5
6

7 Embryonic stem cell derived cardiomyocytes have been widely investigated for stem cell therapy or *in*
8 *vitro* model systems. This study examines how two specific biophysical stimuli, collagen I and cell
9 alignment, affect the phenotypes of embryonic stem cell derived cardiomyocytes *in vitro*. Three
10 phenotypic indicators are assessed: sarcomere organization, cell elongation, and percentage of
11 binucleation. Murine embryonic stem cells were differentiated in a hanging drop assay and
12 cardiomyocytes expressing GFP- α -actinin were isolated by fluorescent sorting. First, the effect of
13 collagen I was investigated. Addition of soluble collagen I markedly reduced binucleation as a result of
14 an increase in cytokinesis. Laden with a collagen gel layer, myocyte mobility and cell shape change were
15 impeded. Second, the effect of cell alignment by microcontact printing and nanopattern topography was
16 investigated. Both patterning techniques induced cell alignment and elongation. Microcontact printing of
17 20 μ m line pattern accelerated binucleation and nanotopography with 700nm ridges and 3.5 μ m grooves
18 negatively regulated binucleation. This study highlights the importance of biophysical cues in the
19 morphological changes of differentiated cardiomyocytes and may have important implications on how
20 these cells incorporate into the native myocardium.

Introduction

The ability of embryonic stem cells to differentiate into cardiomyocytes *in vitro* has motivated numerous studies of possible clinical application,^{24, 32, 48} development of *in vitro* model systems,^{4, 21, 40} and/or generation of a continuous source of contractile cells. Some challenges remain, however, such as how to drive embryonic stem cell derived cardiomyocytes (ESCDMs) into maturation.^{30, 38, 43} In this study, we attempt to characterize the phenotypic changes of ESCDMs with respect to two biophysical stimuli – presence of collagen I and cell alignment.

Collagen I is a critical ECM component in the adult myocardium and a ubiquitous cardiac tissue engineering scaffold material.^{7, 8, 56} The integrin interactions of collagen I in cardiac tissue have also been well studied.^{9, 16, 29} For highly contractile cells, an overlay of collagen I scaffold has been demonstrated to enhance differentiation and increase contractile protein production *in vitro*.⁴⁹ Some preliminary evidence suggests that by injecting collagen I hydrogel with neonatal myocytes into infarcted tissue, cardiac ejection fraction is improved.²⁷ However, more mechanistic studies are required to understand how ECM proteins, collagen I in particular, impact ESCDM function.^{4, 27, 57}

The second biophysical stimulation we focused on is cell alignment. In the myocardium, cardiomyocytes are arranged into layered two-dimensional sheets, precisely oriented to produce a twisting motion during each contraction.^{1, 31} Two ways to induce alignment have been explored *in vitro* – protein patterning, also known as microcontact printing, and topographical patterning. Both patterning techniques can induce anisotropy of neonatal myocyte monolayers.^{2, 17, 23, 25} However, the mechanisms by which patterns affect ESCDM phenotype remains elusive.

In this study, we investigated how two specific biophysical stimuli, collagen I and cell alignment, affect the morphology of embryonic stem cell derived cardiomyocytes. Three phenotypic indicators commonly used to characterize a more mature morphology were used – sarcomere organization, cell elongation, and

1
2
3
4 binucleation.^{39, 43, 44, 50} While surface patterning and ECM interactions have been studied extensively for
5
6 neonatal myocytes *in vitro*, the effects are lesser known for ESCDMs.^{3, 17, 19, 42} Based on this previous
7
8 work, we hypothesized that both cell alignment and interactions with collagen I would enhance the rate of
9
10 differentiation of ESCDMs. This study is an important step toward an improved understanding of how
11
12 the biophysical environment affects ESCDMs.
13

15 16 **Materials and Methods**

17 18 19 **Cell Culture and Differentiation**

20
21
22 Murine embryonic stem cells (mESC - line CGR8) were kindly provided by Dr. Richard Lee, Harvard
23
24 Medical School. The cardiac specific α -MHC promoter was tagged with green fluorescent protein (GFP)
25
26 and thus differentiation could be readily assessed via observation of GFP. To keep ESCs undifferentiated,
27
28 leukemia inhibitory factor (LIF) was present in the medium, comprised of Glasgow Minimum Essential
29
30 Medium (GMEM) (Invitrogen), 1,000U/ml Leukemia Inhibitory Factor (Sigma), 1mM Sodium Pyruvate
31
32 (Invitrogen), 1x Non-Essential Amino Acid (Invitrogen), 15% Knockout Serum Replacement (Invitrogen),
33
34 25mM of HEPES, 10^{-4} M β - mercaptoethanol (Sigma), and 1x Penicillin-Streptomycin (Invitrogen). Cells
35
36 were maintained in flasks coated with 0.1% gelatin in PBS. Cell confluency was tightly controlled not to
37
38 exceed 70%.
39
40
41

42
43 By removing LIF and creating a three-dimensional environment, mESCs spontaneously differentiate. The
44
45 composition of the differentiation medium was similar to that of the maintaining medium. In addition to
46
47 the removal of LIF, knockout serum replacement was replaced by ESC Fetal Bovine Serum (Invitrogen).
48
49 100 μ M of ascorbic acid was added to enhance differentiation.⁴⁶
50
51

52
53 A standard hanging drop technique was used to induce differentiation.³⁷ Briefly, cell suspension solution
54
55 was prepared at 10,000 cells/ml. 30 μ l drops were placed on the inside of a 100mm non-tissue culture
56
57 treated Petri dish, containing 10ml of 1x PBS. Drops, containing small cell aggregates, were cultured for
58
59
60
61

1
2
3
4 2 days before being collected with a 10ml pipette. These aggregates continued to be cultured, in
5
6 differentiation medium, for 3 more days for embryoid body (EB) formation. Once EBs were formed, they
7
8 were collected, seeded on 0.1% gelatin coated 6-well plates and cultured for 4 more days before being
9
10 dissociated and isolated with fluorescent-based sorting. Upon plating, spontaneous contraction and GFP
11
12 expression could be observed usually within 72-96 hours.
13
14

15 16 **Isolation and Cell Seeding** 17

18
19 EBs are composed of stem cells with extensive extracellular matrix proteins and thus standard
20
21 trypsinization alone was not sufficient. Instead, EBs were first washed with PBS twice and incubated with
22
23 0.05% trypsin for 5-7 minutes. After that, EBs were dislodged from the culturing substrate with gentle
24
25 agitation using a 1ml pipettor and transferred into a test tube where ample media were added to neutralize
26
27 the effect of trypsin. At this point, many clumps were still present and the test tube was centrifuged for 5
28
29 minutes at 1,200rpm. After the removal of the supernatant, more trypsin was added and the cells
30
31 incubated for another 5-7 minutes. This second stage caused most of the cells to dissociate. Medium was
32
33 added and the solution was centrifuged again. Once all trypsin-containing media were replaced by fresh
34
35 media, the content was passed through a 40µm cell strainer and transferred to a test tube for sorting.
36
37 Fluorescent activated cell sorting was performed with MoFlo (Cytomation). Either differentiated ESCs
38
39 without GFP or undifferentiated ESCs were used as the negative control. 2-4% of total cells were GFP-
40
41 positive and the purity of the sorted population was consistently higher than 99.95%.
42
43
44
45
46

47 The purified population of cells was resuspended in warm medium to a concentration of 2,000,000
48
49 cells/ml. Four collagen conditions were examined: ESCDM monolayer with no collagen (control),
50
51 ESCDM monolayer supplemented with 50µg/ml of soluble collagen I, ESCDM monolayer laden with
52
53 2mg/ml collagen I hydrogel and isolated ESCDMs suspended in 2mg/ml collagen I hydrogel. ESCDM
54
55 monolayer seeding density was 100,000 cells/cm², due to the limited ability for differentiated
56
57 cardiomyocytes to divide and proliferate. In the soluble collagen condition, the small amount of collagen
58
59
60
61
62
63
64
65

1
2
3
4 did not affect the pH of the medium. In the condition with a collagen gel overlay, 2mg/ml collagen gel,
5
6 prepared on ice, was reconstituted by combining 10x DMEM, 0.5N NaOH, high concentration (3-4
7
8 mg/ml) collagen I (BD Biosciences) and sterile cell culture grade water. 30µl of gel solution was used for
9
10 each 96 well plate, resulting in a hydrogel layer several hundred microns thick. The gel was polymerized
11
12 for 40 minutes in the incubator (37°C, 5% CO₂), followed by the addition of warm medium. The scaffold
13
14 was added to the cell monolayer three days after seeding, when most cells had fully spread and formed
15
16 confluent monolayers. For the condition with ESCDMs suspended in collagen gel, the same collagen
17
18 recipe was followed except that water was replaced with cell solution for a final concentration of 1.5x10⁶
19
20 or 5x10⁶ cells/ml.
21
22
23
24

25 **Microcontact Printing**

26
27
28 Microcontact printing is a technique to transfer specific proteins between two solid surfaces. The
29
30 procedure used is similar to that described in Feinberg et. al.¹⁷ Briefly, molds were fabricated by
31
32 standard soft lithography and stamps with a 20µm/20µm line pattern were made with
33
34 polydimethylsiloxane (PDMS). Stamps were sterilized by sonication in 50% ethanol for 30 minutes and
35
36 stored in 70% ethanol. Stamps were washed, dried and incubated with 0.1% Oregon-green conjugated
37
38 gelatin (Invitrogen) for 1 hour. Rinsed and dried stamps were lowered onto plasma treated surface to
39
40 initiate contact and pressed for 1 minute with mild pressure allowing for proper protein transfer.
41
42
43

44
45 In the following steps, one rinse with sterile PBS was performed between each step. 1% Pluronic-F127
46
47 (Sigma) was added to the stamped and rinsed surface for 15 minutes, followed by incubation of 0.02%
48
49 nonfluorescent gelatin (Gibco) for 15 minutes. Finally, the surfaces were rinsed three times before being
50
51 stored in PBS in the incubator.
52
53

54 **Nanopattern Topography**

55
56
57 Hot embossing generated the submicron-scale substrate topography with an epoxy mold created by a
58
59 three-step molding process. First, a silicon master mold was fabricated using standard photolithography
60
61
62
63
64
65

1
2
3
4 and reactive ion etching (RIE). A 1 μm -thick layer of silicon oxide was thermally grown on a 100 mm
5
6 silicon wafer and features ranging from 500 nm to 1 μm were created by spin-coating a 500 nm layer of
7
8 Shipley 1805 photoresist on the wafer, patterning the photoresist using a standard photomask, and
9
10 developing the patterned photoresist. An anisotropic reactive ion etch using CF_4 and O_2 transferred the
11
12 photoresist features into the silicon oxide to a depth of 1 μm before stripping the photoresist. The second
13
14 mold was made with PDMS. The third epoxy mold was made from a two-part high temperature epoxy
15
16 (Conapoxy FR-1080, CYTEC Industries). For the hot embossing step, the epoxy mold was placed with
17
18 the submicron features in contact with a thermoplastic polystyrene blank in a uniformly heated,
19
20 temperature- and pressure-controlled press. The resulting substrate was a relief replica of the silicon
21
22 master mold and served as the platform for cell culture experiments.
23
24
25
26

27 **Immunofluorescent Labeling**

28
29
30 To visualize sarcomere organization, cells were first washed twice with 1x PBS to remove media and
31
32 fixed with 4% paraformaldehyde (PFA) for 15 minutes in room temperature. 0.1% triton-x was used to
33
34 permeabilize the cell membrane for 2-5 minutes. For the following steps, 2D cultures were incubated with
35
36 the appropriate reagent for 1hr at room temperature, and 3D cultures were incubated overnight at 4°C.
37
38 Cells were first incubated with block ace (Dainippon Pharmaceutical, Tokyo, Japan) to block nonspecific
39
40 binding, followed by incubation of primary antibodies, mouse sarcomeric α -actinin, at dilution factor of
41
42 1:200. Secondary detection antibody (anti-mouse Alexa 568) and 4',6-diamidino-2-phenylindole (DAPI)
43
44 were used to visualize protein of interest and nuclei respectively. In between each of the steps described
45
46 previously, two rinses of 1x PBS were performed. For samples with collagen gel, longer washing
47
48 procedures were adapted and secondary antibody was reconstituted in PBS with 2% rabbit serum and 2%
49
50 bovine serum albumin to further reduce background staining.
51
52
53
54
55

56 **Quantification and Statistical Analysis of Binucleation, Cell Shape and Cell Alignment**

1
2
3
4 Cell elongation, binucleation and cell orientation were quantified by ImageJ. To quantify elongation,
5
6 individual GFP-positive cells were identified, traced and fitted as ellipses. Then the ratio of major and
7
8 minor axis, the aspect ratio, was calculated. For each condition, 10-30 separate regions (330 μ m x 430 μ m)
9
10 were imaged and a total of 60-100 randomly selected cells were traced. Thus, the majority of the cells
11
12 traced were not in contact with each other. To quantify binucleation, each GFP image was merged with
13
14 DAPI image to enhance the identification of nuclei. Number of binucleated cells were then counted. At
15
16 least 500 GFP-positive cells were counted for each experimental condition. To measure alignment angle,
17
18 pattern angle was first determined and then the deviation angle of the major axis of the cell and the
19
20 pattern angle was calculated. At least three independent sets of experiments were performed for each
21
22 condition.
23
24
25

26
27 Data were expressed as mean \pm SEM and analyzed using one-way ANOVA followed by post hoc
28
29 Student's t test. Results with P<0.05 were considered statistically significant.
30
31

32 33 **Results**

34 35 36 **Sarcomere development of ESCDMs suspended in collagen gel or plated on ECM-coated** 37 38 **polystyrene**

39
40
41 In this study, we were interested in how biophysical stimulations affect the morphology of ESCDMs. We
42
43 started the investigation with collagen I, a ubiquitous ECM protein in the adult heart as well as in
44
45 previous *in vitro* cell culture with cardiomyocytes.^{21, 56} We found that suspending ESCDMs in 2mg/ml
46
47 collagen gel does not induce sarcomere development or cell-cell contacts, two key parameters observed
48
49 during proper cardiomyocyte development (Figure 1).^{13, 28, 41} Isolated ESCDMs remain rounded and
50
51 contractile. Immunofluorescent staining of sarcomeric α -actinin reveals a punctate protein distribution,
52
53 lacking any organized structures. Two cell seeding densities (1.5 $\times 10^6$ and 5 $\times 10^6$ cells/ml) exhibited
54
55 similar results. These findings suggest that static culture of single ESCDMs suspended in collagen I gel is
56
57 not conducive for myocyte development.
58
59
60
61

1
2
3
4 In contrast, confluent ESCDM monolayers with well-developed sarcomeres, along with stress fibers, are
5
6 observed in cells seeded on ECM-coated polystyrene. Sarcomeres, albeit immature, can be observed 48
7
8 hours after seeding and become more clearly evident for all three conditions – no collagen, with soluble
9
10 collagen and with a laden layer of collagen gel (Figure 2a).
11
12

13 14 **Effect of collagen I on cell elongation**

15
16
17 Elongation of ESCDMs was measured by the aspect ratio – the ratio of the major and minor axis -- of
18
19 each cell. Figure 2b shows the aspect ratio of ESCDMs over time, exposed to collagen I in different forms.
20
21 Regardless of how collagen I is presented to the cell monolayer, cell aspect ratio increases over time. The
22
23 aspect ratio of ESCDMs laden with a layer of collagen I is reduced slightly but significantly compared to
24
25 control where no additional collagen is added. Interestingly, the rate of increase in aspect ratio is
26
27 dependent upon the collagen condition (Figure 2c). Clear increase in aspect ratio over time can be
28
29 observed for the three different collagen I conditions but the increase of aspect ratio is highest for the
30
31 soluble collagen condition, followed by the control condition and the collagen gel condition. On average,
32
33 the aspect ratio of ESCDMs increases by 9.6% per day for the condition with soluble collagen, 7.5% for
34
35 control, and 4.6% for the condition with collagen gel.
36
37
38
39

40 **Effect of collagen I on cell binucleation**

41
42
43 Binucleation, like cell elongation measured by aspect ratio, increases over time (Figure 3a). Binucleation
44
45 has been suggested to be a phenotypic indicator of maturation *in vivo* and *in vitro*.^{44, 53} Effects of collagen
46
47 I on binucleation depend on how collagen I is presented. Presented as a hydrogel, it has little impact on
48
49 binucleation. A small increase in binucleation can be seen after 2 weeks of culture with collagen gel,
50
51 compared with control. When collagen I solution is added into the medium, it strongly inhibits
52
53 binucleation. After 14 days, ESCDMs cultured with soluble collagen have 50% fewer binucleated cells
54
55 compared with the control.
56
57
58
59
60
61
62
63
64
65

1
2
3
4 To confirm whether the reduction of binucleation is due to a decrease in karyokinesis or an increase of
5
6 cytokinesis, we counted the number of cells. We found an increasing number of cells when ESCDMs are
7
8 cultured with soluble collagen I, under which condition ESCDMs are more likely to undergo cytokinesis
9
10 and complete the cell cycle (Figure 3b).

11 12 13 14 **Effect of Surface Patterning on ESCDM Alignment**

15
16
17 The second biophysical cue we investigated is cell alignment. ESCDMs cultured on MCP and NPT
18
19 surfaces align with the pattern surface (Figure 4). For the MCP surface, gelatin conjugated with Oregon
20
21 Green is used to visualize and measure the pattern angle. For the NPT surface, the ridges and grooves
22
23 alter between 3.5 μ m and 700nm. Aligned sarcomeres can be observed for both patterning techniques.
24
25 Sarcomere development is strongly dependent on the periodicity of NPT surface as the sarcomere width
26
27 coincides with the width of the ridges. This same phenomenon is not observed for MCP surface.
28
29

30
31 For cells cultured on MCP and NPT surfaces, the angle between the major axis of the cell and the pattern
32
33 was calculated (Figure 5). Alignment can be observed within 48 hours: almost all cells cultured on MCP
34
35 and NPT surfaces align within 20 degrees of the pattern orientation (Figure 5a). The same strong
36
37 alignments persist over time (Figure 5b&c). By day 7, more than 70% of the cells cultured on NPT
38
39 surfaces align within 10 degrees from the pattern. Interestingly, cell alignment on MCP surface is better
40
41 retained with collagen gel overlay after 2 weeks. 60% of cells in that condition remained aligned within
42
43 10 degrees while alignment in other conditions declined to 30% (Figure 5d).
44
45
46

47 48 **Effect of Surface Patterning on ESCDM Elongation**

49
50
51 Cells cultured on patterned surfaces, both MCP and NPT, exhibit elongated features (Figure 4) although
52
53 the rate of elongation is highest for cells cultured on isotropic surfaces (Figure 6a&b). There is virtually
54
55 no increase in aspect ratio for cells on MCP surfaces suggesting that the cellular response to the surface
56
57 has saturated after 48 hours.
58
59
60
61

1
2
3
4 Elongation is mostly attributed to a decrease in minor axis length rather than an increase in major axis
5
6 length (Figure 6 c&d). Significant reductions in minor axis are observed for both the isotropic and NPT
7
8 conditions and this explains the shrinkage of the monolayer away from the walls at longer time points.
9

10 11 **Effects of surface patterning on binucleation**

12
13
14 Percentage of binucleation increases over time for all patterning conditions. Binucleation rate between
15
16 day 2 and day 7 of ESCDMs on MCP surface is much higher than in cells on isotropic surfaces (Figure
17
18 7a). Markedly reduced binucleation was observed for ESCDMs on NPT surfaces, compared with
19
20 isotropic surface regardless of presence of collagen gel (Figure 7b). We found an increase in the number
21
22 of ESCDMs on NPT surfaces indicating that the reduction in binucleated cells is a result of cells
23
24 completing the cell cycle and being able to undergo cytokinesis (Figure 7c). This is similar to the finding
25
26 for ESCDMs cultured with soluble collagen.
27
28
29
30

31 **Discussion**

32
33
34 In this study, we explored the effects of cell alignment and the addition of extracellular matrix protein,
35
36 collagen I specifically, on changes of embryonic stem cell derived cardiomyocytes phenotype. This work
37
38 is motivated by two observations. First, due to the limited regenerative ability of the heart,⁵⁵ differentiated
39
40 stem cells have been considered as a possible source of functional cardiomyocytes. They can also be used
41
42 as *in vitro* model systems.^{11, 35} Second, spontaneously contractile cardiomyocytes can be used as
43
44 miniature actuators. To date, most research focused on biomachines utilizes neonatal myocytes.^{26, 47, 51}
45
46
47 Stem cell derived cardiomyocytes have the advantage of being an unlimited and continuous source of
48
49 contractile cells. However, little is known about how biophysical factors affect ESCDMs and we attempt
50
51 here to gain a better understanding by first probing two stimuli inspired by the natural environment of the
52
53 myocardium as well as the previous literature.
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 We have portrayed a rather complex picture of the relationship between collagen I and ESCDMs. We
5
6 chose collagen I because of its abundance in the adult heart even though other ECM proteins are present
7
8 at various stages during development.⁷ It is also ubiquitously used as a tissue engineering scaffold *in*
9
10 *vitro*.^{33,49} First, we observed that by suspending ESCDMs in collagen as single cells statically, no
11
12 sarcomeres or cell-cell contacts are formed, even at a high cell density. This result is similar to the
13
14 findings from Souren et. al. where neonatal cardiomyocytes embedded in collagen gel remain isolated and
15
16 contract asynchronously.⁴⁵ The lack of adequate growth factors or matrix proteins may be one explanation
17
18 for this finding since Zimmermann et. al. successfully developed 3D cardiomyocyte construct with the
19
20 addition of MatrigelTM and chick serum.⁵⁶ Another possible explanation is that the stiffness of the
21
22 hydrogel, estimated around 10 KPa,⁵² is softer than optimal for myogenesis.^{5, 15, 22} On the other hand,
23
24 according to Discher et. al., substrates that are too stiff, such as polystyrene, are suboptimal for myocyte
25
26 development as well.¹⁴ However the stiffer substrate is better able to withstand the traction force required
27
28 for sarcomere development,^{42, 54} and this may provide another possible explanation for the differences
29
30 observed.
31
32
33
34
35
36

37 Secondly, cell elongation is impeded and alignment maintained in the presence of collagen gel overlay.
38
39 (Figure 2b) This might be due to the physical constraint the hydrogel imposes on the monolayer, perhaps
40
41 by binding to the monolayer, and/or by the weight of the gel. One study has found that a collagen gel
42
43 overlay improved the differentiation of skeletal myotubes presumably by imposing a constant load on the
44
45 monolayer.⁴⁹ Combined with MCP, the collagen gel accelerates binucleation, as demonstrated by the
46
47 significant increase in binucleation between days 2 and 7, although the increase in binucleation between
48
49 day 7 and 14 is not statistically different from control (Figure 7a). Although the mechanism of this
50
51 phenomenon remains to be elucidated, this finding is one example of the combinatorial effects of two
52
53 biophysical stimulations on ESCDMs.
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 While this study focuses on the effects of collagen I, other ECM proteins, such as vitronectin or
5
6 fibronectin, may be present in the experimental system due to the presence of serum in the medium.

7
8 These ECM-integrin interactions have been demonstrated to be critical during heart development.^{8, 20, 36}
9

10
11 In this study, variation due to the presence of serum was mitigated by using the same lot of serum
12
13 although further studies could be envisioned to specifically investigate the effects of other ECM proteins
14
15 on ESCDMs.
16

17
18 Lastly and unexpectedly, collagen I, presented in a soluble form in medium, is a strong negative regulator
19
20 of binucleation. This effect is not seen when it is presented as a hydrogel. Soluble collagen increases
21
22 cytokinesis and promotes ESCDMs to complete the cell cycle. This suggests that how ESCDMs respond
23
24 to collagen I depends on the way it is presented to the cells. This is reminiscent to the differential
25
26 responses of cells to exogenous and matrix-bound growth factors and this finding is, to our understanding,
27
28 the first study to explore the effects of exogenous collagen I on ESCDMs.¹²
29
30

31
32
33 The second biophysical stimulation we tested is the effect of cell alignment, induced by microcontact
34
35 printing and nanopattern topography, on ESCDM morphology. In this study, only one set of geometric
36
37 dimensions of each patterning techniques is explored. Bursac et. al. found that varying MCP dimensions
38
39 did not cause a statistically significant difference in the electrophysiological properties of neonatal
40
41 myocytes.¹⁰ For nanoscale topography, Au et. al. found neonatal myocytes exhibited clearer sarcomere
42
43 structures on surfaces with 0.5 μ m-wide ridges and 0.5 μ m-wide grooves than 1 μ m-wide ridges and 3 μ m-
44
45 wide grooves, although it is unclear whether the difference arises from differences in duty cycle or the
46
47 exact dimensions.² Due to the limited understanding of the effects of NPT and the difficulty to directly
48
49 compare the two patterning techniques,^{2, 25} we focused on characterizing their effects on ESCDMs
50
51 separately compared with the isotropic control.
52
53
54
55

56
57 In this study, consistent with previous literature, we report that both patterning techniques induce cell
58
59 alignment and elongation, as observed in cardiomyocyte sheets *in vivo*.⁷ The increase in aspect ratio over
60
61

1
2
3
4 time is mostly attributed to a decrease in width and the lateral dimensions of the cells remain significantly
5
6 smaller than adult myocytes (although cell volumes were not measured).⁶ Longer culture times and
7
8 mechanical/electrical stimulations may be necessary for enhanced differentiation and maturation.^{18, 34, 43}
9

10
11 In terms of binucleation, the MCP surface alone, without the addition of collagen, slightly but
12
13 significantly increased the percentage of binucleation compared with a smooth surface. In contrast,
14
15 compared with the isotropic case, ESCDMs cultured on NPT surface observed markedly reduced
16
17 binucleation, due to increased cytokinesis. It is reasonable to believe that the finding for MCP surfaces is
18
19 less dependent on the geometric dimensions but it is less clear whether varying NPT dimensions will
20
21 produce the same finding. Nevertheless, from this study, we are able to conclude that induced cell
22
23 alignment affects the binucleation of ESCDMs *in vitro*.
24
25
26

27
28 Presence of collagen I and alignment are two important biophysical characteristics of the adult
29
30 myocardium and here we adopted these two stimuli and characterized their effects on ESCDM phenotypic
31
32 changes *in vitro*. We are able to demonstrate that by affecting them, we can alter the morphology of
33
34 embryonic stem cell derived cardiomyocytes. This is an important step in advancing our understanding of
35
36 how to utilize embryonic stem cell derived cardiomyocytes as a cardiovascular disease treatment option.
37
38 By being able to control the phenotype *in vitro*, this opens the prospect of using ESCDMs as actuators for
39
40 biomachines.

6
7 Figure 1: ESCDMs embedded in collagen I hydrogel
8
9

10 ESCDMs are suspended in 2mg/ml collagen I hydrogel immediately after fluorescent sorting. Seeding
11 density was 1.5×10^6 /ml for (a)-(e) and 5×10^6 /ml for (f). These cells are fixed after 21 days. Scale bar for
12 (a)-(f): 100 μ m; (g): 10 μ m.
13
14
15
16
17

18 Figure 2: Effect of collagen on cell morphology and elongation on day 2, 7 and 14
19
20

21 (a) Representative images of ESCDMs cultured on gelatin coated polystyrene on day 2, day 7 and day 14.
22

23 Sarcomeres, visualized with sarcomeric α -actinin, are readily observed as early as 2 days after seeding.
24

25 Scale bar = 50 μ m.
26
27

28 (b) Aspect ratio of ESCDMs increases over time regardless of the condition of collagen gel. There is no
29 significant difference in aspect ratio for soluble collagen, compared to control. There is a slight decrease
30 in aspect ratio for the collagen gel condition compared to control after 14 days. Asterisks represent
31 statistical difference ($p < 0.05$) of the data point of interest compared to day 2 of the same condition and
32 diamond (\diamond) stands for statistical difference ($p < 0.05$) of the data point of interest compared to the control
33 condition without additional collagen I of the same day.
34
35
36
37
38
39
40
41
42

43 (c) There is a difference in the rate of aspect ratio increase for different collagen conditions. ESCDMs
44 cultured with soluble collagen elongate most rapidly, followed by control and collagen gel.
45
46
47

48 Figure 3: Percentage of binucleated cells with various collagen I condition
49
50

51 Effect of collagen I on binucleation is presented. (a) ESCDMs are either exposed to no collagen, soluble
52 collagen (50 μ g/ml) or 2mg/ml collagen gel laden on top of the monolayer seeded on an isotropic surface.
53 Binucleation increases over time. Soluble collagen, supplemented in the medium, has a strong negative
54 effect for binucleation. (b) Number of cells for different collagen conditions. Asterisks represent

64
65

1
2
3
4 statistical difference ($p < 0.05$) of the data point of interest compared to day 2 of the same condition and
5
6 diamond (\diamond) stands for statistical difference ($p < 0.05$) of the data point of interest compared to the control
7
8 condition without additional collagen I of the same day.
9

10
11 Figure 4: cell alignment with microcontact printing and nanopattern topography
12

13
14
15 (a) Two methods of patterning were tested – microcontact printing (MCP) and nanopattern topography
16
17 (NPT). MCP was visualized by printing gelatin conjugated with Oregon green.
18

19
20 (b&c) Cells exhibit clear alignment when cultured on MCP and NPT surfaces. These are representative
21
22 images of nuclei (DAPI), sarcomeric α -actinin and merged cells from day 14 samples with 50 μ g/ml
23
24 soluble collagen. Scale bars: (b) 50 μ m, (c) 10 μ m.
25
26

27
28 Figure 5: histograms of cell alignment at different time points
29

30
31 Histograms of cell alignment at (a) day 2, (b) day 7, and (c) day 14 are plotted. Three surface patterns are
32
33 compared: no patterns, MCP, and NPT. Three extracellular matrix incorporations are compared for day 7
34
35 and day 14 (the conditions do not apply to day 2 samples because they are applied on day 3): no
36
37 additional ECM, 50 μ g/ml soluble collagen I in media and 2mg/ml collagen hydrogel laden on the surface
38
39 of the monolayer. Because of the secretion of ECM by the cells, we tested if the alignment would be
40
41 maintained on MCP surface at day 14. (d) illustrates that while ESDMs cultured without collagen and
42
43 with soluble collagen lose alignment, alignment for ESCDM monolayers laden with collagen gel is
44
45 rescued.
46
47
48

49
50 Figure 6: Effect of surface patterning on elongation without the addition of collagen
51

52
53 Effect of surface patterning on cell elongation is measured. (a,b) Aspect ratio of cells on isotropic and
54
55 NPT surfaces increases over time while that of cells on MCP surface remains constant. (c,d) The average
56
57 dimensions of the major and minor axes are also recorded and it can be seen that most increase in aspect
58
59 ratio is attributed to a decrease in minor axis. Asterisks represent statistical difference ($p < 0.05$) of the data
60
61

1
2
3
4 point of interest compared to day 2 of the same condition and diamond (\diamond) stands for statistical difference
5
6 ($p < 0.05$) of the data point of interest compared to the isotropic condition of the same day.
7
8

9
10 Figure 7: Effect of surface patterning on binucleation

11
12 (a) Binucleation with surface patterning. MCP accelerates binucleation between day 2 and day 7. (b) NPT
13 is a negative regulator of binucleation. (c) By examining the number of cells, there are a higher number of
14 cells on NPT surface after 14 days suggesting that the decrease in binucleation is a result of an increase in
15 cytokinesis. Asterisks represent statistical difference ($p < 0.05$) of the data point of interest compared to
16 day 2 of the same condition and diamond (\diamond) stands for statistical difference ($p < 0.05$) of the data point of
17 interest compared to the isotropic condition of the same day.
