Due to the condition of the original material, there are unavoidable flaws in this reproduction. We have made every effort to provide you with the best copy available. If you are dissatisfied with this product and find it unusable, please contact Document Services as soon as possible.

Thank you.

DUE TO THE POOR QUALITY OF THE ORIGINAL THERE IS SOME SPOTTING OR BACKGROUND SHADING ON THIS THESIS.

ACKNOWLEDGEMENT

The author wishes to express his appreciation for the help and advice of Professor A. L. Townsend, under whose supervision this thesis was carried out. Sincere thanks are due to Mr. A. B. English for giving so generously of his time and advice, especially after the untimely death of Mr. A. W. Lawson, designer of the dynamometer.

To Professor G. B. Wilkes and Mr. L. R. Vianey of the Heat Measurements Laboratory and to professor P. E. Kyle of the Metals Processing Laboratory, the author wishes to express his appreciation for valuable advice and the loan of equipment from their respective departments.

The entire staff of the Machine Tool Laboratory proved to be of great assistance in the completion of this thesis. The work of R. J. Bowley, Mr. George Harkins and Mr. Earl Luther deserves special mention.

Finally, to Mr. E. M. Ferguson of the Horton Manufacturing Company, Minneapolis, Minnesota, the author expresses his sincere appreciation and thanks for the gift of a Horton Variable Speed Pulley which greatly simplified the procedure and technique of this thesis.

INTRODUCTION AND PURPOSE

A great many investigations have been made and pages of literature have been written on the machining of metals and yet it seems as though only the surface of this subject has been scratched. Taylor, Herbert, Woxen, Klopstock, Ernst, Boston and many others have carried on thorough investigations on the physics of cutting and machinability in general. All agree that cutting is a shearing failure in the plastic region, but besides this point there is little general agreement, and this thesis is no exception.

Ihis lack of agreement is due largely to the various individual definitions of machinability and the use of widely different materials and cutting conditions. It was hoped at the beginning of this thesis that this would be the first of a long line of theses at M.I.T. devoted to the study of all of the factors influencing machining, and that the results obtained could be applied to any material under any set of conditions after a series of standard tests had been made to determine material constants. These theses should also be so planned as to include all of the various definitions of machinability.

At the present time the machinability of a metal is defined in three ways. First, machinability may be a measure of the power required to remove a chip; second, it may be an index of the abrasiveness of the metal, that is, the influence that a particular metal has on the tool life; and third, it may be an index to the quality of surface finish that may be obtained. In this investigation, the power criterion was used to define machinability.

Before starting the actual experimental work, it was necessary to pick out a few variables from a rather awe inspiring list of possible variables. This list of possible tactors which may affect machining includes, surface speed of the billet, feed, depth, side rake angle, back rake angle, side cutting edge angle, front cutting edge angle, side and front clearance and relief angles, nose radius of tool, height of tool with respect to centers, temperature of the tool, temperature of the billet, physical properties of the billet (hardness, tensile strength, yield point, etc.), microstucture of billet (microconstituents, grains size, etc.), physical properties of the cutting tool, use of cutting fluids, chemical analysis of the billet, etc. I chose the first four variables on the list for this investigation,

namely, surface speed, feed, depth and side rake angle, as I felt that these were probably the most important and should be investigated first. As a side line to the main investigation, I chose the temperature of the billet as another possible variable and did a little investigation into it's influence on machining.

A statement of the main purpose of the thesis would be as follows: (1) to observe the influence of certain variables, namely speed, depth, feed and side rake angle, on the power required to remove metal, changing one variable at a time and holding the others constant; (2) to set up an equation for power consumed which would include on the right hand side the above variables raised to known powers and a constant K, this constant to be largely dependent on the material being cut, although it may also be affected by certain supressed variables; and (3) if it appears that this equation may hold for different materials, the only change in the equation being in the constant K, a standard test will be devised to determine this constant, the value of the constant will then be an index to machinability based on power consumption.

DESCRIPTION OF APPARATUS

The lathe used in this investigation was a fourteen inch Reed-Prentise with a five toot bed. It was driven by a $7\frac{1}{2}$ horse-power motor through a Horton Variable Speed Pulley. (Fig. #I) By means of the change gears and the Horton Pulley, it was possible to obtain any desired surface speed irrespective of the diameter of the billet.

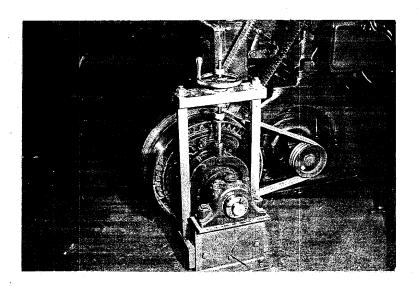

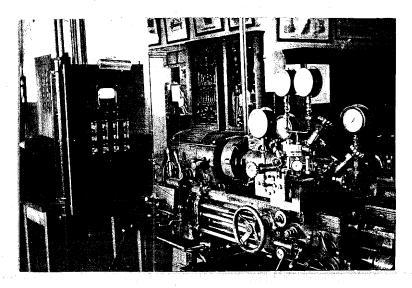

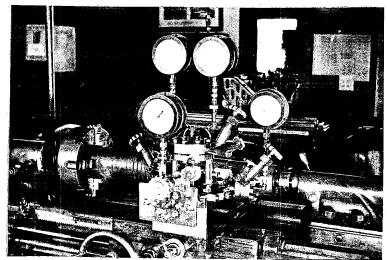

Fig. 1

To measure the forces on the cutting tool, a three component lathe tool dynamometer was employed. This dynamometer (Fig. #2) was designed by the late Mr. A. W. Lawson, instructor in the Machine Tool Laboratory at Massachusetts Institute of Technology. Rex AA high speed steel tools (see Appendix G for composition and heat

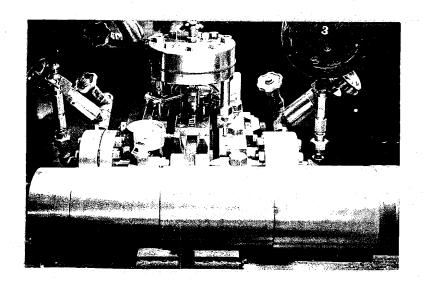

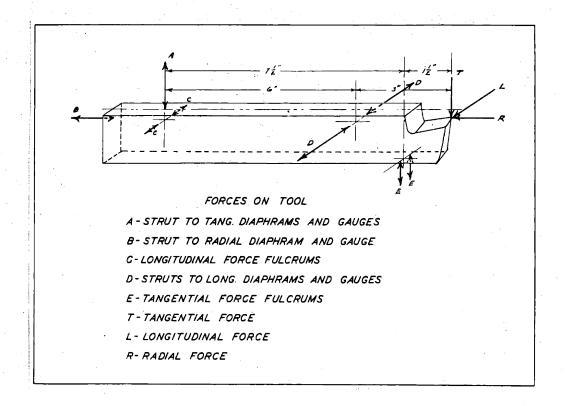

Fig. 2

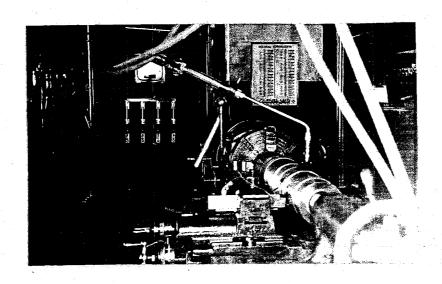

treatment) were clamped into a floating tool holder. The tool holder had been machined out of a solid piece of steel and was so counter-balanced that it remained perfectly level when supported by only two steel struts at the forward end. These struts (E in Fig. 3) were adjustable so that the point of the tool could be placed at or above the height of centers. All the pivots and struts used in this dynamometer were ball pointed and acted on hardened steel sockets in order to eliminate as much friction as possible.

At the top and to the rear of the tool holder, a strut (A in Fig. 3) transmitted the tangential or down-ward force T on the tool point to a large diaphram, the pressure being recorded on a Crosby Bourdon gage. Another strut (B in Fig. 3) at the rear of the tool holder, approximately at the height of the cutting edge of the tool, connected the tool holder to another diaphram and gage. This gage measured the radial force R on the tool. At the front end of the tool holder and at the approximate height of the cutting edge, two struts were placed (D in Fig. 3), one on either side, to transmit the longitudinal force L to two diphrams and gages.

The technique used in the operation of the dynamometer was such that the tool holder was always maintained in its original level position. Hydraulic plungers on the gage side of each diaphram were used to set up a force equal and opposite to the mechanical force delivered by the strut. Dial gages were placed so as to measure any change in the position of the tool holder. All the dials were set at zero when the tool was balancing and unloaded. As the load was applied to the tool, the oil pressure on the gage side of the diaphram was increased so as to maintain the dial gage at zero. Pressure readings were only made when all of the dial gages were at their original or zero position.

For the experiments on the cutting at elevated temperatures, the dynamometer could not be used. The cutting tools were, therefore, held in the regular tool post and all the power measurements were made with the wattmeter. The setup for heating and cutting the billet is shown below in Fig. 4.

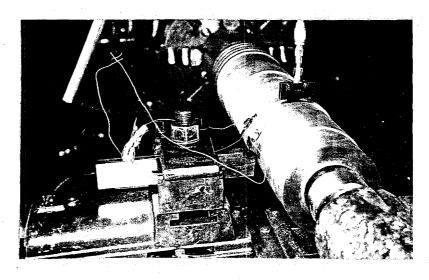

Fig. 4

A two inch oxy-acetylene descaling tip was used to apply the heat to the billet. The application of the flame was about three inches ahead of the tool.

The measurement of the temperature of the billet presented quite a problem. The tool-work thermocouple method as employed by Herbert, Woxen, Boston and others was considered but finally discarded as it was felt that this method would not give the temperature of the billet but rather the temperature at the point of the tool. This temperature would, of course, be considerably higher than the billet temperature due to the heat evolved in the rupturing of the metal and the frictional heat caused by the chip rubbing on the tool point.

A thermocouple as illustrated below in Fig. 5 was finally made and mounted so as to rub on the surface of the billet just ahead of the cutting tool, between the tool and the flame.

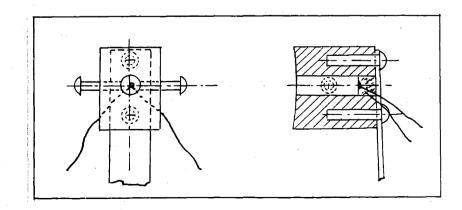

Fig. 5

A copper-constantine thermocouple (calabration chart in appendix G) was silver soldered to a short piece of copper rod. This rod was held in a piece of asbestos wood with two steel set screws. The end of the rod to which the thermocouple was soldered was insulated from the room temperature by a packing of asbestos fibre. The surface of the asbestos wood was ground to a radius of six inches. A piece of spring steel held the block against the billet with a constant normal force. The thermo-electric force was measured with a Wilson-Maeulen Millivoltmeter.

111

PROCEDURE

A - Calibration of Lathe and Horton Pulley.

In order to use the wattmeter reading of the power input as a check on the power output as given by the dynamometer, it was necessary to determine very carefully the efficiency of the lathe and Horton Pulley for the different sets of change gears that might be used and for different percentages of slip in the Horton Pulley.

A prony brake was mounted on a shaft held in the lathe chuck and a platform scales were used in this callibration. The necessary tables of data and the efficiency charts are included in the appendices A and B respectively.

B - Calibration of Diaphrams and Gages.

The diaphrams and gages had been calibrated by Albert Musschoot and James Stewart in 1936, using a Riehle testing machine, and their calibration data appears in Appendix G. This calibration was checked in 1937 by R. W. Vose using a 3000 pound Moorehouse proving ring. Since the two calibrations checked very closely, it was felt that further calibration was not necessary. The tigures obtained by Musschoot and Stewart are used in the calculations.

C - Cutting at Room Temperature.

In order to obtain the necessary data for this investigation, it was necessary to make a great many runs. Each of the four variables had to be varied over a certain range while the other three were held constant. Four values of surface speed were used, 30, 40, 50 and 60 feet per minute; seven values of feed were chosen, $3\frac{1}{2}$, 7, 14, 28, 21, $10\frac{1}{2}$, and $5\frac{1}{4}$ thousandths of an inch per revolution; three values of depth, $1/32^n$, $1/16^n$ and $1/8^n$; and four values of the side rake angle, 15, 20, 25, and 30 degrees.

All the tools were ground on a special grinding wheel equipped with a tilting protractor table and a protractor guide so that all the angles of the tool could be easily reproduced. All the angles of the tools were kept constant except the side rake angle. (See Appendix G for tool dimensions) Eight tools were used. Tools I and 2 had a 15° side rake angle; 3 and 4, a 20° angle; 5 and 6, a 25° angle; and 7 and 8, a 30° angle.

The technique used in handling the dynamometer is very important and considerable time was spent in developing a suitable technique. For the sake of future investigators, I will try to explain the procedure very closely so that unnecessary time in their investigations

need not be wasted.

The tool is first placed in the tool holder and adjust the justed with the gage provided so that it extends just the right amount from the tool holder. It is then clamped firmly in position. The two front struts are then adjusted to bring the cutting point at the right height. In this thesis all of the cuts were made with the tool at the height of centers. Next check with a small bench level to see that the tool is level and square with the billet. When the tool is perfectly level set the temperary stop at the bottom and rear of the tool holder to the correct height. This stop is only used to adjust the tangential and radial struts and must be screwed out of the way when the actual cuts are made.

The longitudinal, tangential and radial stuts are then adjusted so that a small pressure is recorded on their respective gages. It was found that the best results were obtained when the struts were adjusted so that the longitudinal and radial gages carried an initial pressure of tive pounds per square inch and the tangential gage recorded an initial pressure of one pound per square inch. The dial gages are now placed in position and their scales so adjusted that the indicators are in the zero position. If the dial gages are clamped tightly in position and the

struts are locked with the lock nuts provided, this one initial adjustment may be all that is necessary. Frequent checks should be made, however, to be sure that there has been no change in the zero position.

Before making the runs, the lathe should be allowed to run idle for approximately one half hour to insure that the motor is at the normal operating temperature.

The tool is now brought up until it just touches the surface of the billet and the reading on the micrometer dial of the cross-feed screw is noted. With the tool carraige at the end of the billet, the tool is screwed into the desired depth of cut. The surface speed of the billet is then adjusted with the Horton Pulley and accurately checked with a hand tachometer.

before engaging the feed clutch, an additional pressure was applied to the longitudinal strut by means of the plunger on the longitudinal diaphram. As the tool begins to cut, the plungers for the tangential and radial diaphrams were adjusted simultaneously so as to keep their respective dial gages at the zero position. With these two gages at zero and the full cut being made, the longitudinal plunger is readjusted so as to bring its dial gage to zero. When all of the dial gages were at

zero and the billet was turning at the right speed, the pressure gages and the wattmeter were read and their values recorded. Of course, it was impossible for one man to make four simultaneous readings. A certain amount of error, therefore, was unavoidable. The pressure gages remained fairly constant throughout a cut but the wattmeter fluctuated considerably, which made it very difficult to read and added to the probable error. It is for the above reasons that too much weight is not to be placed on the percentage errors between the mechanical and electrical measures of power consumption as shown in the charts in Appendix C.

As a rule, fourteen runs were made with each tool before resharpening. These cuts averaged a didtance of about 3/4" along the surface of the billet, and the approximate cutting time before resharpening was 15 minutes. With only two exceptions (on the 1/4" cuts) the tool was always in good cutting condition when it was removed from the holder for resharpening.

The actual depth of the cut was determined by measuring the diameter of the billet with a micrometer before and after the cut was made.

Photographs were taken with a microscope attachment of all the cuts in an attempt to get some measure of sur-

face conditions. Some of these pictures will be found in Appendix I.

D - Cutting at Elevated Temperatures.

The procedure of cutting at elevated billet temperatures was quite different from that above. The tool was held in the regular tool post, all power measurements being made with the wattmeter. A few runs were made with no heat applied to determine the amount of fritional heat developed by the rubbing of the thermocouple over the surface of the billet. These results are included in Appendix G. The actual cut was then started, and after it had progressed a short distance the heating torch was ignited and the temperature of the billet began to rise. Frequent reading of the wattmeter and the millivoltmeter were recorded. The cut continued until the cutting edge of the tool broke down. The billet was then allowed to cool and a second run was made.

DISCUSSION OF THEORIES AND RESULTS

A - Cutting at Room Temperature.

In the introduction it was stated that power consumption was probably a function of feed, depth, tool angle and speed, or an equation of the following sort

$$P = K F^{W} D^{X} A^{Y} S^{Z}$$

where F is feed in thousandths of an inch per revolution, D is depth in thousandths of an inch, A is the side rake angle in degrees and S is the surface speed in feet per minute. K is a constant whose dimensions are rather complicated, but since K is to be an index of machinability, its dimensions are unimportant. P is power consumption measured in horse-power.

It is assumed that K is a constant of the material being cut and is dependent only on the material. This, however, need not be true since a large number of variables that were listed in the introduction were suppressed in this investigation. That is, it is very possible that power may also be a function of back rake angle, cutting edge angles, nose radius, etc. We will not know this definitely, however, until future investigations have been made to determine the influence

of these other variables on machining.

For the time being, therefore, we will assume that K is a material constant and its value will be influenced only by the microstructure and physical and chemical properties of the material being cut. The proof of this assumption would be very helpful, for then it might be possible to predict K, or in other words machinability, by means of hardness, grain size, tensile strength, etc.

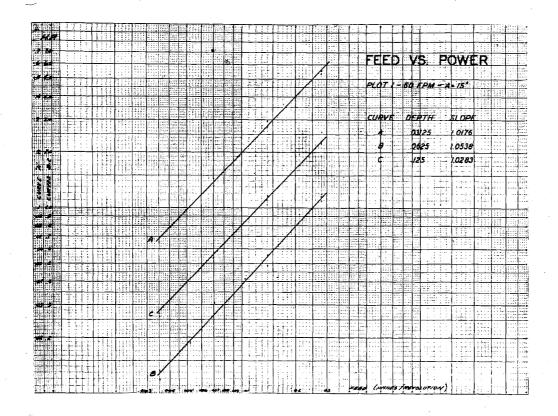

The values of the exponents w, x, y and z in equation (I) were determined by plotting one variable at a time versus power, for example

12) $\log P = [\log K + x \log D + y \log A + z \log S] + w \log F$ but the part of equation (2) in brackets may be combined to form a new variable Q and the equation then becomes

(3)
$$\log P = \log Q + w \log F$$
, or

$$(4) \qquad \log P - \log Q = w \log F$$

If we, therefore, plot feed versus power on log log paper, the average slope of the resulting set of curves will be the value of w. Plot I, below, is a typical Feed vs. Power graph. (See Appendix D for

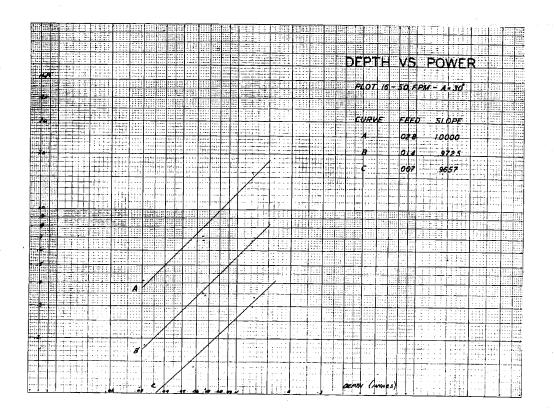

other Charts 1. The average value of the 24 curves of Feed vs. Power was 1.1048.

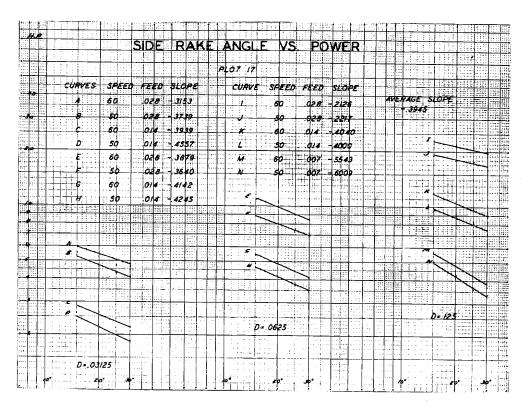

Plot 16 is typical of the curves obtained by plotting Depth vs. Power. The average slope in this case being 1.0000.

Plot 17 is the entire set of curves for Side Rake Angle vs. Power, the average slope being -.3945.

Substituting the above values of w, x and y into equation (1) we have

(5)
$$P = K F^{1.1048} D A^{-.3945} S^{z}$$

leaving z the only unknown exponent. Unfortunately, the runs, numbers I through 350, which contained the data for the surface speed variable were not consistent with the reruns, numbers 351 through 542. It seemed after the runs had been made that the first billet was not as homogeneous as the second. All data available, however, on the affect of speed of loading on the power to rupture metals seemed to indicate that the range of speeds here tested would have no affect on power consumption. It is, therefore, assumed that S appears in the equation to the first power, and the final equation is

(6)
$$P = K F^{1.1048} D A^{-.3945} S$$

In order to determine the value of K, the equation would be written

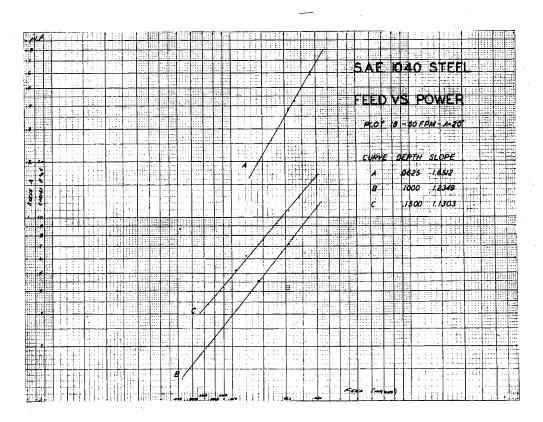

(7)
$$K = \frac{P \cdot A \cdot 3945}{D \cdot S \cdot F^{1.1048}}$$

The accompaning nomographic chart was set up for the rapid calculation of equations (6) and (7), and is the basis for the proposed standard test to determine machinability.

In order to check the validity of the assumption that equation (6) should hold for all similar metals (steels, for example) a series of runs were made on a

billet of S.A.E. 1040 steel (see Appendix G for properties). Plot 18, below, is the Feed vs. Power curve for the series of runs. In all cases the data from the light cuts seemed to be somewhat erratic, and for this reason, too much weight should not be placed on the slope of curve A in this plot. The slopes of curves B and C come close to the average value of the slope for feed as determined on the Vanadium "D" stock. The deviation of slope B from this average was only 11.8%, and the deviation of slope C only 2.36%.

It seems very likely, therefore, that the original assumption is correct and the equation is valid. Time

did not permit making more tests on other materials, but these, of course, should be made as further and more absolute proof of the equation.

The average value of K for the Vanadium "D" stock was $.237\times10^{-4}$, the largest deviation from this value being but 5.5%.

The value of K for the S.A.E. 1040 stock as determined from slope C Plot 18 was .153×10⁻⁴. This, I believe, is very close to the real value of K for this material as curve C is the closest of the three curves to the curves found for the Vanadium "D" stock. The average value of K as determined from curves B and C was .160×10⁻⁴, deviating only 4.57% from the value of K as determined from curve C alone. The average value of K as determined from curve C alone. The average value of K as determined from all three curves was .137×10⁻⁴, a deviation of 10.46% from what I believe to be the better value.

From these values of K it would seem that the Van-adium "D" stock was 55% harder to machine than the S.A.E. 1040 steel. This is on the basis of power consumption.

On the basis of the results of this thesis, the following standard test for determining machinability is proposed.

The tool to be used in the standard test for machinability shall be made of high speed steel of the 18-4-1 type of composition. It shall have the following dimensions; front cutting edge angle, 11°; side cutting edge angle, 30°; side and front clearance angles, 6°; back rake angle, 6°; side rake angle, 20°; and nose radius, 3/64°.

Nine cuts shall be made, three each at the following depths, 100, 125 and 150 thousandths of an inch, using all of the following values of feed during each cut, 7, 10.5, 14, 21 and 28 thousandths of an inch per revolution.

The data obtained from these cuts will then be plotted on log log paper, Feed vs. Power. The value of K for each of the three curves will be computed using the nomographic chart, and the average value of K obtained will be the index of machinability for that material. This index is based on the power consumption definition of machinability.

B - Cutting at Elevated Temperatures.

The investigation on the affect of billet temperature on machining was started after reading a paper by Hans Ernst of the Cincinatti Milling Machine Company on some experiments he had carried out on aluminum bars. He used dry ice and boiling water for controlling the billet temperature. He found a decided improvement in surface finish at temperatures of 60° below zero.

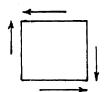

At first it was thought that by raising the temperature of the billet, the work-hardening effect of
machining would be greatly reduced and consequently a
lower power consumption would be observed. This theory
was quickly exploded as soon as the runs were made. Instead of noting a decrease in power as the temperature
of the billet increased, it was abserved that the power
also increased.

This increase in power is probably due to three things. First of all, the thermal expansion of the billet may affect the power consumption in two ways, an increase in the radius would cause a corresponding increase in the depth of cut, and the increase in the length of the billet would result in an increased pressure on the tail-stock center. The increase in power, however, due to the thermal expansion was practically negligable since the in-

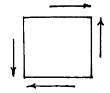

crease in radius was of the magnitude of a few thousandths of an inch. By using a ballbearing tail-stock center, the increase in frictional drag, due to the increased pressure on the center, was not of great importance.

A second factor which led to an increase in power was the setting up of high internal stresses by the uneven temperature distribution throughout the billet. This factor is probably of much greater importance than the first. Very rough calculations showed that with a surface temperature of 650 degrees fahrenheit there was a tangential compressive stress of 40,000 psi. (exact calculations were impossible with the data available.)

This stress would result in a negative shear stress of approximately 20,000 psi. Being a negative shear, it was in the opposite direction from the shear stress necessary to remove the metal.

Shear due to Temperature distribution.

Shear to Remove Metal.

This factor, undoubtably, caused a large increase in the power consumption. The cutting tool had to overcome this large internal shear stress before it could start cutting

the chip from the billet.

The third factor, and by far the most important of the three, lies in the physical properties of the metal itself. Although no tensile tests were made on the Vanadium "D" stock at elevated temperatures, sufficient data has been published to show that steels of similar composition show an increase in tensile strength up to a certain point and then a rapid falling off as the temperature is increased from room tempenature on up. The maximum tensile strength is observed between 650 and 700 degrees Fahrenheit.

Taking everything into consideration, the cutting at elevated temperatures was not a very satisfactory experiment. At the elevated temperatures, tool life was reduced to practically nothing and power consumption was materially increased. Just opposite of Ernst's results on aluminum, a noticably finer finish was observed when machining at the higher temperatures.

٧

SUMMARY OF RESULTS AND RECOMMENDATIONS

At the beginning of this thesis, an equation with four unknown exponents was set up. This equation was

$$P = K F^{W} D^{X} A^{Y} S^{Z}$$

By using conventional type high speed cutting tools and varying the side rake angle as well as the feed, depth and cutting speed, the exponents in the above equation were determined.

w = 1.1048

x = 1.0000

y = -.3945

z = 1.0000

The equation for power consumption then becomes

$$P = K F^{1.1048} D A^{-.3945} S$$

where feed and depth are in thousandths of an inch, A is the side rake angle in degrees, S is the surface speed in feet per minute and P is the power consuption in HP.

The value of K is assumed to be an index of machinability, with machinability, in this case, defined by power consumption. The value of K for the Vanadium "D" stock was $.237 \times 10^{-4}$, and for the S.A.E. $1040 \cdot .153 \times 10^{-4}$.

A proposed standard test for determining machinability was set up as follows:

The tool to be used in the standard test for machinability shall be made of high speed steel of the 18-4-1 type of composition. It shall have the following dimensions; front cutting edge angle, 11°; side cutting edge angle, 30°; side and front clearance angles, 6°; back rake angle, 6°; side rake angle, 20°; and nose radius, 3/64°.

Nine cuts shall be made, three each at the following depths, 100, 125 abd 150 thousandths of an inch, using all of the following values of feed during each cut, 7, 10.5, 14, 21 and 28 thousandths of an inch per revolution.

The data obtained from these cuts will then be plotted on log log paper, feed vs. Power. The value of K for each of the three curves will be computed using the nomographic chart, and the average value of K obtained will be the index of machinability for that material. This index is based on the power consumption definition of machinability.

A few of the pictures of the billet surface are included in Appendix I. It was almost impossible to tell, either with the naked eye or from the pictures, any difference in the surface finish obtained when the surface speed, depth of cut and side rake angle were changed. Increasing the feed, of course, increased the roughness of the finish. In general, the finish obtained under all conditions was very good.

The results of machining at elevated billet temperatures showed that power consumption rose as the temperature of the billet was increased. Tool life was reduced to but a few minutes of cutting, but surface finish
was greatly improved at the higher temperatures.

R ECOMMENDATIONS

(1) It is recommended that for undergraduate research, further work should be carried out to check the valid—ity of the Power equation and the accuracy of the Stand—ard Test. The check on the equation should be made, if possible, using Vanadium "D" stock, otherwise S.A.E. 1040 stock. After the equation has been checked and a suit—able technique established, the Standard Test should be applied to as many samples of steel that can be obtained.

- For graduate research, it is suggested that some of the other possible variables be investigated to see what Influence they have on power and the constant K. Some of these variables might be side cutting edge angle, back rake angle and the use of cutting fluids. It may be found that the equation proposed in this thesis is too simple and that some more terms must be added to make the equation more general. When the present equation or a more general equation has been established and the contant K has been proven to be dependent only on the material itself for its value, it is suggested that an investigation be made to determine the influence of the microstructure and the physical and chemical properties of the material on K. It is very possible that the value of K could be predicted knowing the chemical analysis. hardness, tensile strength and grain size of a certain piece of steel.
- (3) It is further suggested for graduate research, that an attempt be made to find a relationship between the established equation for power consumption and an equation for tool life similar to that of Woxen. It is very possible, however, that no direct relationship exists, and in that case, we would have two different constant terms, each one being an index to machinability, but based on different definitions.

#### HEAT TREATMENT OF TOOLS

TOOL MATERIAL, Rex AA Steel - 18 Tungsten
4 Chromium
1 Vanadium

#### TREATMENT FOR TOOL:

Preheat - 1550°F, for about 20 minutes per inch
of thickness of the tool. Furnace
atmosphere is not particularly important, although it is desirable
to have a slightly reducing atmosphere, if possible.

Hardening Temperature - 2400°F for a time long enough to bring the tool to furnace atmosphere plus a soaking time of one minute.

Atmosphere of Furnace for Hardening Operation - 8-12% CO. It should never, at any time, be oxidizing, as an oxidizing atmosphere apparently sets up an exothermic reaction which gives a tool temperature, at least on the surface, higher than the furnace temperature.

Quenching Medium - Any good quenching oil. Quench then withdraw after bringing it to a black heat, then requench, to avoid brittleness.

Tempering - 120-240 minutes at a temperature of 1075 F. Keep atmosphere slightly reducing to prevent oxidation, but the exact composition is not particularly important. Air cool, being careful not to cool too rapidly, as by cooling on an iron plate, or in water.

Musschoot and Stewart.

## PROPERTIES OF S.A.E. 1040 STEEL

# APPENDIX H

Calculations

#### POWER CALCULATIONS

HP (consumed) =  $\frac{\text{Tangential Force X Surface Speed}}{33,000}$ 

Tangential Force = Lever Ratio X Gage Constant
X Gage Reading

Assuming that the Force acts at one-half the depth of the cut

Lever Ratio = 
$$7.5/1.5 - \frac{D}{2} = 15/3 - D$$

Gage Constant (Diaphram #3) = 7.10

Therefore,

Tangential Force =  $15/3-D \times 7.1 \times G$ 

and,

$$HP = \frac{15/3 - D \times 7.1 \times G \times S}{33,000}$$
