection of material

Solving for V , one obtains

$$V = \kappa \left(\frac{l-z}{z l r} \right)$$

κ = thermal diffusivity

Letting

$$r = 1/10$$

$$\kappa = 0.01 \text{ cm}^2/\text{sec}$$

$$l = 100 \text{ km}$$

$$z = 50 \text{ km}$$

one obtains an average velocity of 0.3 cm/yr.

The heat lost from the flow would continually raise the temperature near the base of the lithosphere, increasing the region subject to viscous flow. This attrition of the lithosphere would reach equilibrium either when the heat lost to the surface by conduction balanced the heat brought up by mass transport or when melting of the lower crust caused efficient heat transfer to the surface. The growth of the asthenosphere at the expense of the lithosphere

might take several million years if the induced flow was a moderate fraction of the subduction rate, say about 1 cm/yr. No obvious mechanical or thermal difficulties therefore arise from the suggested flow of the asthenosphere into the lithosphere of the island arc. Unlike the mechanism of frictional heating, intrusions from the asthenosphere could provide a source of magma and the observed high heat flow on island arcs.

4.3 Summary and conclusions

Four classes of hypotheses for the origin of island arc volcanics: (1) melting temperature lowered by subducted material; (2) frictional heating on fault zone; (3) upwelling of material into the lithosphere of island arc; and (4) concentration of pre-existing melt in asthenosphere were appraised by constructing physical models for comparison with observed data. To be valid, an hypothesis should be compatible with the following characteristics of island arc volcanism.

(A) Continual eruption with zone of compression.

This volumetric constraint is satisfied easily by hypotheses (1) and (2) since a new source region is continuously supplied by subducted material. For hypothesis (3) reflux of material from the lithosphere back into the asthenosphere must be postulated for the source of

volcanics to be adequate. Hypothesis (4) seems to imply insufficient generation of magma.

(B) High eruption temperature.

This eliminates hypothesis (1) as far as thermal models are concerned although some subducted material could be incorporated in the magma, without greatly modifying the melting point.

(C) Sharp volcanic front and landward diminution of volcanism. Hypotheses (1) and (2) can be expected to satisfy this since less melting would occur at greater depths. Hypothesis (3) is compatible as the intrusion would be shallower nearer to the arc. It is difficult to explain the widespread nature of volcanism with hypothesis (4).

(D) Enriched incompatible elements in source region.

Any of the hypotheses would satisfy this because regions with greater fractions of melt contribute disproportionately to the final melt if segregation occurs at small fractions of melt.

(E) High heat flow and crustal temperatures.

Only a large scale flux of material from the asthenosphere seems capable of causing this. A hot region between the slab and the crust of an island arc would reduce friction on the fault plane. The friction necessary to cause melting would also probably induce flow in the lower lithosphere. It is conceivable that frictional heating may be important

beneath island arcs which do not have high crustal temperatures. Friction might also increase the temperature of previously hot material which upwelled from the asthenosphere.

It may thus be concluded that serious objections exist to all the hypotheses except induced flow beneath the island arc. Unfortunately this hypothesis is most difficult to model physically, since protracted mathematics and unknown physical parameters would be involved. Flow voluminous enough to be the source of island arc volcanics could reasonably occur beneath island arcs, but little can be said on the detailed geometry of such flows without additional direct data.

FIGURE CAPTIONS

- Figure 4.1 Schematic diagram shows proposed origins of island arc volcanics. Upper left: subducted oceanic crust or sediments melt at a reduced temperature. Lower left: frictional heating along the fault plane raises the temperature until melting occurs. Upper right: pre-existing magma in the low velocity zone is concentrated by the geometry of the slab or by hydrodynamic flows in the flow pattern. Lower right: material from the low velocity zone intrudes the lower lithosphere and partially melts as it rises.
- Figure 4.2 Initial Pb (208/204) is plotted against initial Pb (206/204) for various recent volcanic rocks. No correction has been made for inter-laboratory biases. Island arc volcanics: small open circles (Armstrong, 1971); small filled circles, Japan (Tatsumoto and Knight, 1969); "V", Vesuvius (Oversby and Gast, 1968), and filled squares, alkali basalts (Tatsumoto, 1969). Oceanic volcanics: large open circles, Tristan island (Oversby and Gast, 1968); open squares, Azores islands (Oversby, 1971); vertical diamonds, Canary islands (Oversby et al., 1971); open triangles, Easter island

(Tatsumoto, 1966); and horizontal diamonds, mid-oceanic tholeiites (Tatsumoto, 1966a,b); and "I" Iceland' (Welke et al., 1968). Note that the isotope ratios of island arc and oceanic volcanics overlap.

Figure 4.3 Schematic diagram of the model used to obtain the conditions necessary for melt to segregate from a mostly crystalline mush. The grains and the melt (speckled) are assumed to act as two viscous fluids whose interaction is governed by the relative viscosity of the materials, the width of the conduit (h) and the grain size (a). Rigid boundary conditions are assumed at the edges of the conduit.

Figure 4.4 Slab models were calculated numerically with a 20 km distance translation on a 10 km grid spacing for various amounts of frictional heating applied between 40 and 90 km depth. The upper figures show the slab after 1.1 my of 8 cm/yr subduction. The lower figures are after 2.1 my of subduction. The amount of frictional heat corresponds to stresses of 4, 3, and 1 kb from left to right. Note that a region of excess temperature is present in the leftmost model.

Figure 4.5 Detailed thermal model of a slab sinking at 8 cm/yr shows the effects of large amounts of frictional heating. Heat equivalent to a stress of 4 kb is applied in a 3.5 km wide shear zone at the top of the slab between 40 km and 90 km depth. A region of temperature sufficient to cause partial melting has formed by 1.42 my. The calculation technique is described in Chapter 2.

Figure 4.6 Detailed thermal model in Figure 4.7 after 0.30 my more subduction. Above: the frictional heating continues down to 120 km. Below: the frictional heating is stopped at 90 km. Note that the heated region corresponds to the high temperature region above the slab.

Figure 4.7 Substantial flow in the high viscosity upper asthenosphere induced by a small amount of coupling with the slab. The viscosity of the upper fluid is 1000 times the lower fluid. In this model the slab is assumed to be completely decoupled from the high viscosity upper asthenosphere except within a short distance of the asthenosphere-upper asthenosphere boundary. The details of the flow pattern in the upper region are sensitive to the choice

of boundary conditions although the geometry of the pattern is not. Note that the flow in the lower region is similar to the flow in Figure 5.5. The width of the upper eddy is the same order as the thickness of the upper fluid. The numerical method used to compute the model is described in Appendix A.

Figure 4.8 Schematic diagram shows the preferred hypothesis for the origin of island arc volcanics. Material near the base of the lithosphere becomes entrained with the slab and is carried to depth. Material from the low velocity zones ascends to take its place and melts due to adiabatic decompression. The volcanoes which tap the flow near the turning point are most active since the fraction of partial melt is highest there. Volcanoes farther landward are less voluminous and tap a partial melt richer in incompatible elements. The residuum, a depleted mantle, is returned to depth completing the cycle.

CHAPTER 5. INTRA-ARC BASINS

Small basins, floored by oceanic crust, often exist behind island arcs (Menard, 1967; Karig, 1970). Most of these basins are in the western Pacific, including the Sea of Okhotsk, the Sea of Japan, and the Lau-Havre basin. Other such basins include: the Andaman Sea behind the Indonesian arc, the Aves basin behind the Lesser Antilles arc, the Tyrennian Sea behind the Calabrian arc and the basin behind the south Sandwich arc. The basins are generally less than a few hundred kilometers wide. Some are much narrower, including the Taupo depression, a continuation of the Lau-Havre basin into New Zealand, the Okinawa trough, and the Bouldir depression, behind the Aleutian arc.

Vening Meinesz (1951) first considered these basins in relation to convection currents in the earth. Recent advances in global tectonics and a large accumulation of oceanographic data have resulted in interest in these basins (e.g., McKenzie and Sclater, 1968; Karig, 1970). A discussion of the origin of these basins is in order since proposed mechanisms for their origin are similar to those proposed for island arc volcanics. The physical models developed in Chapter 4 are directly relevant to this problem.

5.1 Spreading origin of intra-arc basins

Although it is possible that certain intra-arc basins may be underlain by older oceanic crust trapped behind a younger arc, geological evidence such as anomalously thin sediments, truncation of older geologic features, and freshly erupted basalts (Belousov and Rudich, 1961; Rodolfo, 1969; Karig, 1970, 1971a,b, 1972; Karig and Glassley, 1970; Sclater et al., 1972) indicates that some type of crustal spreading or oceanization formed the basins. Geophysical evidence including the attenuation of short period seismic waves (Molnar and Oliver, 1969; Barazangi and Isacks, 1971; Utsu, 1971), shallow seismicity (Sclater et al., 1972) and high heat flow (McKenzie and Sclater, 1968; Yasui et al., 1970) support the same hypothesis. Extensive material transport of heat to shallow depths is necessary to explain this high heat flow in intra-arc basins, since heat generated near the slab cannot be conducted to the surface in a reasonable amount of time (McKenzie and Sclater, 1968; Minear and Toksöz, 1970a,b; Toksöz et al., 1971; Hasebe et al., 1970).

The crust in wider intra-arc basins is not distinguishable from crust produced at normal mid-ocean ridges (Menard, 1967; Murachi et al., 1968; Sclater et al., 1972). Magnetic anomaly patterns have been found in the Sea of Japan (Yasui et al., 1967) and the Lau-Havre basin (Sclater et al., 1972) but are not suitable for determining a spreading

history. In some cases geological evidence indicates that the spreading rate is a sizable fraction of the subduction rate at the associated trench (Karig and Glassley, 1970; Karig, 1971a,b). The direction of spreading may not be perpendicular to the arc (Karig, 1972; Sclater et al., 1972). Intra-arc spreading apparently begins on a well-defined fracture about 50 or 100 km landward of the volcanic front as both sides of younger basins are usually bounded by well-developed escarpments which appear to have once been conjunct.

Only limited evidence on the temporal relationship between the initiation of island arc volcanism and intra-arc spreading is available. Geological evidence indicates that spreading in the Sea of Japan began in the Early Miocene soon after the arc became volcanically active (Minato et al., 1965). The Bouldir depression has formed in the Aleutian arc since the Pliocene, although subduction also began as recently as the Pliocene (Hays and Ninkovich, 1970; Burk, 1965).

Horizontal tension probably exists beneath intra-arc basins and compression beneath the volcanic belt as mechanisms of shallow earthquakes are probably compressional normal to the arc near the volcanic belt and tensional in the intra-arc basin behind the arc. In Japan some of the compressional earthquakes are exceptionally large and have many aftershocks (Ichikawa, 1966). In other regions,

earthquakes away from the slab which are large enough to determine focal mechanisms are fairly rare. Two earthquakes in the Andaman Sea, an intra-arc basin behind the Indonesian arc, were extensional. However, the axis of tension of only one of those earthquakes was normal to the strike of the arc (Fitch, 1970). Two new earthquake mechanisms were obtained in this study (Figure 5.1). One earthquake located near the volcanic Tonga arc was compressive (Figure 5.2). The other earthquake located in the Lau-Havre basin behind the arc was tensional (Figure 5.3). The data were not sufficient to resolve the strike of the nodal planes for either earthquake.

5.2 Mechanism of spreading

The mechanism for spreading in intra-arc basins is probably related directly to the descent of the slab. Spreading centers are abandoned after they have migrated away from the arc. Basins occur behind arcs on several plates including both east and west dipping subduction zones in the western Pacific. The mechanism causing the opening of the basin must be secondary to the primary formation of sea-floor, for only about 5% of the earth's oceans are intra-arc basins (Menard, 1967).

Two classes of mechanisms have been proposed. Friction along the fault plane may heat the mantle and cause a

thermal diapir to rise beneath the arc (Hasebe et al., 1970; Oxburgh and Turcotte, 1971; Karig, 1971; Matsuda and Uyeda, 1971); or hydrodynamic forces or other stress related to the descent of the slab may create local tension beneath the arc allowing hot material from the low velocity zone to upwell passively (Holmes, 1965; Isacks et al., 1968; Kraus, 1971; Wiggins, 1971; Sleep and Toksöz, 1971). Data which establish the existence of spreading in intra-arc basins are not likely to be relevant in discriminating between these hypotheses. The time scale on which the mechanisms operate and the stress distribution which the mechanisms imply are likely to be useful if compared with observed data.

There are serious objections to the hypothesis that frictional heating along the fault plane is the cause of intra-arc basins. As was shown in Chapter 4, it is highly unlikely that a shear zone along the slab in the asthenosphere or the mesosphere could generate enough heat to cause a thermal maximum. Even if this heating occurs, it would take a much greater time than observed for intra-arc spreading to begin, since the rate with which a thermal diapir can ascend is low. Induced flow in the mantle would also tend to convect downward any material heated near the slab.

Forces related to the descent of the slab are a more probable cause of intra-arc spreading, although constructing

a physical model is somewhat difficult. Any mechanism of this type would be compatible with earthquake source mechanisms which imply that the stress in the lithosphere near the fault plane is compressive while the stress further away is tensional.

A qualitative picture of the forces acting on the lithosphere of an island arc can easily be obtained. The lithosphere beneath the island arc is acted on horizontally: by friction along the fault plane, by viscous coupling to any forced flow in the asthenosphere, by the component of pressure normal to the fault plane, and by forces associated with intra-arc basins or island arc volcanism (Figure 5.4). The force on the fault plane tends to push the island arc landward, yet some thought is required to determine the sign of the other forces. Note that no rigid hinge exists at point H (Figure 5.4) where the arc turns down. If extension or contraction of the lithosphere occurs at the island arc, point H is free to move with respect to the adjacent continent, point C. The depression associated with the trench is probably an indication of underpressure resulting from the viscous head loss associated with the descent of the slab (Morgan, 1965; Elsasser, 1967). This underpressure may act across the fault plane putting tension on the lithosphere at the arc. As shown below, flow in the asthenosphere at the base of the lithosphere is toward the slab.

Flow in the asthenosphere appears to be the only one of the forces which could produce tension away from the island arc and compression near it. It is unlikely that underpressure on the fault plane dominates the stress balance, since tension, not the observed compression, would then occur immediately behind island arcs. Friction along the fault plane has the wrong sign.

Numerical and analytical models of the flow induced by the slab were constructed to obtain quantitative constraints on the distribution of flow induced by the descent of the slab and to determine whether this flow could cause intra-arc spreading. Several models of increasing complexity were computed for flow in this wedge shaped region above the slab. These models included: an infinite wedge shaped region of a single viscosity, a region of a single viscosity bounded by a rigid boundary below, a region consisting of two viscous fluids and bounded by a rigid boundary below. The numerical method is described in Appendix A.

The properties of the more fluid parts of the mantle relevant to the calculation of flow induced by the slab are directly constrained from isostatic rebound studies. The viscosity of the upper mantle below the low velocity zone is about 10^{23} poise (McConnell, 1968; Cathles, 1971). The low velocity zone may have a viscosity of about 10^{20} or 10^{21} poise (Crittenden, 1967). The bottom boundary of the low viscosity zone is not likely to convect with the flow

since this boundary is probably controlled by pressure dependent substitution of $(\text{OH})_4^{-4}$ for $(\text{SiO}_4)^{-4}$ (Sclar, 1970). The lower boundary of the lithosphere is determined by the presence of partial melt. This boundary can convect with the flow since melting is both temperature and pressure dependent.

The flow at the lithosphere-slab corner can be approximated by an analytical solution for flow in a wedge shaped region, since slow viscous flow solutions depend most strongly on the nearest boundaries (Moffatt, 1964; McKenzie, 1969). The flow in the asthenosphere at the base of the lithosphere is seaward. Intense underpressure tending to pull the lithosphere at the arc downward is also produced by the flow. Unlike horizontal movements, the vertical movements caused by this force cease when the surface mass deficiency balances the force. If the lithosphere of the island arc is modeled as a free surface rather than a rigid boundary, a maximum velocity of intra-arc spreading of about half the subduction rate can be obtained from a similar analytic solution (Moffatt, 1964). No information on a preferred point of intra-arc spreading can be obtained from either analytic solution. Models containing some stratification, therefore, need be considered.

A somewhat realistic numerical model presumes a rigid boundary at the base of the flow (Sleep and Toksöz, 1971) (Figure 5.5). The rigid boundary may be thought of as

representing the top of the mesosphere or the top of the lower mantle. In either case for the model to be realistic, insignificant flow must be excited in the lower region modeled as a rigid boundary. A series of eddies inside the region of flow, each about 1.4 zone widths wide, resulted in the calculation. All eddies other than the one nearest the slab are only of mathematical interest since the amplitude ratio of successive eddies is about $1/350$ (Moffatt, 1964). A model (Figure 5.6) showed that stratification of viscosity in the mantle would not significantly effect the flow pattern induced by the slab. (For numerical reasons it is easier to calculate steady state flow with the boundary of the fluids fixed. Because the boundary does not move a significant distance in the time mechanical equilibrium is established, the streamlines calculated are valid instantaneous streamlines.) When a shear zone was assumed to exist along the slab in a high viscosity region above the asthenosphere, the flow in the asthenosphere was not greatly altered and an additional eddy developed in the high viscosity region (Figure 4.7).

Each of the three models has a point of maximum tension on the lithosphere of the island arc at the divergence point of the first eddy. Intra-arc spreading would be expected to begin there, unless the point of initial break-up was controlled by weaknesses in the lithosphere of the arc. In the constant viscosity model this region is about twice

the thickness of the asthenosphere from the lithosphere-slab corner. In the two layer, constant slab velocity model, it is about 1.5 thicknesses of the region away from the corner. In the shear zone model (Figure 4.7), the point of divergence is twice the thickness of the upper high viscosity layer from the corner. The former two models place the point of maximum tension too far landward from the observed points of initial intra-arc spreading, although the ultimate widths of intra-arc basins are in agreement with this spreading location. An initial spreading center a few tens of kilometers from the volcanic front, as observed, is predicted by the shear zone model. Theoretical viscosity calculations indicate that the intermediate viscosity region at the base of the lithosphere, which, as in the model might couple partially to the slab across a shear zone, is about 10 or 20 km thick (Weertman, 1970).

Induced flow in the intermediate viscosity region near the base of the lithosphere is a reasonable cause for intra-arc spreading since more traction on the base of the more rigid part of the lithosphere would result from flow of a more viscous fluid. Once started, flow in the high viscosity upper asthenosphere would alter the stress balance in the more rigid part of the lithosphere towards tension since the area of the fault plane between the lithosphere of the island arc and the slab is decreased and the area and

viscosity of the fluid acting on the bottom of the lithosphere are increased (Figure 5.7).

The observed self-limiting nature of intra-arc spreading can be explained qualitatively if this mechanism causes spreading. Since spreading is more or less symmetrical (Sclater et al., 1972), for geometrical reasons the dip of the slab must decrease if intra-arc spreading occurs at a significant fraction of the subduction rate. This would increase the area of the fault plane and also the percentage of friction contained in the horizontal component. This would cause the stress balance to become more compressive and retard spreading. Once migration has gone far enough, the stress on the lithosphere near the trench is too small to cause rapid intra-arc spreading. Spreading may then either cease or restart at a new spreading center closer to the arc.

A time dependent convection model thus would be necessary to model this process in detail. Variations in the dip and hinge point of the slab, which are relevant to the problem, would be hard to consider in any tractable numerical scheme. As often happens involving convection in the earth, semi-quantitative constraints can be easily obtained, but any added sophistication would involve a morass of undetermined free parameters and interminable mathematics.

Flow from the asthenosphere into the lower part of

the lithosphere, the preferred hypothesis in the previous chapter for the origin of island arc volcanics, appears capable of causing spreading in intra-arc basins. A complete model of this process was too intractable to construct. Frictional heating appeared to be insufficient to cause the secondary spreading. The observed initial axis and limited duration of intra-arc spreading centers are compatible with the preferred hypothesis.

FIGURE CAPTIONS

- Figure 5.1 First arrivals determined from WWSS records for two earthquakes west of Tonga are plotted on the focal plane projection for shallow focus crustal earthquakes. Compressions are indicated by circles and rarefactions by triangles. The "X" indicates a low amplitude arrival believed to be near the nodal plane. Possible fault planes are shown for reference only. Although the focal mechanism cannot be unambiguously determined, it is clear that the earthquake of JUL 21, 1965, is reverse faulting and the earthquake of OCT 3, 1966, is normal faulting.
- Figure 5.2 The locations of earthquakes for which focal mechanisms were determined are plotted relative to other shallow earthquake epicenters indicated by "X". The Tonga trench is indicated by stippling. Earthquake A is OCT 8, 1966. Earthquake B is JUL 21, 1965. (Modified after Sclater et al., 1972).
- Figure 5.3 The location of the earthquake of JUL 21, 1965 (hexagon) is shown in relation to other nearby earthquakes. Large dots are more accurately located epicenters. The seismic stations NIU,

TGU, PAG, and EUA are situated on the non-volcanically active part of the island arc, while TFA is situated near an active volcano. (Modified after Isacks et al., 1969.)

Figure 5.4 The lithosphere of an island arc is subjected to several kinds of horizontal forces. Friction along the fault plane, σ_{ij} , tends to push the island arc toward the continent at point C. Fluid drag, τ_{xz} , at the base of this lithosphere and the underpressure, P_{ii} , on the fault plane tend to pull the arc away from the continent. Since no rigid hinge exists at point H, the trench, point T, can move with respect to the continent when intra-arc spreading occurs. Island arc volcanism and intra-arc spreading cause additional forces.

Figure 5.5 Numerically calculated streamlines in an asthenosphere bounded above and below by rigid plates, and by a moving slab are plotted in dimensionless units. The stress, τ_{xy} , and underpressure, P , at the base of the lithosphere are strongly concentrated near the slab-lithosphere corner. An intra-arc spreading axis at the divergence point of the first eddy is predicted by this model. (After Sleep and Toksöz, 1971.)

Figure 5.6 Two fluid model for the upper mantle is similar to the one fluid model in Figure 5.5. The viscosity ratio of the upper fluid to the lower fluid is 1:1000. If no shear zone develops in high viscosity regions, viscosity stratification in the upper mantle would have little effect on the flow induced by the slab. Concentration of the flow in the less viscous fluid, however, is noticeable.

Figure 5.7 Flow in the high viscosity region near the base of the lithosphere would change the stress balance in the lithosphere from compressive (above) to tensional (below) since the area of the fault plane below the slab and the lithosphere is decreased and the more viscous fluid acting on the base of the lithosphere produces more drag. This tensional stress is the suggested cause of intra-arc spreading.

CHAPTER 6. CONCLUSIONS AND AFTERTHOUGHTS

This study was undertaken in order to understand the deep structure and geophysical processes beneath island arcs. Mathematical models of physical processes including the gross thermal structure of the slab due to subduction, ray theory P-wave transmission through the slab, detailed effects of frictional heating above the slab on temperature, segregation of melt from a partially molten mush, and secondary flow induced by the descent of the slab, were constructed and compared with observations. Results were limited not so much by the mathematical and numerical difficulties, but by the lack of knowledge of the physical parameters in the interior of the earth, and by the limitations of the approach to the problem which presumed the large scale kinematics.

The gross thermal structure of the slab was found to be insensitive to reasonable variations in the values of physical parameters. Gravity anomalies indicate that much of the weight of the slab is somehow compensated. The dynamics of the entire convection pattern would probably have to be considered to explain the observed maximum depth of earthquakes.

Anomalous seismic travel times and amplitudes confirmed that a slab of high velocity material is associated with deep seismic zones. The interpretation of the data was

limited by difficulties in resolution of the effects of the slab. Improved travel time tables and station corrections would increase the worth of the available data.

Frictional heating along the fault plane, concentration of pre-existing melt in the asthenosphere by hydrodynamic forces, and intrusions of asthenospheric material into the lithosphere of the island arc induced by tectonic forces were considered as causes for island arc volcanism. The latter mechanism was most feasible although lack of knowledge of mechanical properties near the base of the lithosphere precluded construction of a detailed physical model. Frictional heating might be significant in some cases. Improved geochemical constraints on the depth of origin of the magma are needed.

Intra-arc basins behind island arcs are the result of crustal spreading. Induced flow, related to the descent of the slab, is the most plausible mechanism for the formation of such basins. The seismicity of the basins can be explained by such a mechanism. Again, lack of knowledge of physical properties near the base of the lithosphere precluded detailed modeling.

The results of this study were in general compatible with the plate tectonic hypothesis. Useful results were obtained by the process of physical modeling. It is likely that additional results can be obtained by applying the calculations of this study to different problems.

Consideration of the dynamics in addition to the kinematics of gross plate motions will be necessary in some cases.

APPENDIX A

Numerical Methods

This paper is concerned with solving equations of heat and mass transfer applicable to flow in this interior of the earth. A full solution of the problem is not attempted but rather the temperature field is determined in regions where the velocity field can be directly estimated from observations. The fluid flow equation is also solved for limited regions for which control on the boundary conditions can be obtained directly from knowledge of plate motions.

The relevant equations are the Navier-Stokes equation

$$\rho \frac{\partial \mathbf{v}}{\partial t} + \rho (\mathbf{v} \cdot \text{grad}) \mathbf{v} = -\text{grad } p + \eta \nabla^2 \mathbf{v} - \rho \alpha g T \quad (\text{A.1})$$

and the heat flow equation

$$\frac{\partial T}{\partial t} + \mathbf{v} \cdot \text{grad } T = \frac{1}{\rho C} \text{div} (k \text{ grad } T) + \frac{H}{\rho C} \quad (\text{A.2})$$

The notation is

- v velocity
- ρ density
- t time
- p pressure
- η viscosity
- α coefficient of thermal expansion
- g acceleration of gravity

T temperature
C specific heat (at constant pressure)
H internal heat production
k thermal conductivity

For the earth, the inertial terms on the left hand side of equation (A.1) can be ignored.

A.1 Calculation of slab models

The computation scheme used herein is similar to that used by Toksöz et al. (1971). The basic model consists of a slab of material moving downward into the mantle at an angle to the surface. The surrounding mantle is assumed to be fixed (Figure A.1). The computational scheme consists of explicitly translating temperatures between grid points in the slab and allowing the slab to warm up over a time interval Δt , which corresponds to the amount of movement at the assumed velocity. The heat flow equation was solved after each translation step using the alternating-direction implicit finite difference scheme (Peaceman and Rachford, 1955). This technique used by Toksöz et al. (1971) was modified so that the slab could dip at an arbitrary angle and a self-adjoint form was used for the derivatives. The finite difference equation implicit in the x direction is

$$\begin{aligned}
\frac{T_{n,m}^{\rho+1} - T_{n,m}^{\rho}}{\Delta t} &= \frac{\beta}{\Delta x^2} \left\{ (k_{n+1,m} + k_{n,m}) (T_{n+1,m}^{\rho+1} \right. \\
&\quad \left. - T_{n,m}^{\rho+1}) - (k_{n-1,m} + k_{n,m}) (T_{n,m}^{\rho+1} \right. \\
&\quad \left. - T_{n-1,m}^{\rho+1}) \right\} + \frac{\beta}{\Delta z^2} \left\{ (k_{n,m+1} + k_{n,m}) (T_{n,m+1}^{\rho} \right. \\
&\quad \left. - T_{n,m}^{\rho}) - (k_{n,m-1} + k_{n,m}) (T_{n,m}^{\rho} - T_{n,m-1}^{\rho}) \right\} \\
&\quad + \beta H
\end{aligned} \tag{A.3}$$

where

$$x = n\Delta x$$

$$z = m\Delta z$$

$$t = \rho\Delta t$$

$$\beta = (\rho C)^{-1}$$

This set of equations can be written as

$$A_n T_{n-1,m}^{\rho+1} + B_n T_{n,m}^{\rho+1} + C_n T_{n+1,m}^{\rho+1} = D_n \tag{A.4a}$$

where

$$A_n = -(k_{n-1,m} + k_{n,m}) (0.5\beta/\Delta x^2) \tag{A.4b}$$

$$B_n = \Delta t^{-1} + (0.5\beta/\Delta x^2) (k_{n-1,m} + k_{n+1,m} + 2k_{n,m}) \tag{A.4c}$$

$$C_n = -(k_{n+1,m} + k_{n,m}) (0.5\beta/\Delta x^2) \tag{A.4d}$$

$$\begin{aligned}
D_n = & (0.5\beta/\Delta z^2) - (k_{n,m-1} + k_{n,m+1} + 2k_{n,m})T_{n,m}^\rho \\
& + (k_{n,m-1} + k_{n,m})t_{n,m-1}^\rho + (k_{n,m+1} + k_{n,m})T_{n,m+1}^\rho \\
& + T_{n,m}^\rho/\Delta t + \beta H
\end{aligned} \tag{A.4e}$$

For each grid line the set of implicit equations can be solved as a tridiagonal matrix. The iteration is completed by solving for $T_{n,m}^{\rho+2}$ using equations that are implicit in z . The relevant formulae can be obtained by adding 1 to the index ρ and interchanging x with z and m with n .

Boundary conditions were zero heat-flux on the sides $n = 1$ and $n = N$, zero temperature at the surface, and heat flux of F at the bottom, $m = 1$.

A.1.1 Thermal conductivity

Two formulations were used for calculating thermal conductivity. One set of models used a formulation by MacDonald (1959)

$$k = k_1 + (16n^3 s T^3) / (n \epsilon_0 + 120 \pi \sigma_0 \exp(-E/KT)) \tag{A.5}$$

where

- k_1 lattice conductivity, 0.25×10^6 erg/cm-sec-°C
- T absolute temperature
- K Boltzmann's constant
- E width of energy gap for electronic conduction, 3 e.v.

s	Stefan-Boltzmann constant
n	index of refraction, 1.7
ϵ_0	low temperature opacity, 10 cm^{-1}
σ_0	electrical conductivity, $10 \text{ ohm}^{-1} \text{ cm}^{-1}$

The other set of models used the experimental results of Schatz (1971) on olivine. In this case the lattice conductivity is the larger of

$$k_1 = (30.6 + 0.21T)^{-1} \quad (\text{A.6a})$$

$$k_1 = 0.003 + (3 \times 10^{-6})z \quad (\text{A.6b})$$

where z is in kilometers, T in $^{\circ}\text{K}$ and the unit of conductivity is $\text{cal/cm-sec-}^{\circ}\text{C}$. The radiative conductivity is given by

$$k_r = 0 \quad T \leq 500^{\circ}\text{K} \quad (\text{A.7a})$$

$$k_r = 5.5 \times 10^{-6} (T - 500) \quad T > 500^{\circ}\text{K} \quad (\text{A.7b})$$

A.1.2 Phase changes

An improved method was used for calculating heating due to phase changes. The amount of each phase present was evaluated at points where a phase change might occur assuming that the fraction of the high pressure phase increases linearly with depth over a finite depth interval and the depth of the interval is dependent on temperature. The function A is evaluated

$$A = \left(\frac{\partial T}{\partial z_i} z + T_0 - T \right) / B \quad (\text{A.8})$$

and then limited by 0 and 1 to give the mass fraction of phase i

$$f_i^{\rho+1} = 0 \quad A \leq 0 \quad (\text{A.9a})$$

$$f_i^{\rho+1} = A \quad 0 \leq A \leq 1 \quad (\text{A.9b})$$

$$f_i^{\rho+1} = 1 \quad A \geq 1 \quad (\text{A.9c})$$

The amount of phase change heating in one translation step is given by

$$\Delta t H_i = \rho \Delta f_i (T_{\text{abs}} \Delta S_i - p \Delta V_i) \quad (\text{A.10})$$

Δt = length of time step

H_i = power production from phase i

ΔS_i = entropy of phase change

ΔV = volume of phase change

The following phase changes were included in various models

	$T_0, ^\circ\text{C}$	$\frac{\partial T}{\partial z}, \frac{^\circ\text{C}}{\text{km}}$	$B, ^\circ\text{C}$	$\Delta S, 10^6 \text{ erg/g}^\circ\text{C}$	$\Delta V \text{ gcm}^3/\text{g}$
1. basalt-eclogite	-80	17	50	-1.17	-0.065
2a. olivine-spinel	-1120	9	50	-0.713	-0.0265
2b. olivine-spinel	-1380	9	300	-0.713	-0.0265
3. post-spinel	-87000	150	50	-0.594	-0.0262

A.1.3 Convective geotherm

The migration of ridges with respect to trenches precludes a permanent region of trapped flow at the core of a convection cell in the upper mantle. The minimum amount of average upward velocity in the upper mantle, not including slabs, is that amount needed to produce the spreading oceanic lithosphere. This average velocity can be used to approximate a geotherm if the surface heat flux is "known". Starting with the z-component of the heat flow equation in steady state

$$\rho c V_z \frac{\partial T}{\partial z} - \frac{\partial}{\partial z} k \frac{\partial T}{\partial z} = H \quad (\text{A.11})$$

the vertical derivative of vertical heat flux can be found by differentiating by parts

$$\frac{\partial F}{\partial z} = \frac{\partial}{\partial z} \left(-k \frac{\partial T}{\partial z} + \rho c V_z T \right) = T \frac{\partial}{\partial z} (\rho c V_z) + H \quad (\text{A.12})$$

F = vertical heat flux.

This equation can be solved by a self-consistent iteration procedure

$$F_{j+1}^{\rho+1} = F_j^{\rho+1} + H_j^\rho \Delta z + [(\rho c V_z)_{j+1} - (\rho c V_z)_j] * T_j^\rho \quad (\text{A.13})$$

ρ (superscript) iteration number

j (subscript) vertical increment number (+ = up)

Δz vertical grid spacing

The bottom heat flux, $F_0^{\rho+1}$, is adjusted such that the

surface heat flux has the assumed value. An improved temperature was obtained by numerically integrating downward from the known surface temperature using the expression for vertical heat flux solved for temperature

$$T_j^{\rho+1} = (F_{j+1}^{\rho+1} + T_{j+1}^{\rho+1} \cdot k_j^{\rho} / \Delta z) / [(\rho c v_z)_j + k_j^{\rho} / \Delta z] \quad (\text{A.14})$$

Conductivity, k_j^{ρ} , was evaluated at a temperature of $(T_{j+1}^{\rho} + T_j^{\rho})/2$. The adiabatic and phase change heating parts of H_j^{ρ} were evaluated at T_j^{ρ} . The relevant formulae of calculating these parameters are given in Section A.1.1 and A.1.2.

The velocity v_z was adjusted so that mass was conserved in the main part of the flow. The mass flux was assumed to be

$$v_z = z/S \quad 0 \leq z \leq L \quad (\text{A.15a})$$

$$\rho v_z = (L + A) \rho_0 / 2S + (z - A)^2 \rho_0 / 2S(L - A) \quad L \leq z \leq A \quad (\text{A.15b})$$

$$\rho v_z = (L + A) \rho_0 / 2S \quad (\text{A.15c})$$

For purposes of calculation the parameters were assumed to be

surface heat flux	$F_n = 71 \text{ ergs/cm}^2\text{-sec}$
grid spacing	$\Delta z = 1 \text{ km}$
replacement time of lithosphere	$S = 120 \text{ my}$
depth of base of lithosphere	$L = 80 \text{ km}$
depth of base of asthenosphere	$A = 150 \text{ km}$

weighted density of A and L $\rho_0 = 3.38 \text{ g/cm}^3$

The iteration converged in less than ten iterations starting from $T = 0$ everywhere. The calculation can be valid only away from those parts of the flow which thermally equilibrate with slabs and away from the bottom boundary layer of the convection cell. The estimate of temperature obtained by this method is at worst a smoothly varying solution which is adiabatic in the interior but conductive near the surface. At best it is a zero order solution to a much more complicated problem. Considering that the parameters in the calculation are poorly known, little improvement in the average geotherm of the mantle could be obtained from a more sophisticated calculation.

A.1.4 Accuracy and stability

A complete analysis of the stability and accuracy of the method used to calculate the geotherm in descending slabs would be intractable because the method is an exceedingly complicated mixture of explicit and implicit calculation. The scheme used herein is identical to the scheme used by Toksöz et al. (1971) except for the use of self-adjoint operators, which conserve energy, and for modification of the method used to calculate heat sources. The analyses for stability and accuracy of the earlier scheme (McKenzie, 1971; Minear and Toksöz, 1971; Toksöz et al.,

1971) also apply to the newer scheme. Rather than repeating the results of those papers, the importance of different kinds of numerical errors to the final results will be discussed.

The formulation of truncation error for the scheme with constant conductivity is sufficient to illustrate the numerical effects on the attenuation of thermal anomalies. Wavenumbers perpendicular to the slab are the most strongly excited during the calculation and also the most dangerous with regard to numerical inaccuracies. After two time steps (one implicit in \underline{x} , one implicit in \underline{z}), such a wavenumber is attenuated by a factor of (Peaceman and Rachford, 1955)

$$\theta = \left(\frac{1 - 2\beta \sin^2(\pi y/4)}{1 + 2\beta \sin^2(\pi y/4)} \right)^2$$

where

$$\beta \equiv 2\kappa\Delta t/\Delta x^2$$

$$y \equiv \lambda_{\min}/\lambda$$

$$\lambda_{\min} = 2^{3/2}\Delta x = \text{minimum wavelength on grid}$$

This compares with the exact attenuation factor

$$\Omega = \exp(\beta\pi^2 y^2/2) \tag{A.17}$$

For small β the scheme is thus accurate to the second order in β .

In the problems considered here, the shortest

wavelength components of temperature are re-excited by the heat sources and by the slab motion in each time step. In this case more accuracy is needed than in problems where short wavelengths decay, and one might expect that a value of β much less than 0.5 might be needed. However, even in this case, $\beta = 0.5$ is sufficient for accuracy. This can be seen by considering a continuous heat source that contributes an amplitude of 1 to the shortest wavelength component in one time step. Then its contribution from the previous time step is θ , and the total amplitude expected is

$$T \sim \sum_0^N \theta^N = \frac{1}{1-\theta} \quad (\text{A.18})$$

Unless θ is near unity, as would occur if β was larger than 1, the higher order terms of the series would have little effect. It is sufficient for the purpose of this numerical calculation to have wavelengths which have attenuated in the exact solution attenuate in the model. Unless $\beta > 1$, numerical errors build up on about the same time scale as the wavelength attenuates. The criteria used by McKenzie (1971) that the ratio of $|1 - \Omega/\theta| < 0.02$ for 20% accuracy is misleading, since this small numerical error acts similarly to a 2% change in conductivity and can cause a large relative error in the results only after the thermal anomaly is mostly attenuated. It should be remembered that long wavelengths are more accurate than

short wavelengths, and that the truncation error does not effect total heat energy.

Another source of error is from the method used to model the motion of the slab. The discrete translation steps tend to excite the wavenumbers parallel to the slab, perpendicular to the most strongly excited wavenumber. When an excessive translation distance was used the effect was evident, and could thus be removed in subsequent calculations.

A.2 Flow in stratified viscous fluid

In this section a numerical method for determining the two-dimensional flow pattern in a stratified viscous fluid is derived from the variational principle of minimum work. It is convenient to define a stream function, ψ , such that

$$v_x = \partial\psi/\partial y \quad (\text{A.19a})$$

$$v_y = -\partial\psi/\partial x \quad (\text{A.19b})$$

since the fluid flow equation A.2 can be reduced to

$$\nabla^4\psi = 0 \quad (\text{A.20})$$

The stream function has the property that particles in the fluid remain on surfaces of constant ψ called streamlines. The variational principle requires that the integral of viscous dissipation over all years be a minimum

$$\delta \sum_{i,j} \int \eta \left[\frac{\partial v_i}{\partial x_k} \left(\frac{\partial v_i}{\partial x_k} + \frac{\partial v_k}{\partial x_i} \right) \right] dV = 0 \quad (\text{A.21})$$

when zero stress or constant velocity boundary conditions are assumed. In two dimensions the integrand can be written in terms of ψ

$$\eta \left\{ 4 \cdot \left(\frac{\partial^2 \psi}{\partial x \partial y} \right)^2 + \left(\frac{\partial^2 \psi}{\partial y^2} - \frac{\partial^2 \psi}{\partial x^2} \right)^2 \right\} \quad (\text{A.22})$$

The boundary conditions at the boundary of two viscous fluids are that material is conserved at the boundary

$$\psi_1 = \psi_2 \quad (\text{A.23})$$

that velocity parallel to the boundary in the x direction is constant

$$\frac{\partial \psi_1}{\partial y} = \frac{\partial \psi_2}{\partial y} \quad (\text{A.24})$$

and that stress is continuous at the boundary

$$\eta_1 \left(\frac{\partial v_x}{\partial y} + \frac{\partial v_y}{\partial x} \right)_1 = \eta_2 \left(\frac{\partial v_x}{\partial y} + \frac{\partial v_y}{\partial x} \right)_2 \quad (\text{A.25})$$

where 1,2 denote evaluation layer 1 or 2.

Thus

$$\frac{\partial^2 \psi_1}{\partial y^2} = \frac{\eta_2}{\eta_1} \frac{\partial^2 \psi_2}{\partial y^2} + \left(1 - \frac{\eta_2}{\eta_1} \right) \frac{\partial^2 \psi}{\partial x^2} \quad (\text{A.26})$$

The numerical relaxation scheme is derived by using the

variation principle to obtain an improved estimate of the value of the stream function at some point 0 (Figure A.2) while leaving the stream function at all other points constant. The formula obtained is applied repeatedly at all the points in the region until a convergent solution is obtained. We assume that point 0 is on the boundary and that no other boundary is within two points of point 0. Only terms involving ψ_0 need be included in the variational integral, since other terms drop out when differentiation with respect to ψ_0 is performed. The expression

$$\left(\frac{\partial^2 \psi}{\partial y \partial x} \right)^2$$

is most easily evaluated at points a, b, c, and d. The boundary condition A.26 can be used to show that for evaluation around point 1

$$\int_{x,y} dV \left[\frac{\eta_1}{2} \left(\frac{\partial^2 \psi_1}{\partial y^2} - \frac{\partial^2 \psi}{\partial x^2} \right)^2 + \frac{\eta_2}{2} \left(\frac{\partial^2 \psi_2}{\partial y^2} - \frac{\partial^2 \psi}{\partial x^2} \right)^2 \right] \quad (\text{A.27})$$

$$= \frac{1}{h^2} \frac{\eta_1 \eta_2}{(\eta_1 + \eta_2)} (\psi_5 + \psi_8 - \psi_{12} - \psi_0)^2$$

h is the grid spacing.

Those terms in the variational integral containing ψ_0 are

$$2h^2 E_0 = 4\eta_1 (\psi_5 - \psi_1 - \psi_2 + \psi_0)^2 + 4\eta_1 (\psi_6 - \psi_3 - \psi_2 - \psi_0)^2$$

$$4\eta_2 (\psi_8 - \psi_1 - \psi_4 + \psi_0)^2 + 4\eta_2 (\psi_7 - \psi_3 - \psi_4 - \psi_0)^2$$

$$\begin{aligned}
& + \eta_1 (\psi_9 - \psi_0 - \psi_5 - \psi_6)^2 + \eta_2 (\psi_{11} + \psi_0 - \psi_8 - \psi_7)^2 \\
& + 2 \frac{\eta_1 \eta_2}{\eta_1 + \eta_2} \left((\psi_0 + \psi_{12} - \psi_8 - \psi_5)^2 \right. \\
& \left. + (\psi_0 + \psi_{10} - \psi_6 - \psi_7)^2 \right) \tag{A.28}
\end{aligned}$$

By setting $\frac{\partial E_0}{\partial \psi_0} = 0$

we obtain the relaxation formula

$$\begin{aligned}
\psi_0 = & \left(9\eta_1 + 9\eta_2 + 4 \frac{\eta_1 \eta_2}{\eta_1 + \eta_2} \right)^{-1} \left[8\eta_1 \psi_2 + 4(\eta_1 + \eta_2) (\psi_1 + \psi_3) \right. \\
& + 8\eta_2 \psi_4 + (\psi_5 + \psi_6) \left(-3\eta_1 + 2 \frac{\eta_1 \eta_2}{\eta_1 + \eta_2} \right) \\
& + (\psi_7 + \psi_8) \left(-3\eta_2 + 2 \frac{\eta_1 \eta_2}{\eta_1 + \eta_2} \right) - ((\psi_{12} + \psi_{10}) \\
& \left. 2 \frac{\eta_1 \eta_2}{\eta_1 + \eta_2} - \eta_1 \psi_9 - \eta_2 \psi_{11} \right] \tag{A.29}
\end{aligned}$$

For $\eta_1 = \eta_2$ the formula reduces to the standard numerical expression for the biharmonic equation

$$\begin{aligned}
\psi_0 = & \frac{1}{20} \left(8(\psi_1 + \psi_2 + \psi_3 + \psi_4) - 2(\psi_5 + \psi_6 + \psi_7 + \psi_8) \right. \\
& \left. - (\psi_9 + \psi_{10} + \psi_{11} + \psi_{12}) \right) \tag{A.30}
\end{aligned}$$

It is more convenient at interior points away from boundaries to use a two step relaxation formula due to Burgraff (1966)

$$\psi_0 = \frac{1}{4} (\psi_1 + \psi_2 + \psi_3 + \psi_4 + h^2 \Omega_0) \quad (\text{A.30a})$$

$$\Omega_0 = \frac{1}{4} (\Omega_1 + \Omega_2 + \Omega_3 + \Omega_4) \quad (\text{A.30b})$$

The boundary condition to a rigid wall normal to y

$$\psi_0 = \text{constant} \quad (\text{A.31a})$$

$$\Omega_0 = -(2/h^2) (\psi_4 - hV) \quad (\text{A.31b})$$

V the velocity of the wall

The two step relaxation procedure used in the interior is unconditionally stable (Burgraff, 1966). The program for computing was checked by comparison of the results with special cases (Burgraff, 1966; Pan and Acrivos, 1967) and by comparison with results obtained numerically for a fluid with a variable viscosity (D.J. Andrews, personal communication). Even when the viscosities of different layers differed by a factor of 1000, the program converged after a few hundred iterations.

FIGURE CAPTIONS

- Figure A.1 Schematic representation of the computational scheme, input parameters, and boundary conditions used to calculate thermal models of slabs. (Modified after Toksöz et al., 1971).
- Figure A.2 Finite difference grid is used to obtain an improved value of the stream function at point 0 by numerical relaxation. The line through points 12, 1, 0, 3 and 10 is the boundary between the two fluids of different viscosity. The stream function is defined at numbered points. For convenience certain derivatives were evaluated at letter points during the derivation of the finite difference formula.

APPENDIX B

Measured Earthquake Amplitudes

The measured amplitudes for the earthquakes and nuclear explosions used in this study are plotted in Figures B.1, B.2, B.4, B.6, B.8, B.9, B.11, B.12, B.13, B.14, B.15, B.16, B.17, and B.18. The amplitudes could not be computed on an absolute scale because the period of the first motion could not be accurately measured. Relative amplitudes for each event are sufficient for the purpose of this paper. The amplitudes indicated by a given amplitude on the scale of a figure or by a given interval number should not be compared between earthquakes or between the short and long periods of an earthquake, since the scales have been adjusted to avoid large ordinate or interval class values. The distribution of interval class numbers with respect to terrestrial co-ordinates are plotted for earthquakes which were not explicitly used in the main text in Figures B.3, B.5, B.7, and B.10. The earthquakes are grouped by location with the Aleutian earthquakes plotted in Figures B.2 through B.11, the Tonga-Kermadec earthquakes in Figures B.12 through B.17, and the Kurile earthquake in Figure B.18. Within each group the ordering is chronological.

FIGURE CAPTIONS

Figure B.1. The amplitude of the first peak to peak motion measured on the short period, vertical component of WSS records is plotted as a function of distance for the LONGSHOT (above) and MILROW (below) events. Stations in the predicted shadow zone are indicated by circles. The cross bars terminating lines extended from the symbols are station corrected values. Stations used for LONGSHOT in order of increasing distance included: CMC, LON*, SEO* (This station may have been dead for MILROW), BKS*, BOZ, GUA*, NOR*, DUG, GSC, RCD, ANP, GOL, GDH*, TUC, ALQ*, KEV*, HKC*, KTG*, BAG*, LUB, MDS, RAB, AAM*, JCT, DAL, DAV*, AKU*, HNR*, OXF, AFI*, SCP, NUR*, KON, NHA, OGD, ATL*, WES*, SHL, ESK*, LAHI RARI NDI*, VAL*, CTA, MSH, QUE, STU*, BEC*, TAB*, TRI, IST*, POO, SHI, PTO, RIV*, PDA, PTO, RIV*, PDA, TOL*, KOD, BHP, SJG*, JER, MAL*, and ADE. Stations used for both events are indicated by '*'. Stations used only for MILROW included: MAT, GEO, COP, and LOR. Numbered interval classes differing by factors of two are formed by the assumed amplitude-distance curve.

Figure B.2. Observed short (above) and long (below) period amplitudes from the earthquake of 5 Feb 1965, at 9h (earthquake #4, Stauder, 1968a) are plotted as a function of epicentral distance. The cross bars on top of lines extending from symbols indicate the amplitude as corrected for source mechanism. No correction is plotted when the correction is smaller than the symbols. Triangles indicate stations between -50 and 50 degrees azimuth. Other stations are indicated by circles. Open symbols are less accurate measurements due to small signal, high noise, or poor records. The assumed long and short period amplitude curves divided the data into interval classes differing by factors of two. Stations in order of increasing epicentral distance include: CMC, LON, NOR, BOZ, RCD, GDH, GOL, HKC, BAG, KEV, TUC, MAN-S, KTG, RAB, DAV, LUB, UME-S, HNR-S, FLO, AAM, NUR, NHA, PMG, KON-L, SCP, BLA, WES, GEO, COP, LAH-L, NDI-L, ESK, VAL, CTA, QUE, STU, TRI, LEM, POO, LPS-S, SHI-L, AQU, KOD-L, TOL, RIV-L, and SJG. Stations for which only short or long period readings were made are indicated by 'S' or 'L' respectively.

Figure B.3. The amplitudes for the earthquake of 5 Feb 1965, at 9h are plotted as in Figure 3.17.

Figure B.4. The amplitudes measured for the earthquake of 5 Feb 1965, at 20h (earthquake #5, Stauder, 1968a) are plotted as in Figure B.2. Stations included: CMC, NOR, BOZ, DUG-S, RCD, GDH, GOL, BAG, MAN, TUC, KEV, KTG, RAB, DAV, LUB, UME-S, AAM, PMG, NUR, KON, SCP, COP, NDI, ESK, VAL, QUE, STU, LEM, BEC, TRI, POO, LST, SHI, AQU, KOD-L, PTO, TOL, and SJG.

Figure B.5. The amplitudes for the earthquake of 5 Feb 1965, at 20h are plotted as in Figure 3.17.

Figure B.6. The amplitudes measured for the earthquake of 6 Feb 1965, (earthquake #6, Stauder, 1968a) are plotted as in Figure B.2. Stations included: CMC-S, NOR, DUG-S, RCD-S, GOL, GDH, TUC, BAG, KEV, MAN, KTG, RAB, LUB, DAV, HNR, FLO, UME-S, AAM-S, NUR-S, PMG-S, NHA-L, SHL-L, SCP, KON, BLA, COP, NDI, ESK, CTA-S, VAL, QUE, STU, BEC-L, TRI-S, LEM, POO, IST, SHI, AQU-S, PTO, JER, SJG, and ADE-L.

Figure B.7. The amplitudes for the earthquake of 6 Feb 1965, are plotted as in Figure 3.17.

Figure B.8. The amplitudes measured for the earthquake of 7 Feb 1965, at 2h are plotted as in Figure B.2. Stations included: CMC, LON, COR-L, BKS, ANP-L, NOR, BOZ, DUG, RCD, BAG, GDH, GOL, MAN, KEV, TUC, KTG, RAB, LUB, FLO, PMG, AAM, SHL, NUR, KON, SCP, BLA, LAH-L, NDI, COP, ESK, CTA, QUE, VAL, STU, POO, TRI, BEC, IST, SHI, AQU, KOD, RIV, PTO, ADE, and SJG-S.

Figure B.9. The amplitudes measured for the earthquake of 7 Feb 1965, at 9h (earthquake #8, Stauder, 1968a) are plotted as in Figure B.2. Stations included: CMC, LON, BKS, BOZ, NOR, DUG, RCD, GOL, TUC, KTG, BAG, LUB, FLO, AAM, DAV, UME-S, SCP-S, PMG, NUR-S, BLA, SHL-L, KON, COP-S, ESK, LAH, NDI, VAL, CTA, QUE-L, STU, IST-L, POO, SHI, RIV-L, KOD-L, and SJG.

Figure B.10 The amplitudes for the earthquake of 7 Feb 1965 at 9h are plotted as in Figure 3.17.

Figure B.11 The amplitudes measured for the earthquake of 2 Jun 1966 are plotted as in Figure B.2. Stations included: KIP, CMC, SEO-S, LON, COR, BKS, BOZ, NOR, DUG, GDH, HKC, TUC, ALQ, KEV, KTG, RAB, LUB, HNR-L, FLO-L, AKU, UME-L, AAM-S, PMG, NOR, SHL, CHG, SCP, KON, BLA, COP, LAH, NDI, ESK, SNG, CTA, MSH, VAL, STU, BEC, LPS, TRI, POO, IST, SHI, PTO, JER, ADE-S, and SJG. This earthquake was used to obtain source corrections for LONGSHOT.

Figure B.12 The amplitudes measured for the earthquake of 21 Jul 1964, are plotted as in Figure B.2 except that triangles denote stations between 210 and 330 degrees azimuth. Hexagons indicate low amplitude precursors. Stations included: TAU-S, CTA, PMG, ADE, KIP, SBA, GUA, MUN-S, SPA-S, MAN, BAG, ANP, HKC, BKS, TUC, DUG, ALQ, CHG, LUB, BOZ, NHA, and LPS-S.

Figure B.13 The amplitudes measured for the earthquake of 5 Aug 1964, are plotted as in Figure B.12. Stations included: CTA, ADE, PMG, SBA, MUN, GUA, KIP, MAN, BAG, ANP, HKC, BKS, GSC-L, TUC, ANT, CHG, NNA-S, and ALQ.

- Figure B.14 The amplitudes measured for the earthquake of 18 Mar 1965, are plotted as in Figure B.12. Stations included: RIV, RAB, CTA, PMG, TAU, ADE-S, KIP-S, GUA, HKC, TUC, LON, DUG, ALQ, COL, BOZ, GOL, RCB-S, and LUB-S.
- Figure B.15 The amplitudes measured for the earthquake of 20 Aug 1965 are plotted as in Figure B.12. Stations included: CTA, RAB, TAU-S, PMG, ADE, KIP, GUA, SBA, MUN, SPA-S, MAN, MAT-S, BAG, LEM, ANP-L, BKS, SEO, SOM, COR, TUC, DUG, ALQ, BOZ, LUB, COL, and LPS.
- Figure B.16 The amplitudes measured for the earthquake of 10 Aug 1966, are plotted as in Figure B.12. Stations included: RIV, RAB, CTA, PMG-S, TAU, ADE, KIP-S, GUA, SBA, MUN, DAV, SPA-S, MAN-L, MAT, BAG, ANP, BKS, SEO, TUC, LON, DUG, ALQ, BOZ, COL, LUB, GOL, JCT, PEL-S, and LPS.
- Figure B.17 The amplitudes measured for the earthquake of 12 Aug 1967 are plotted as in Figure B.12. Stations included: CTA, TAU-S, RAB, PMG, ADE-S, KIP-S, GUA, SBA, MUN, DAV, SPA, MAN, BAG, MAT, ANP-L, BKS, SEO, HKC, LON, ALQ, BOZ, LUB, COL, and GOL.

Figure B.18 The amplitudes for the earthquake of 4 Aug 1964 are plotted as in Figure B.2 except that triangles denote stations between -100 and 10 degrees azimuth. Stations included: COL, HKC, BAG, MAN, KIP, CMC, NHA, RAB, NOR, PMG-L, HNR, LON, KEV, NDI-L, LAH, BKS, BOZ, KTG, NUR, QUE, DUG, CTA, GSC, AKU-S, RCD-S, KON, GOL, TUC, COP-L, ALQ, SHI-S, IST, STU, RIV-S, VAL-L, SCP-L, JER, MUN-S, and BLA.

BIOGRAPHICAL NOTE

The author was born in Kalamazoo, Michigan on February 14, 1945, the son of Norman C. Sleep and Caroline Sleep (née Harvey). At age 5 his family moved to Parchment, Michigan, where he attended the Parchment Public Schools. After graduating from high school in 1963, he enrolled at Michigan State University, graduating with a B.S. in mathematics in 1967. During part of this time he was also employed in the paper industry in Parchment and Kalamazoo, Michigan. In September, 1967, he entered Graduate School at the Massachusetts Institute of Technology. He is the author of the following papers:

Sleep, N.H., Sensitivity of Heat Flow and Gravity to the Mechanism of Sea-Floor Spreading, J. Geophys. Res., 72, 542, 1969.

Sleep, N.H. and S. Biehler, Topography and Tectonics at the Intersections of Fracture Zones with Central Rifts, J. Geophys. Res., 75, 2748, 1970.

Sleep, N.H. and M.N. Toksöz, Evolution of Marginal Basins, Nature, 233, 548, 1971.

Sleep, N.H., Thermal Effects of the Formation of Atlantic Continental Margins by Continental Break Up, Geophys. J. Roy. Astron. Soc., 24, 325, 1971.

Sleep, N.H., Crustal Thinning on Atlantic Continental
Margins: evidence from older margins, Proc. NATO
Advanced Study Institute, Newcastle, England, in
press, 1972.
