Supporting Information

ABSTRACT: Transition-metal dichalcogenides (TMDs) have emerged in recent years as a special group of two-dimensional materials and have attracted tremendous attention. Among these TMD materials, molybdenum disulfide (MoS₂) has shown promising applications in electronics, photonics, energy, and electrochemistry. In particular, the defects in MoS₂ play an essential role in altering the electronic, magnetic, optical, and catalytic properties of MoS₂, presenting a useful way to engineer the performance of MoS₂. The mechanisms by which lattice defects affect the MoS₂ properties are unsettled. In this work, we reveal systematically how lattice defects and substrate interface affect MoS₂ electronic structure. We fabricated single-layer MoS₂ by chemical vapor deposition and then transferred onto Au, single-layer graphene, hexagonal boron nitride, and CeO₂ as substrates and created defects in MoS₂ by ion irradiation. We assessed how these defects and substrates affect the electronic structure of MoS₂ by performing X-ray photoelectron spectroscopy, Raman and photoluminescence spectroscopies, and scanning tunneling microscopy/spectroscopy measurements. Molecular dynamics and first-principles based simulations allowed us to conclude the predominant lattice defects upon ion irradiation and associate those with the experimentally obtained electronic structure. We found that the substrates can tune the electronic energy levels in MoS₂ due to charge transfer at the interface. Furthermore, the reduction state of CeO₂ as an oxide substrate affects the interface charge transfer with MoS₂. The irradiated MoS₂ had a faster hydrogen evolution kinetics compared to the as-prepared MoS₂, demonstrating the concept of defect controlled reactivity in this phase. Our findings provide effective probes for energy band and defects in MoS₂ and show the importance of defect engineering in tuning the functionalities of MoS₂ and other TMDs in electronics, optoelectronics, and electrochemistry.

KEYWORDS: transition-metal dichalcogenides, hydrogen evolution reaction, ion irradiation, X-ray photoelectron spectroscopy, Raman spectroscopy, scanning tunneling microscopy

Molybdenum disulfide (MoS₂), a layered material in the family of transition-metal dichalcogenides (TMDs), has attracted tremendous attention in recent years due to its extraordinary performance in electronic transistors,^{1,2} flexible and transparent displays,^{3–5} optoelectronic devices,^{2,4–7} sensors, and energy applications.^{4,8} As a material with an extra-large surface-to-bulk ratio, single-layer (SL) MoS₂ is highly conducive to forming defects.⁹ The defects

in MoS₂ play an essential role in tuning the properties of SL MoS₂ in various ways and so affect the performance of devices based on MoS₂. They can, for example, enhance the electrochemical activity^{10,11} and tune the electronic,¹² mag-

netic,¹³ and optical¹⁴ properties of MoS₂. For example, in electrochemical applications, recent experiments and theories^{10,11,15} show that S-vacancies in the basal plane of MoS₂ can activate the catalytic reactivity of MoS₂. By introducing S-vacancies and suitable strains in SL MoS₂, Li *et al.*¹¹ achieved the highest activity so far for the hydrogen evolution reaction (HER). In terms of electronic properties, on the other hand, defects such as vacancies, dislocations, and grain boundaries reduce the electronic mobility in MoS₂ prepared using chemical vapor deposition (CVD), by several magnitudes compared to MoS₂ exfoliated from single-crystal bulk.¹² Regarding optical properties, Tongay *et al.*¹⁴ experimentally demonstrated that S-vacancies induce new photoluminescence (PL) peaks and enhance the PL intensities. In magnetism, Han *et al.*¹³ reported

ferromagnetic effects resulting from anion and cation vacancies and vacancy clusters in MoS₂.

Although the role of MoS₂ defects in altering the properties has been widely recognized, there are still open questions at a deeper and mechanistic level for connecting the presence and type of defects to electronic, optical, and catalytic characteristics. For example, only S-vacancies were considered in activating the MoS₂ basal plane to enable the HER, while other types of defects, such as Mo-vacancies, have not been studied in detail.^{10,11} Moreover, CVD MoS₂ shows n-type electronic conductivity.¹⁶ Qiu *et al.*¹⁷ and Ugeda *et al.*¹⁸ believed that this phenomenon is caused by the S-vacancies and by the resulting defect donor states in MoS₂. However, Komsa *et al.*¹⁹ found that through first-principles calculations, the S-vacancies form acceptor states rather than donor states in the

MoS₂ energy bands. Therefore, the n-type conductivity in CVD MoS₂ remains elusive despite the fact that S-vacancies are the most common defects in MoS₂ prepared by the CVD process. Recently, Yu *et al.*²⁰ proposed that the donor states in polycrystalline MoS₂ stem from defect complexes made of a dislocation and two S-vacancies.

To understand the role of defects in MoS₂ functionality, in this work, we systematically assessed the impact of defects on the electronic structure of SL MoS₂ model system on several different substrates. The SL MoS₂ used in our study was prepared through CVD synthesis.²¹ The substrate layers used beneath the MoS₂ layer were Au, SL boron nitride (BN)/Au, SL graphene (SLG)/Au, and CeO₂/Au. Methods commonly used to create defects in MoS₂ in literature included vacuum thermal annealing,^{14,17,22} electron irradiation,^{9,12} plasma treatment,¹⁰ Se insertion,²³ and ion irradiation.^{14,24–30} In this work, we introduce lattice defects in SL MoS₂ by both thermal annealing in vacuum and by Ar⁺ ion irradiation. While both approaches to create defects in MoS₂ have been used in previous literature as noted above, here we reveal the electronic structure induced by lattice defects formed in those ways. This information helps to interpret the mechanisms by which the defects alter the properties of MoS₂. The presence of defects in MoS₂ was confirmed by X-ray photoelectron spectroscopy (XPS) as well as Raman and PL spectroscopies. Both XPS and scanning tunneling microscopy/spectroscopy (STM/STS) showed that the defects in the MoS₂ can change the electronic energy levels in MoS₂ and introduce defect states in the bandgap. Raman and PL spectroscopies can be sensitive and convenient tools to probe the defects in MoS₂. The presence of defect states within the bandgap was observed using STS, which is likely to be associated with S-vacancies and Mo-vacancies, and matches well with our molecular dynamics (MD) and density functional theory (DFT) simulations. In addition, the reduction in the oxide substrate (CeO₂) was also found to change the band alignment between MoS₂ and the substrate. This finding demonstrates that MoS₂ electronic structure is tunable by controlling the defect and charge-transfer states of the underlying red-ox active oxide substrate. We also demonstrated that the introduction of defects by ion irradiation can effectively enhance the HER activity. As a result, our work provides a detailed electronic structure description of defected MoS₂ on various substrates and demonstrates that introducing defects can be effective in improving the functionality of 2D materials.

RESULTS AND DISCUSSION

Single-layer MoS₂ forms a hexagonal lattice structure from the top view and has three sublayers of atoms, one layer of Mo atoms sandwiched between two layers of S atoms (Figure 1a).^{4,5} Figure 1a also shows the structures studied in this work and the processes of thermal annealing and ion sputtering. First, we look at the impact of thermal annealing on the electronic structure of SL MoS₂ on various substrates. XPS measurements were performed on the MoS₂ samples on different substrates after transfer and after annealing at 300 °C and 450 °C under 10^{−10} mbar base pressure. Figure S1f shows a representative XPS survey spectrum of SL MoS₂ on Au/quartz substrate. The optical microscope images of all the samples, as well as the atomic structure of MoS₂, are shown in Figure S1. Peaks of all the elements can be easily observed and are labeled, including Mo 3p, Au 4d, C 1s, Mo 3d, S 2p, and Au 4f. We mainly study the Mo 3d_{5/2} peak position relative to the Au 4f_{7/2}

peak. A change in this relative position is indicative to charge transfer between MoS₂ and Au (Figure 1b). We define ΔE as the binding energy difference between the Au 4f_{7/2} and Mo 3d_{5/2} photoemission peaks (labeled in Figure 1b,c). We use changes in ΔE as a measure of the energy level shifts in MoS₂.

For MoS₂ transferred on to different substrates, the Au 4f_{7/2} has almost no variation in binding energy (Figure 1b,c). In contrast, Mo 3d_{5/2} has different binding energies depending on the substrate, as seen in Figure 1c. The Mo 3d_{5/2} peak is at 229.74 eV for MoS₂/Au after transfer (prior to annealing), but shifted to higher binding energies by 0.06, 0.08, and 0.13 eV for MoS₂/SLG/Au, MoS₂/BN/Au, and MoS₂/CeO₂/Au, respectively, as shown with black squares in Figure 1c. The different binding energy of Mo 3d_{5/2} electrons is attributed to the different band alignments between MoS₂ and the substrates. The mechanism of this phenomenon is illustrated in Figure 1d. The basic assumption is that when MoS₂ in contact with the substrate, there will be a potential energy change that lifts up or shifts down the MoS₂ energy level (Figure 1(d)), as demonstrated in refs 34 and 37. Au has an electron affinity of 5.1 eV, larger than MoS₂ (4.7 eV).^{31–33} Since Au substrate is a metal and has an abundance of electrons, the Fermi level of the semiconducting MoS₂ needs to be aligned with the Fermi level of Au. When MoS₂ is directly in contact with Au, electrons transfer from MoS₂ to Au substrate, leading to a downshift of MoS₂ Fermi level position within the bandgap. It is important to recall that an interface charge or interface dipole can be formed between MoS₂ and Au which is due to the interaction of MoS₂ and Au and the creation interfacial state.³⁴ Such interface charge can cause a small potential drop across the MoS₂ and Au interface, as shown in Figure 1d. When there is a layer of graphene inserted between MoS₂ and Au, electrons from both the MoS₂ layer and graphene will transfer to Au. Interface dipoles were reported to exist in MoS₂/graphene³⁵ and graphene/Au interfaces,³⁶ which lead to a larger potential in MoS₂/SLG/Au compared to MoS₂/Au, as shown in Figure 1d. Accompanied with the creation of a larger potential drop across the interface by inserting SLG (Figure 1d), the binding energy of Mo 3d_{5/2} electrons in MoS₂ increases, resulting in a larger ΔE in MoS₂/SLG/Au compared to MoS₂/Au. Due to the insulating nature of hBN and CeO₂ layers, charge can be accumulated on both sides of the BN and CeO₂ interface, thus contributing to a large potential drop across the middle layer, leading to a down shift of MoS₂ energy level and the alignment of Fermi levels of MoS₂ and Au (Figure 1d). As a result of this down shift of energy level, the Mo 3d_{5/2} binding energy at the MoS₂ surface is further increased by adding a BN and CeO₂ layer. These results indicate that SLG, BN, and CeO₂ can be effective media to partially screen interface charge transfer directly from MoS₂ to Au, which is ubiquitous at the interface of MoS₂ and many metals.³⁴ Therefore, these substrates can facilitate the applications of electronic devices based on MoS₂. It is important to note that the energy shifts of the valence band, conduction band, and core level due to the interface potential drop are not necessarily the same quantitatively. The actual quantitative changes in each energy level depend on the details of how the band structure evolve upon charge transfer at the interface.^{34,37} Our explanation is qualitative and only shows the trend of how the energy level changes for different samples.

Annealing at 300 °C in vacuum increases the variation of ΔE (Figure 1b,c) among the different substrates. As can be seen by data (blue squares) in Figure 1c, upon annealing at 300 °C and compared to the as-transferred states, Mo 3d_{5/2} shifts to even

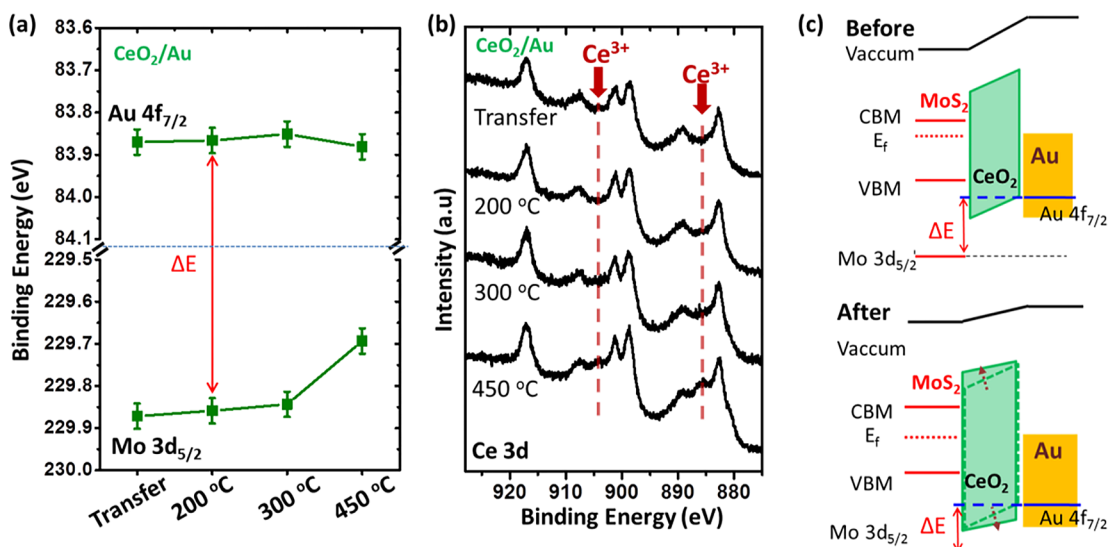

Figure 2. Shift of the Mo 3d_{5/2} binding energy and Ce⁴⁺ reduction to Ce³⁺ during annealing. (a) The binding energies of the Mo 3d_{5/2} and Au 4f_{7/2} electrons for the MoS₂/CeO₂/Au sample after transfer and after annealing at 200 °C, 300 °C, and 450 °C. (b) The Ce 3d X-ray photoelectron spectra of MoS₂/CeO₂/Au samples after each annealing step. The dashed red lines indicate the appearance of Ce³⁺ peaks after 450 °C annealing. (c) Illustration of energy band alignment for the MoS₂/CeO₂/Au sample. The upper graph shows the bands before the Ce⁴⁺ reduction, and the lower one shows the bands after the Ce⁴⁺ reduction.

lower binding energies on MoS₂/Au and MoS₂/SLG/Au, while the Mo 3d_{5/2} remains almost unchanged on MoS₂/BN/Au and MoS₂/CeO₂/Au. The binding energy of Au 4f_{7/2} remains the same after thermal annealing. The removal of water or gas residues between MoS₂ and the substrates and a better contact between MoS₂ and the substrates³⁸ after annealing at 300 °C are a likely reason for these changes. Hence the charge-transfer process between MoS₂ and Au or between MoS₂ and SLG/Au was enhanced by thermal annealing, resulting in a smaller potential drop across the interface and a smaller ΔE values.

Next, we show further evidence to the charge transfer between MoS₂ and different substrates based on the Raman and PL spectra measured after annealing at 300 °C. Figure S2a shows the Raman modes of all the samples, including the E' (around 385 cm⁻¹) and A₁' (around 405 cm⁻¹) modes. All spectra are normalized by the intensity of the A₁' mode. Note that the notations E' and A₁' are for SL MoS₂ with D_{3h} symmetry, and they become E_{2g} and A_{1g}, respectively, for bulk MoS₂ that has D_{6h} symmetry.³⁹ Clearly, the A₁' peak is redshifted after transfer, and all substrates induce peak widening compared to the as-grown sample. Since A₁' is sensitive to doping,⁴⁰ it is reasonable to infer that the substrates introduce p-type doping to MoS₂, which is also consistent with our XPS results and with the literature.⁴¹ The E' peaks also widen and redshift after transfer, which indicates the strain introduced during the transfer process.^{7,42} The corresponding PL spectra shown in Figure S2b, which are also normalized by the A₁' peaks, suggest the presence of strain and doping effects in MoS₂ as well. As can be seen, the as-grown sample shows a strong and narrow PL peak at around 1.85 eV. The suppression of the PL peaks of MoS₂ on Au and SLG/Au substrates is due to the metallic nature of the substrates and the subsequent charge transfer that occurs between MoS₂ and the substrate and the PL quenching effect. We can still observe a very weak PL peak for MoS₂/SLG/Au, which suggests the charge-transfer effect in MoS₂/SLG/Au is not as strong as in MoS₂/Au. This is in line with our XPS results in Figure 1b,c that the binding energy of Mo 3d_{5/2} is slightly higher for MoS₂/SLG/Au than for MoS₂/

Au. The PL peaks for MoS₂/BN/Au and MoS₂/CeO₂/Au are still strong, indicating the insulating nature of these two substrates, again consistent with the findings from XPS in Figure 1b,c. However, the PL peaks are widened compared to as-synthesized MoS₂, which is likely due to the transfer process.

The effect of annealing to a higher temperature, 450 °C is also shown in Figure 1b,c. For MoS₂ on Au, SLG/Au, and BN/Au, the Mo 3d_{5/2} binding energy does not show much difference between 300 °C and 450 °C. However, the CeO₂/Au substrate induces a considerable decrease of ΔE by about 0.18 eV after annealing at 450 °C. Figure 2a also confirms that Au 4f_{7/2} binding energy is not affected either by the thermal annealing or by the reduction of CeO₂. In fact, as observed in Figure 2a, the binding energy of Mo 3d_{5/2} remains at about 229.85 eV for an as-prepared sample as well as after annealing at 200 and 300 °C. After annealing at 450 °C, however, the binding energy of Mo 3d decreases to about 229.7 eV. It is important to recall here that CeO₂ is a red-ox active material and loses oxygen upon annealing in reducing conditions,^{43–47} that is, annealing in ultrahigh vacuum (UHV) as in this experiment. A 450 °C is high enough temperature to enable oxygen mobility and therefore enables reduction of CeO₂ to a reduced, oxygen-deficient state. It is clear in the X-ray photoelectron spectra of Ce 3d electrons in Figure 2b that the Ce³⁺ peaks at binding energies of 886 and 904 eV are enhanced after 450 °C, confirming that Ce⁴⁺ is partially reduced to Ce³⁺. Reduced CeO_{2-x} is a mixed ionic electronic conductor, and electronic conduction occurs through hopping of localized Ce 4f electrons from Ce³⁺ to Ce³⁺ sites.^{48,49} Because of electronic conductivity of reduced CeO_{2-x}, a smaller potential drop takes place in the CeO₂ layer of the MoS₂/CeO₂/Au structure compared to its fully oxidized state and therefore a smaller shift of energy level in MoS₂. Consequently, a smaller binding energy of Mo 3d_{5/2} and a smaller ΔE prevail, as shown in Figure 2c.

Thermal annealing itself did not introduce any noticeable defects into MoS₂. Upon annealing in UHV to 450 °C, our XPS results showed that the Mo 3d peak shapes did not change

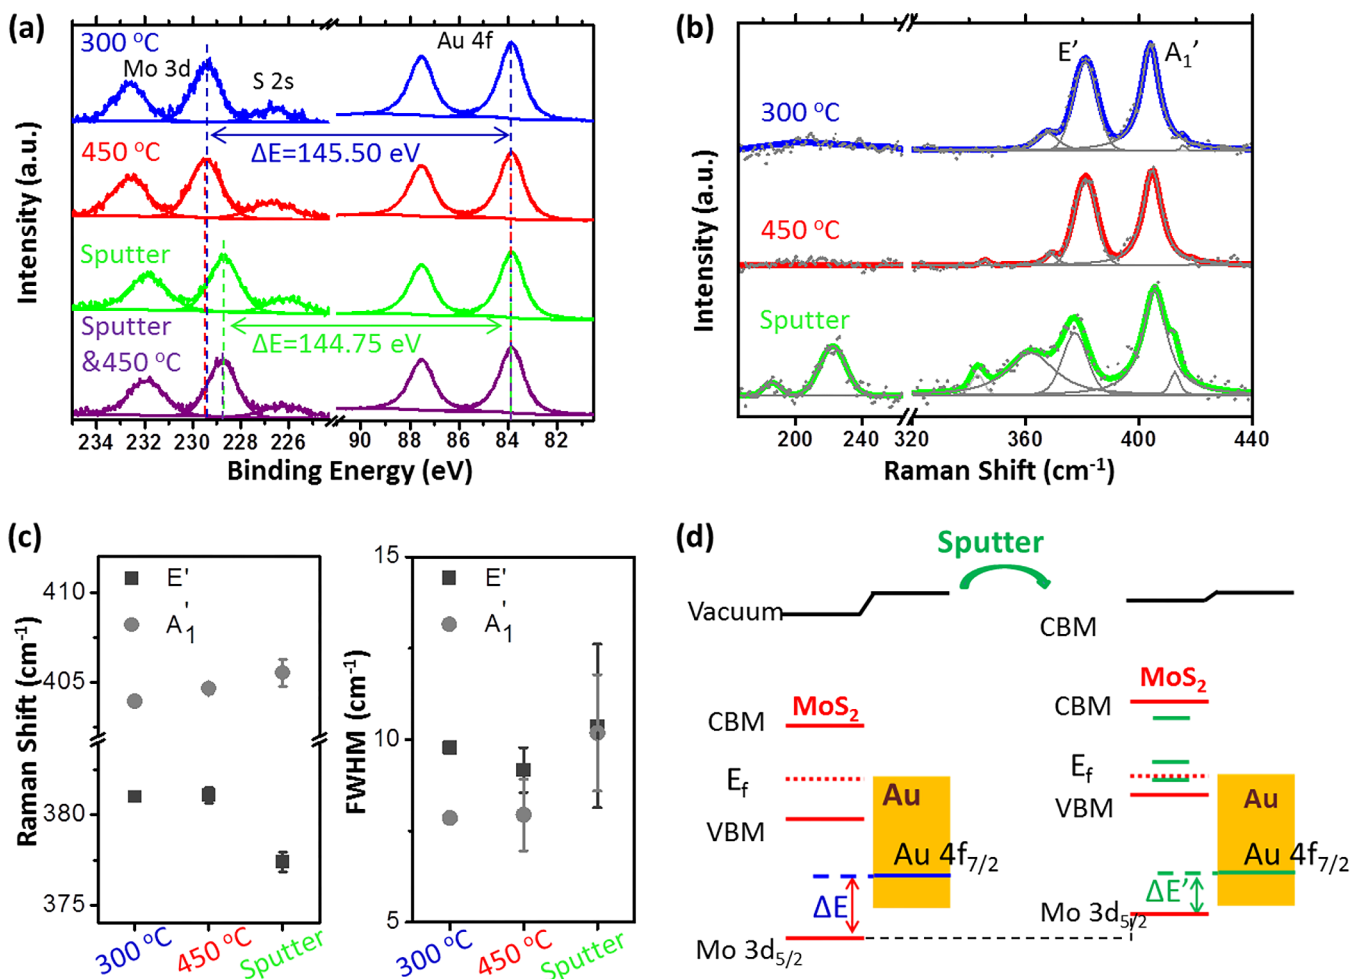

Figure 3. XPS and Raman characterization of samples before and after introducing defects by Ar⁺ sputtering for MoS₂ on Au substrate. (a) X-ray photoelectron spectra of the Mo 3d, S 2s, and Au 4f electrons in the MoS₂/Au sample after annealing at 300 °C and 450 °C in UHV, sputtering, and sputtering with subsequent annealing at 450 °C. ΔE for the upper two and the lower two plots are shown. (b) Raman spectra of the MoS₂/Au sample after annealing at 300 °C and 450 °C in UHV and after sputtering. The MoS₂ Raman peaks E' and A₁' are labeled. All spectra are normalized by the corresponding A₁' peaks. The measured data are shown as dots. Fitted individual peaks and overall spectra are shown as gray and colored curves, respectively. (c) Raman shift and fwhm of E' and A₁' peaks for the MoS₂/Au sample after annealing at 300 °C and 450 °C and after sputtering. (d) Illustration of energy band alignment for the MoS₂/Au sample. The left graph shows the bands before sputtering, and the right one shows the bands after sputtering.

(Figure 3a). The intensity ratio of the Mo and S photoemission peaks did not change after annealing at 450 °C (Figure S3b). These mean that MoS₂ remained stable and without detectable formation of defects upon annealing alone. This is consistent with Raman results presented later in the paper (Figure 3b,c). However, thermal annealing changed the coupling between MoS₂ and the substrate by improving the contact between MoS₂ and the substrate³⁸ in MoS₂/Au, MoS₂/SLG/Au, and MoS₂/BN/Au or by introducing defects into the reducible substrate CeO₂ in MoS₂/CeO₂/Au. Both effects significantly change the band alignment between MoS₂ and the substrate and can have a significant impact on the device performance, since many electronic and optoelectronic devices depend on the energy levels and band alignment of MoS₂.³⁸

As stated in the Introduction, ion irradiation is another way to create defects and defect-induced electronic states in 2D materials. Heavy ion irradiation is shown to introduce extended defects such as incisions and folds in 2D materials including MoS₂.⁵⁰ Here we focus on lattice defects that can be created by low-energy ion irradiation. We introduced lattice defects into SL MoS₂ by low-energy Ar⁺ sputtering and studied the change

of photoemission binding energy, peak shape, and optical properties for MoS₂ on Au substrates. As shown in Figure 3a, the defects introduced by ion irradiation did significantly alter the band alignment between MoS₂ and Au. The Mo 3d_{5/2} binding energy decreased by 0.8 eV, and the Au 4f_{7/2} peak remained unchanged after sputtering with 0.5 keV Ar⁺ ion beam for 1 min. In contrast to this significant energy shift upon sputtering, no change in ΔE was detectable between annealing at 300 °C and 450 °C. Re-annealing the sputtered samples at 450 °C does not change the band alignment further.

To provide more quantitative information about the defects in MoS₂ after sputtering, we performed Raman and PL spectra measurements on the MoS₂/Au samples before and after sputtering. Figure 3b shows the Raman spectra of MoS₂/Au after 300 °C and 450 °C annealing and sputtering. The E' and A₁' modes of MoS₂ are easily observed, and all spectra are normalized by A₁' modes. As can be seen, Raman spectra do not show considerable differences for 300 °C and 450 °C annealing, but after sputtering, E'/A₁' modes are red/blue-shifted, and both are widened (Figure 3c). There is a shoulder (at around 362 cm⁻¹) on the left of E' mode and one (at

around 415 cm^{-1}) to the right of A_1' mode, which are assigned as defect modes,²⁸ but without a clear identification of the defect type. Both peaks are significantly enhanced after sputtering, another feature confirming the introduction of defects with sputtering. At about 220 cm^{-1} , there is an LA mode which also indicates the existence of defects for MoS_2 , and this mode becomes considerable after sputtering.²⁸ The corresponding PL peaks (Figure S3c) show that after sputtering, PL peaks totally disappear. PL in MoS_2 is generated due to the radiative decay of excitons which binds electrons and holes near the edges of conduction and valence bands.^{5,51} The reduction of the PL peak intensities indicates that the electronic structure changed due to a large defect density, and the population of the defect states increases the nonradiative decay channel of excitons.

The evolution of Raman peaks with thermal annealing and sputtering is summarized in Figure 4c. There is an obvious red

Figure 4. STM image and dI/dV on MoS_2 with and without defects on HOPG substrate. (a) STM constant current image of MoS_2 on HOPG, and the Moiré pattern between MoS_2 and HOPG hexagonal lattices can be observed. Imaging conditions: $I_{\text{tun}} = 50\text{ pA}$, $V_{\text{sample}} = -1.5\text{ V}$. (b) Zoom-in on the MoS_2 zone in the STM image in (a). (c) dI/dV spectrum on the MoS_2 on HOPG prior to ion irradiation. A lock-in preamplifier was used with 30 mV at 1 kHz frequency. The Dirac cone of graphite and the MoS_2 band gap can be observed. The four dI/dV curves were measured at different locations on the sample. (d) dI/dV spectrum of MoS_2 on HOPG after being ion irradiated with 500 eV Ar^+ . Three clear defect states can be observed. The curves were measured at different locations on the sample.

shift in E' peak and blue shift in A_1' peak after sputtering. Both peaks are widened as well, and the variation for the peaks also increases after sputtering. As reported before,²⁸ defects in MoS_2 can cause the frequency shifts and widenings in E' and A_1' peaks observed here. From the Raman signatures, we can also deduce interdefect distances to be $1.60 \pm 0.03\text{ nm}$ (defect density $7.46 \pm 0.42 \times 10^{12}\text{ cm}^{-2}$) after sputtering.²⁸ Thus, our Raman measurement manifests itself as a sensitive and nondestructive approach to probe the defects in MoS_2 , which is in good agreement with the XPS measurements. The introduction of defect states in MoS_2 is illustrated with green levels within the gap in Figure 3d. The reason for the change of band alignment between MoS_2 and Au as observed in XPS measurement (Figure 3a) is likely due to the creation of defect

states within the band gap of MoS_2 , which greatly facilitates the charge-transfer process between MoS_2 and Au. Hence, a decrease of interface potential drop and a smaller ΔE (Figure 3d) were observed. More detailed information on defect-related states in the gap will be discussed in STM/STS Measurements section later.

Besides MoS_2/Au , we also observed similar Raman and PL changes on other samples after sputtering. For example, Figure S4 shows the Raman and PL spectra of $\text{MoS}_2/\text{BN}/\text{Au}$ sample after $300\text{ }^\circ\text{C}$ and $450\text{ }^\circ\text{C}$ annealing and after sputtering. Similar defect-related Raman modes (the 362 cm^{-1} mode and the LA mode at 220 cm^{-1}) appear after sputtering, E' and A_1' peaks widen after sputtering, and they red and blue shift, respectively, all indicating the introduction of defects (Figure S4c,d). The PL peak for $\text{MoS}_2/\text{BN}/\text{Au}$ disappears after sputtering, indicating the introduction of in-gap defect states and the change of energy band structure (Figure S4b).

As shown above, the XPS and Raman spectroscopy indicate formation of defect states within the bandgap of MoS_2 , leading to a stronger charge transfer between MoS_2 and Au substrate. To provide more direct information on the electronic structure of ion irradiated MoS_2 , we performed scanning tunneling microscopy (STM) and tunneling spectroscopy (dI/dV spectroscopy) on SL MoS_2 in its as-transferred state and after introducing defects by Ar^+ sputtering. We transferred pristine MoS_2 onto highly oriented pyrolytic graphite (HOPG) substrates using a water-assisted method, leaving a clean and residue-free surface of MoS_2 . The boundary between HOPG substrate and SL MoS_2 can be seen clearly in Figure 4a, with the Moiré pattern of MoS_2 and HOPG lattices in MoS_2/HOPG region shown in Figure 4b. The presence of the Moiré pattern indicates a coherent interface between MoS_2 and HOPG substrate. The dI/dV spectra, representing the density of states (DOS), on MoS_2 on HOPG prior to irradiation is in Figure 4c. The dI/dV shows both the Dirac cone of graphite and the edges of the conduction band and valence band of MoS_2 . The HOPG substrate contributes to the dI/dV spectra, and hence it was difficult to precisely quantify the MoS_2 bandgap. Based on the slope change in the spectra, we approximate the bandgap to be 1.9 eV , a slightly smaller value than other works reported for pristine monolayer MoS_2 .^{52–55} The MoS_2 layers were sputtered with 500 eV Ar^+ ions for 1 min in the STM chamber, the same procedure as the other samples presented in Figure 3. Sputtering led to poor image resolution, and therefore it was not possible to obtain tunneling spectra precisely on individual atomic defects. We collected spectra on various locations to obtain a general result on the defected surface. The dI/dV spectra shown in Figure 4d are representative spectra that show defect states after ion irradiation. Three new peaks in the bandgap located approximately 0.3 eV (#1), 1.2 eV (#2), and 1.6 eV (#3) below the conduction band minimum can be observed (Figure 4d). Previous work has reported the STS of bulk MoS_2 which shows in-gap defect states as well.⁵⁶ Since the defect density in our sample is large, as quantified from Raman to be close to 10^{12} cm^{-2} , we may see defect states from several defect types and configurations in the dI/dV spectra. These results qualitatively indicate the existence of different types of defects located at different energy positions. This is a reasonable outcome given the nature of ion irradiation induced defects. As will be shown by theoretical calculations later, the peaks closer to valence band (#2, #3) are likely related to the Mo-vacancies, and the one closer to the conduction band (#1) may arise from single or double S-vacancies.¹¹ Calculations of

defect states arising from different type of defects as described below support this interpretation. The variation of dI/dV taken at different locations at the surface is also shown in Figure S5.

To identify the likely type of defects upon irradiation of MoS₂ and to associate those defects with the electronic states shown in Figure 4d, MD simulations and first-principles calculations, respectively, were carried out. In MD simulations, Ar⁺ ion with incident energy of 500 eV was initially placed at 20 Å above the freestanding SL MoS₂ sheet, and the incident direction is perpendicular to the MoS₂ sheet (Figure 5a). The

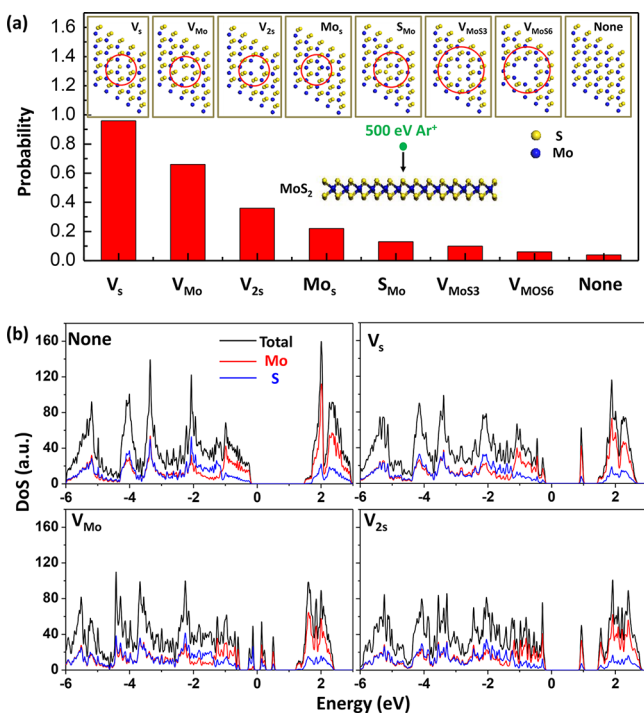

Figure 5. Possible defect structures that can be introduced by sputtering and the local electronic structure changes caused by these defects. (a) The probability density for different defect structures to form after 500 eV Ar⁺ sputtering, as found from MD simulations. (b) The total DOS and the contributions from the Mo and S states in MoS₂ with no defects and with three types of defects, V_s , V_{2s} , and V_{Mo} .

most likely defect configurations upon ion irradiation in MoS₂ were found as single S-vacancy (V_s), single Mo-vacancy (V_{Mo}), double S-vacancy (V_{2s}), S replaced by Mo (Mo_s), Mo replaced by S (S_{Mo}), Mo and three S-vacancy (V_{Mo3s}), and Mo and six S vacancy (V_{Mo6s}) (Figure 5a). Figure 5b presents the DOS as a function of energy for SL MoS₂ without defects, and the DOS with V_s , V_{Mo} , V_{2s} (the three most probable defects) as determined by DFT calculations. From Figure 5b, S-vacancies introduce defect states within the energy gap close to the bottom of the conduction band, while the less probable Mo-vacancy is more likely to introduce defect states closer to the top of the valence band.¹² This result is consistent with previous reports.^{12,57,58} Using STEM, Zhou *et al.* observed single-vacancy, double S-vacancy, and vacancy complex of Mo as intrinsic defects in SL MoS₂. They reported that S-vacancies caused defects state within the band gap that is closer to conduction band, while the vacancy complex of Mo lead to states that are closer to valence band.¹² Tongay⁵³ reported S vacancy formation in SL MoS₂ after He⁺ irradiation, which introduced defect states near the conduction band. Comparing

the electronic structure of defected MoS₂ probed by dI/dV (Figure 4d) with the DFT results, we infer that the S-vacancies (both single and double S-vacancies) and single Mo-vacancies dominate the changes in the electronic structure resulting from Ar⁺ sputtering observed in both XPS and dI/dV .

It is worth noting that we cannot rule out the contribution from other defect configurations, such as Mo_s , S_{Mo} . However, their presence is expected to be less than the three major defects examined in Figure 5b. The electronic structures of SL MoS₂ with these defect configurations are shown in Figure S6. Some of these defects states have signatures in DOS as V_s , V_{2s} , and V_{Mo} . As can be seen from Figure 5 and Figure S6, the main defects we observed in MD simulation are vacancies for the irradiation conditions we used. Interstitials are barely observed. This is because interstitials are very unstable. Due to the small migration energy of interstitials, they tend to migrate to other sites and form stable and regular defect forms. Figure S7 shows a representative relaxation process of S interstitial formed by Ar⁺ sputtering. The formation of vacancies is mainly balanced by sputtered ions. As shown in Figure S7c, the number of sputtered atoms as a function of Ar⁺ sputtering energy reached a peak at 500–600 eV. In previous works, thermal annealing at 500 °C is considered to mainly cause S-vacancies in MoS₂.⁵⁷ Here we report that with ion sputtering introduces other types of defects because of atom sputtering and mixing effects. Hence ion sputtering provides a potential way to tune the defect states of MoS₂ and other 2D materials, beyond thermal annealing and thermodynamic defect equilibria. Furthermore, as expected, our MD simulation results demonstrate the possibility of forming different defect configurations by varying the ion energy, as shown in Figure S8 for 200, 500, and 2000 eV Ar⁺ ion sputtering. By selecting the appropriate ion sputtering conditions, it is possible to tune the properties and performance of 2D functional materials.

Finally, as one demonstration of tuning the functionality of MoS₂ through defect engineering, we test the HER activity of the as-synthesized MoS₂ single layer and the one with defects introduced by ion sputtering. We use an inert substrate, glassy carbon, for this experiment. As shown in Figure 6a, the pristine MoS₂ transferred on glassy carbon shows strong E' and A_1' Raman peaks with no defect peaks at 362 or 220 cm⁻¹. After

Figure 6. Raman characterization and HER measurement of MoS₂ on glassy carbon. (a) Raman spectra of the sample without sputtering (top spectrum) and after 2 min 0.5 keV Ar⁺ sputtering (bottom spectrum). The dots are measured data, and the solid curves are fitted peaks and spectra. The peaks at around 220 and 362 cm⁻¹ indicate defects. The spectra are normalized by the corresponding A_1' modes. (b) Linear sweep voltammetry curves for glassy carbon substrate and for MoS₂ on glassy carbon before and after sputtering with Ar⁺ ions. The inset figure shows the HER measurement set up.

500 eV Ar⁺ ions sputtering MoS₂ for 2 min, the sample shows distinct defect peaks, and the intensities of E' and A₁' peaks are decreased, consistent with Figure 3b. The HER reaction kinetics is faster, with a higher current density on MoS₂ that was ion sputtered (Figure 6b). This result clearly demonstrates the enhancement of HER kinetics after introduction of defects, because of activating the inert basal plane of MoS₂ for HER by creating S vacancies^{11,59} upon Ar⁺ irradiation. Results indicate a good potential for the application of defect engineering of MoS₂ and other TMD materials.

In addition to hydrogen evolution and catalytic devices, the defect and interface engineering of MoS₂ can also be applied in electronic and photonic devices. For example, the band alignment of MoS₂ and the substrate may create interfacial regions for effective light harvesting or generation.^{60–62} The substrates are known to affect also the PL properties of MoS₂, inducing tunable light-emitting features.⁶⁰ Since defects influence the light emitting, electron mobility, and ferromagnetic properties of MoS₂, customized electronic and photonic devices with targeted defects can be fabricated. For example, as indicated by previous studies, stronger PL was observed by introducing defects in MoS₂, which may inspire MoS₂-based photonic devices.¹⁴ Meanwhile, as defects and substrates alter the band structure of MoS₂, targeted selection of substrates can help engineer various electronic devices that can be designed and engineered, such as tunneling field-effect transistors.^{63,64} In addition, using oxide substrates such as CeO₂ in this work, electronic and photonic devices tunable by temperature can potentially be fabricated and operated.

CONCLUSION

In conclusion, we performed a systematic study of the effects of substrate and defects on SL MoS₂ electronic structure using XPS, Raman and PL spectroscopies, and STM/STS. Thermal annealing in UHV considerably improved the contact between MoS₂ and substrate, facilitating charge transfer between MoS₂ and metallic substrates like Au and SLG/Au and causing energy band shift in MoS₂. In addition, and importantly, reduction of the CeO₂ substrate upon annealing significantly affects the energy band alignment of MoS₂ and CeO₂/Au substrate, because the reduction introduces electronic conductivity into this substrate. Defects introduced by ion sputtering influenced the electronic structure of MoS₂ and band alignment of MoS₂/Au heterostructure. The local defect states within the band gap were identified by STM and dI/dV spectra. The MD and DFT simulations indicate that these defect states are likely to be single and double S vacancies and single Mo vacancies. In addition, we demonstrated that the introduction of defects by ion sputtering enhances HER activity of SL MoS₂. Tunability of defect types and concentrations in MoS₂ by ion sputtering at different energies provides a possibility to engineer the properties of MoS₂ as well as other 2D materials. This work demonstrates an effective set of spectroscopic methods, supported by atomistic and electronic calculations, to probe the band shift, charge transfer, and defect states in MoS₂, which are sensitive to substrate, thermal annealing and ion sputtering. Our results show the importance and potential of defect engineering in tuning the functionality of MoS₂ and other TMD materials in electronics, optoelectronics, and electrochemistry.

METHODS

CVD Synthesis of Monolayer MoS₂. Monolayer MoS₂ films were grown on SiO₂/Si substrates by atmospheric pressure CVD.²¹ Prior to the growth, the substrates were etched in KOH solution for 5 min to make them hydrophilic and rinsed with deionized (DI) water. Then, perylene-3,4,9,10-tetracarboxylic acid tetrapotassium salt (PTAS) was spin coated on substrate for different samples. The sulfur precursor (15–33 mg) was loaded in an alumina boat and placed at 14 cm from the furnace center. MoO₃ powder (18–20 mg) was added to a second alumina boat, of which the PTAS-coated substrates were placed on top of the alumina boat facing down. The second boat was loaded into the center of the furnace for growth. The growth process was performed in a tube furnace at a sample temperature of 650 °C. The growth was carried out for 3 min, during which argon (5 sccm) was used as a carrier gas. An argon flow rate of 1000 sccm was used before the growth to purge the tube and after the growth to quench the growth process.

MoS₂ Transfer. To transfer MoS₂ from a Si/SiO₂ substrate to another substrate, PMMA was first spin-coated on MoS₂ on the Si/SiO₂ substrate. After baking at 80 °C, the chip was put in KOH solution, which etched away the SiO₂ layer. After rinsing in DI water, the MoS₂-PMMA film was transferred onto the target substrate, followed by soaking in acetone to remove the PMMA layer. The procedures to transfer monolayer graphene or BN were generally the same as for MoS₂, except that FeCl₃ was used to etch the Cu substrate for CVD grown graphene and BN. The detailed growth procedure for monolayer BN and graphene can be found in previous reports.^{65–67} The Au layer was deposited on quartz substrate by sputtering. Pulsed laser deposition was used to synthesize the CeO₂ thin layer on Au substrate using a KrF excimer laser with a wavelength of 248 nm. The films were deposited at 600 °C under 10 mTorr oxygen pressure. After the growth process, the films were cooled down to room temperature in 2 Torr oxygen pressure to oxidize the films.

To transfer MoS₂ to graphite substrate for STM/STS measurement, water-assisted transfer (PMMA-free) was used. In the process, a PDMS piece about 1 cm³ with a drop of water was pressed on as-grown MoS₂ on Si/SiO₂ substrate. A small area of MoS₂ was attached to PDMS, which was then pressed on to the target substrate. After removing PDMS, MoS₂ was left clean on the target substrate with no PMMA residues.

XPS Measurements. An Omicron EA 125 hemispherical analyzer and Omicron DAR 400 Mg/Al dual anode nonmonochromatic X-ray source were used for the X-ray photoelectron spectroscopy (XPS) measurements for probing the surface chemistry and core level peaks of MoS₂ on different substrates. Peak-fitting and chemical qualification were performed using the CasaXPS software.

STM/STS Measurements. A variable-temperature scanning tunneling microscope (VT-STM) (Omicron GmbH, Germany) was used to probe the surface morphology and to obtain surface electronic structure information with high spatial resolution at room temperature. STM/STS was performed in UHV (1 × 10⁻¹⁰ mbar) chamber at constant-current mode using W tips. A tip bias voltage of 1.5 V and feedback tunneling current of 50–100 pA was used during the measurements. The tunneling spectra were collected using a lock-in preamplifier to increase the signal-to-noise ratio. For surface cleaning, the samples were annealed in the STM chamber at 350 °C in vacuum for 3 h before STM/STS measurement. For performing STM/STS on MoS₂, HOPG substrate rather than Au/quartz was used, because MoS₂ on HOPG provided higher quality STM/STS data compared to other substrates.

Thermal Annealing and Ion Irradiation of MoS₂. The thermal annealing and ion irradiation were carried out using the direct heating stage and Ar⁺ sputtering gun, which were installed in the same UHV chamber as STM/STS and XPS. The Ar⁺ ion energy was 500 eV with a fixed emission current of 20 mA.

Raman and PL Spectroscopy Measurements. A Horiba-JY HR 800 system was used to measure the Raman and PL spectra of MoS₂. The 532 nm laser was focused using a 100× objective down to a spot size of 1 μm on the sample surface. The laser power on the sample was

controlled at 0.5 mW, and a 600 lines/mm grating was used. The Raman and PL peak parameters were obtained by fitting the spectra using Gaussian/Lorentzian line shape.

HER Measurements. The HER measurement was carried out using a three electrode system, using MoS₂ on glassy carbon as the working electrode, carbon rod as the counter electrode, and Ag/AgCl electrode as the reference electrode. 1 M H₂SO₄ was used as the electrolyte. Before each measurement, the cell was purged with Ar for 30 min to remove any residual gas. A Parstat 2273 potentiostat was used to perform the linear sweep measurements with a scan rate of 6 mV/s.

Atomistic Simulations and Electronic Structure Calculations. MD simulations were performed using the large-scale/molecular massively parallel simulator (LAMMPS).⁶⁸ Ion irradiations were conducted on a free-standing SL MoS₂. The incident Ar⁺ ion was initially placed at 20 Å above the MoS₂ sheet, and the incident direction was perpendicular to the MoS₂ sheet. The incident energies were varied from 50 eV to 1000 keV, and 100 independent simulations were carried out for each specific energy. The first-principles level calculations of the electronic structure were carried out based on the spin-polarized DFT⁶⁹ employing periodic boundary conditions as implemented in the Vienna *ab initio* simulation package (VASP).^{70,71} The projector augmented wave (PAW)^{72,73} pseudopotentials and the generalized gradient approximation (GGA)⁷⁴ functional of Perdew, Burke, and Ernzerhof (PBE)⁷⁴ were used.

Present Address

[†]Guangzhou Key Laboratory for Surface Chemistry of Energy Materials, New Energy Research Institute, School of Environment and Energy, South China University of Technology, Guangzhou, Guangdong, 510006, China

Author Contributions

• These authors contributed equally to this work. Y.C., S.H., B.Y., and J.K. initiated and designed the project. Y.C. performed the XPS measurements, S.H. performed the PL and Raman spectroscopy measurements, and K.A. performed the STM and STS measurements. X.J. and X.L. performed CVD synthesis of SL graphene and MoS₂. K.Y., X.W., and J.X. performed DFT and MD simulations. All authors discussed the results, analyzed the data, and contributed to the writing of the manuscript.

Notes

The authors declare no competing financial interest.
