Abstract

Engineers design for an inherently uncertain world. In the early stages of design processes, they commonly account for such uncertainty either by manually choosing a specific worst-case and multiplying uncertain parameters with safety factors or by using Monte Carlo simulations to estimate the probabilistic boundaries in which their design is feasible. The safety factors of this first practice are determined by industry and organizational standards, providing a limited account of uncertainty; the second practice is time intensive, requiring the development of separate testing infrastructure. In theory, robust optimization provides an alternative, allowing set based conceptualizations of uncertainty to be represented during model development as optimizable design parameters. The hybrid intelligent design perspective, considering the ways in which humans and computers interact as teams in order to solve engineering design problems, prompts the question of how these theoretical benefits translate to design practice. In this work, we analyzed present use of geometric programs as design models in the aerospace industry to determine the current state-of-the-art, then conducted a human-subjects experiment to investigate how various mathematical representations of uncertainty affect design space exploration. We found that robust optimization led to far more efficient explorations of possible designs with only small differences in an experimental participant's understanding of their model. Specifically, the Pareto frontier of a typical participant using robust optimization left less performance "on the table" across various levels of risk than the very best frontiers of participants using industry-standard practices. This analysis perspective can be applied broadly to provide insight on how design concept generation is affected by the inclusion of computational tools.

Acknowledgments

This past year has been hectic, but I have been lucky to have the support of many lovely people, and I'd like to give thanks to a small subset of those people here.

To my advisor, Maria Yang: Thank you for always encouraging me and believing in me. I learned so much about the design process and conducting research thoughtfully from you, and I can't wait to continue exploring this area in the future.

To Edward Burnell: Ned, you introduced me to this lab and started my exploration of this space. You have been both a colleague, a mentor, and a friend this past year, and used all three roles to kindle in me a joy of the nature of human-computer interactions in design. You had me use emotionality and theory as much as reason and focus to find questions, hypotheses, conclusions, and hopes regarding my work. I am so grateful I met you.

To Xiqing Wang: Thank you for working with me this past year and bringing your enthusiasm, curiosity, and insight to every meeting. I'm excited to see where your research takes you!

To the experts who helped me (Berk Ozturk, David S. Anderson): Thank you for your patient explanations of the quirks of GPkit and robustness. I have a much deeper understanding of my work thanks to you.

To all the members of Ideation (Jana Saadi, Shiroq Al-Megren, Suji Raviselvam, and Peppino Durizzo): You welcomed me into the lab and made coming in every day so enjoyable. I'm really going to miss the Ideation community.

To my closest friends (Saena Sadiq, Haley Abramson, Srilaya Bhavaraju, Sameena Shaffeeulah, and Max Evans): You kept me sane this past year by listening to my struggles, by sharing my joys, and by providing me with the perspectives I needed. I adore you all so much.

To my family (Mom, Dad, and Divya): Thank you for always loving me and pushing me to be better. I love you.

Chapter 1

Introduction

Hybrid intelligence is an emerging field that analyzes the interaction between engineers and the computational systems they work with to determine how best to mediate the interfaces between them. Hybrid intelligent design specifically focuses on the processes by which computational tools are employed by engineers to design complex systems. Engineering designers use these complex computational models to represent a variety of problems, despite an awareness that the results will not be perfectly recreatable in the physical world. Even if a model were able to perfectly represent a specific problem, environmental conditions and physical realities are rarely stable or knowable; for example, an engineer may declare the density of a metal as a particular value, but, in manufacturing, the metal supplied will vary from supplier to supplier and day to day. Beyond material quantities, such uncertainty is also inevitable for environmental conditions, assembly quality, and many other important components of performance. Accounting for uncertainty is therefore a necessity which designers often represent through the manual implementation of conservative heuristics.

Convex Geometric Programs (GPs), sets of algebraic constraints globally optimizable for a specific cost function, are capable of representing a variety of complex systems. Historically, the inaccessibility of software used to create and solve GPs has restricted their use in engineering design. The Python package GPkit provides a familiar and clear syntax for geometric programs, reducing this barrier to entry [9]. Through GPkit, several engineering design firms have adopted GPs for regular use in their processes, typically

to validate the feasibility of innovative conceptual designs.

At present, GPkit models (along with most other design models) do not provide interfaces specifically for the representation of uncertainty. Designers instead set some parameters' values to a "reasonable worst case", often via multiplication by a blanket "safety factor". Robust optimization aims to address this by allowing specified uncertainties to be set on parameters, then optimizing for the best worst-case performance under a given uncertainty set [5]. This method provides more mathematical guarantees than safety factors do and is more directly translatable to a simulation environment.

How much these mathematical details affect designers and design practice is unclear. The marginal improvement in design quality may or may not be worth the effort of changing designer's conceptualizations of their model. However, we argue that robust optimization's potential benefits come not only from its underlying mathematics, but also from the novel "questions" it lets designers ask of their models. When uncertainty is explicitly defined in robust GPs, it can be optimized for as if it were any other variable. This provides a dynamic understanding of uncertainty, encouraging discussions of robustness earlier in a design process. This study seeks to explore ways in which robust optimization can affect the practice of creating designs, and provides evidence that robust GPs improve design space exploration, increasing designs' quality, quantity, and coverage relative to an underlying Pareto frontier of optimal tradeoffs. Ultimately, this will increase GPkit's accessibility and applicability to design optimization problems both within conceptual airplane design and in a more diverse range of fields.

1.1 Research Questions

Previous work has shown that robust optimization provides a mathematically rigorous method of accounting for uncertainty [41, 34]. However, its effects on the questions designers ask of their models has not yet been analyzed. In this study, we ask the following questions:

RQ1 How do designers conceptualize uncertainty? How do particular conceptualiza-

tions change their comfort with robust optimization?

RQ2 How do different mathematical formulations of uncertainty, as represented in a design model, affect designers' explorations of possible designs?

RQ3 What design processes do robust optimization tools alter or automate?

Our study had two stages. The first, a series of practitioner field interviews, was used to guide the design of the second, a human-subjects experiment in a controlled environment. We address RQ1 by summarizing how current users of GPkit account for uncertainty in their design processes and looking at how experimental participants used robust optimization to account for uncertainty. RQ2 is addressed by analysis of the quality and spread of experimental participants' solutions. RQ3 is touched on in comparisons between processes for uncertainty accounting described in interviews and those seen experimentally, but we anticipate its full investigation to also require field studies of how robust optimization affects organizational processes.

This thesis represents work that will be published in the ASME IDETC-CIE Design Theory and Methodology Conference Proceedings and the Journal of Mechanical Design [31, 32].

Chapter 2

Background

A substantial amount of research has been conducted on software tools for design, analysis, and robust optimization, but the development of particular tools is not our focus. Rather, coming from a hybrid intelligent design perspective, we are interested in how designers use these tools and how the choice, application, and integration of these tools can impact design process exploration. The set of tools designers use varies in their handling and understanding of uncertainty and robustness [24]. To better specify this variety in our model, we define uncertainty as a set of possible values for a set of variables, rather than each of those variables being a fixed constant. Robustness is defined as the ability of the design to still function with small perturbations of these fixed variables; the larger a perturbation that can be handled, the more robust the design is.

2.1 Hybrid Intelligent Design

Advances in electric engineering and computer science have allowed us to answer large and complex questions; modern computational power has the capability to explore solution spaces quickly to find an optimum. Computation excels at solving problems given explicit definitions for quantitative objectives and constraints. These numeric delineations require a reliance on humans to specify these metrics such that they represent the complexity of the situation in a consistent and predictable fashion. Defining these models requires the knowledge of lived experience and adaptability to combine infor-

mation from disparate, and frequently unpredictable, areas. By being able to work with abstract mental models, humans can consider possible solutions outside of the rigid space a computer operates within. Effective cooperation and communication between humans and computers is necessary for both to explore a broader design space.

These teams of humans and computers can outperform either humans or computers alone by leveraging the strengths of each side. The paradigm of these interactions is using humanity's applied knowledge to adaptively ask questions and using computational power to search for specific answers, which then can prompt more questions. One of the earliest and most vivid examples is centaur chess, in which human and AI teams were allowed to collaborate while playing chess. These competitions, organized shortly after Deep Blue, an IBM AI, beat the reigning chess champion in 1997, showed that human-computer teams could outperform both humans alone as well as computers alone. Importantly, it was also not the "all-star" team of the strongest AIs paired with the strongest players that won. It was amateur players working with weaker AIs. The necessity is not in optimizing the individual components of a human-computer system, but rather optimizing the process of integration of humans and computers together, known as hybrid intelligence [12].

While human-computer interaction (HCI) is similar conceptually to hybrid intelligence, its perspective tends to focus on direct physical changes to improve surface level interaction. For example, common HCI metrics of improvement would be a task completion rate or an error rate per task. Frequently, its goal is to make UI incorporate invisibly and seamlessly into standard practices. However, this emphasis can unnecessarily limit software design by preventing it from challenging conventional processes. Hybrid intelligence aims to understand the back and forth, the give and take, of the interaction between humans and computers [18, 20]. Hybrid intelligent design further specifies hybrid intelligence to answering engineering design questions, which involve unique, often ill-defined sets of constraints.

2.2 Frameworks for Early Stage Design

Many frameworks exist for early stage design processes for products and engineered systems, including Pahl and Beitz' systematic approach to engineering design and Ulrich, et al.'s widely known process for product design and development [29, 37]. Underpinning both approaches is the notion of a design specification and/or initial prototype created by an engineering and design team. The initial prototypes being considered in this study are Python codes using the GPkit library [9]. The current design specification of these models does not include a method of accounting for uncertainty; we will refer to the additional design specification of uncertainty as the conceptualization of uncertainty within the model.

2.3 Design Models

Human participants in engineering organizations use software "design models" to enumerate parameters of their designs and implement interactions amongst these parameters. Design models are often made from materials like parameterized CAD assemblies (to construct a shape from geometric constraints) [21, 36], spreadsheets (to calculate performance) [30, 27], and "mathematical programs" (to take in a desired performance and put out a design that achieves it) [22].

Design models serve as loci for understanding what will be built, while encoding (and sometimes concealing) decisions on why [33]. This makes them an important arena for intra-organizational design politics, but just how participants' perspectives clash and coalesce around these models depends also on the structure they are part of [21, 8]. Design models express their agency both by shaping the structure and, within a structure, by determining their outsiders and insiders, spectators and maintainers, and formal and informal power structures [21, 16].

2.4 Design Tools and the Designer

Software tools, most notably CAD, are essential to creating design models, and a number of studies have considered the impact of these tools on early stage designs. In the exploratory phases of design, studies with practicing engineers and student designers have observed that the use of CAD too early in the design process can have a negative effect on design creativity, known as "premature fixation" [33, 14]. High fidelity digital tools require more time and effort on the part of the designer than lower fidelity tools, making designers more invested in a design and less likely to discard it. This is an observation of not only the design tool, but the way that designers use the tools in practice. Our study takes a similar designer-focused perspective on exploration using a design tool by formulating a constrained but realistic design problem with minimal interface complexity. Our design tool is GPkit, and we investigate the effect of a more detailed but potentially confusing mathematical model of uncertainty on the ability of users to find optimal solutions using this tool. The exact mathematics behind how uncertainty is calculated will be referred to as the formulation of uncertainty.

2.5 Design Optimization and the Designer

An overarching goal of design optimization research is to create tools and systems that can support designers by generating the “best” solutions by searching through the set of all possible solutions, or the design space. The majority of research in design optimization concentrates on the development of better and faster algorithms and strategies, and only limited research has been conducted on how designers themselves reach globally or locally optimal solutions, and how this is affected by their tools.

In an early study of how humans deal with coupled problems, Hirschi and Frey compared the time to solve coupled and uncoupled parametric design problems [17]. For uncoupled problems, the time to solve was of the order of $O(n)$ where n is the number of input variables, and increased dramatically to $O(n^{3.4})$ for coupled problems. Notably, coupled problems with more than four variables were found to be very difficult and frus-

trating for the participants. Similarly, human studies by Flager et al. showed that an increase in problem complexity caused a significant decrease in solution quality [15]. A study by McComb et al. showed specifically that more complex 2D trusses led to worse performance [23]. Austin-Breneman et al. found that, despite domain expertise and optimization training, graduate students asked to collaboratively design a simplified satellite had trouble exploring the design space because of the complexity of subsystems and subsystem interactions, and few teams found designs on the Pareto-optimal frontier [2]. In interviews with space system designers, it was found that teams in industry routinely restricted the information shared with each other in ways that made exploration much more difficult both in practice and from the perspective of optimization theory [3]. Yu's study of desalination systems found that software choices could enable novices to explore complex system designs almost as well as experts, with some caveats [39]. Designer satisfaction with rapid prototyping process has been explored by Neeley, et al., who found that designers tended to be more satisfied with design outcomes when given the opportunity to explore more design space initially [28]. Specific questions of how real-time interfaces affect design outcomes were present in the first direct manipulation CAD software, [36] in early studies of the effect of analysis speed on structural design exploration and outcomes, [7] and in more recent research on human-computer optimization in circuit-routing [35] and in architectural design [26].

We hope to extend such studies by directly measuring the effects of real-time software decisions and algorithms on design outcomes and process. Previous studies by Barron et al. and Egan et al. [4, 13] have looked at the effects of visualization and search techniques in custom tools that use different visual representations and search strategies than designers may be accustomed to; in contrast, our study uses familiar visual representations and interaction modalities but changes the conceptualization and formulation of the design problem. Since this design problem has two goal parameters, we define "optimality" in terms of the Pareto frontier—a subset of the possible solutions such that each solution on the Pareto frontier is either better in the first goal parameter or the second goal parameter compared to any other solution.

2.6 Geometric Programs

Geometric programs are nonlinear optimization problems of a set of posynomial constraints and a cost function known as the objective. A posynomial is a sum of monomials, where a monomial is a set of variables raised to any positive real power multiplied together with a positive coefficient. Formally, a posynomial $p(x)$ can be defined as

$$p(x) = \sum_{k=1}^{K} c_k \prod_{j=1}^{n} x_j^{a_{j,k}} \tag{2.1}$$

where x is a vector of all variables, n is the length of x and therefore the number of variables, K is the number of monomials, all c_k are positive real numbers, and all $a_{j,k}$ are real numbers [6].

A geometric program is defined by minimizing a posynomial objective function subject to posynomial constraints that must be less than or equal to some positive value. Geometric programs have the practical feature that, when transformed logarithmically, they become convex, guaranteeing only one local minimum exists—the global minimum. This allows for gradient descent in log-space to always find the globally optimal solution. GPkit serves as a Python interface for geometric program solvers such as MOSEK and cvxopt [25, 1] that allows users to define these objectives and constraints intuitively. It then can solve for the optimal solution and can visualize the structure of the models and the feasible solution space. GPkit has enabled engineering designers who are not experts in mathematical optimization to create, solve, and understand GP models by black-boxing computational details and providing diagramatic representations of the underlying mathematics. If negative c_k values are necessary, a signomial program can be used, which can be optimized via multiple geometric program approximations.

2.7 Robust Convex Optimization

While geometric programs are highly generalizable, they run the risk of being overly specialized solutions relative to the uncertainty that exists. To account for that uncertainty, Robust, an add-on GPkit package, allows for the inclusion of standard deviations on

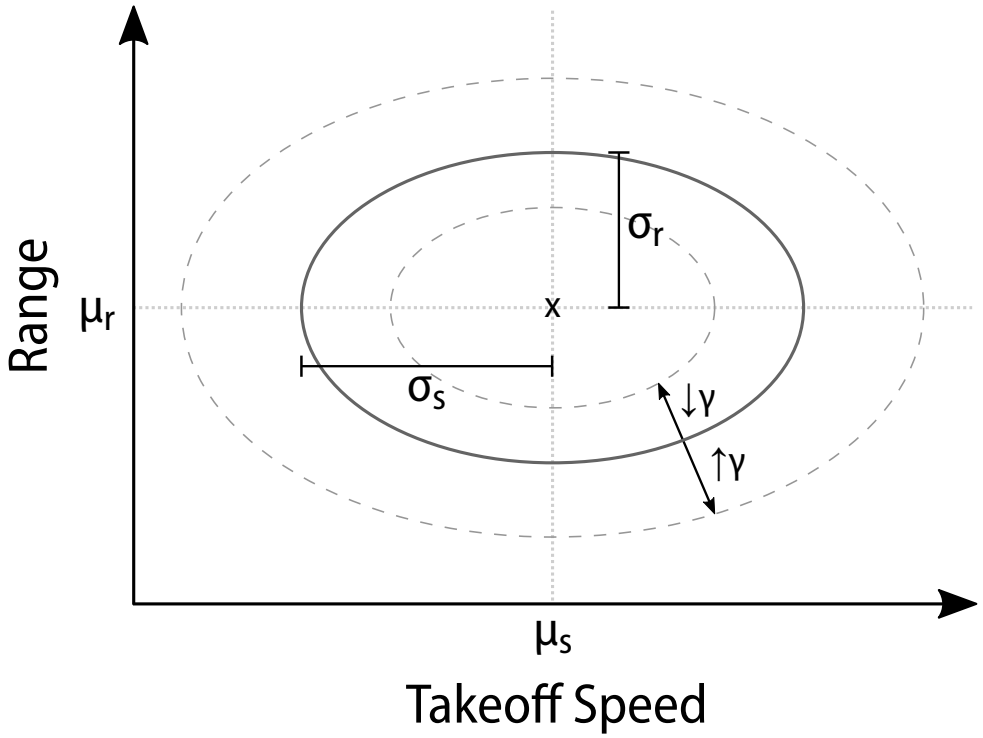

Figure 2-1: Elliptical Uncertainty
μ_r is the expected range, σ_r is the standard deviation of the possible ranges, μ_s is the expected takeoff speed, σ_r is the standard deviation of the possible takeoff speeds. In robust optimization, each design's worst case of the range of possibilities of the ellipse would be found, and the design with the optimal "worst case" would be chosen. Increasing γ accounts for more uncertainty by scaling up the ellipse, as γ is a multiplier of the standard deviations.

each variable, as well as an overall "Gamma" factor (γ) that scales the amount of uncertainty accounted for, then optimizes the worst point of a region of uncertain parameters. The region can either account for a certain number of standard deviations of each parameter ("rectangular" uncertainty) or of a combination of all parameters ("elliptical" uncertainty). A visual explanation of elliptical uncertainty is in Figure 2-1. This process is generally known as robust optimization. Work on Robust has shown that the current standard of multiplying each uncertain variable by a margin does not actually take into account the worst combined case mathematically, and that robust optimization is necessary to fully account for uncertainty [41]. While the quantitative case for using Robust

has been made, the question of how this affects the overall design process, particularly in the context of design space exploration, has not yet been answered.

Chapter 3

Practitioner Interviews

This study was divided into two stages. The first exploratory stage (practitioner interviews) produced qualitative data on Robust adoption's benefits, risks, obstacles, and conditions. From the information gathered in these interviews, we designed the experimental second stage to address the concerns raised and to provide these users with further guidance on how and when to incorporate robust optimization into their existing models.

3.1 Methods

To understand current practices of accounting for uncertainty in design models, we interviewed five GPkit users with a flexible questionnaire focusing on how they accounted for uncertainty within their models. Each of the five interviews lasted for half an hour to an hour and took place off campus, either at the interviewee's place of work or at a public location like a coffee shop. Interviewees varied in the extent of their experience with GPkit, their interactions with GPkit (developers versus designers), and their affiliations (academic versus commercial), though all were in the field of aerospace, where most GPkit models are made; a detailed breakdown can be seen in Table 3.1. First, we asked about each designer's work to encourage engagement in the conversation and to understand their background. We then explored the workflows of their projects before and after using GPkit, asking them to speak of particular projects to ground their answers.

Table 3.1: Practitioner Demographics
Each column represents an interviewed practitioner, each row a trait. An "X" indicates that the practitioner has this trait. "Developer" means they have been involved in GPkit's development process; "Designer" means they have created GPkit models as a part of a longer product development process. "Academic" and "Commercial" refer to the contexts in which the practitioner has worked with GPkit. "Experienced" refers to having multiple years of experience using GPkit.

	1	**2**	**3**	**4**	**5**
Developer		X	X		
Designer	X	X		X	X
Academic	X	X	X	X	
Commercial	X	X			X
Experienced	X	X	X	X	

We then asked more targeted questions about uncertainty, looking for specific methods. Finally we asked broadly about inefficiencies they had encountered while modeling, to understand how salient issues surrounding uncertainty are relative to other concerns.

These interviews were the backbone of our experimental design for the second stage, for we based its guiding questions on the concerns expressed by those interviewed.

3.2 Results

When we asked interviewees how they accounted for uncertainty during conceptual stages of design, we received two responses: either they 1) multiplied uncertain parameters by a margin or safety factor of 20% (considered an industry standard) or 2) did not account for uncertainty at those stages. Some interviewees mentioned checking if their design was robust to small perturbations in environmental conditions via Monte Carlo simulation, but usually as a final check of a model's solution, not during model development. Most interviewees believed they *should* be accounting for uncertainty, but did not consider it a priority due to a perceived lack of social pressure to do so; if none of their peers were trying to account for uncertainty, why should they? Almost everyone interviewed considered uncertainty quantification an important problem, but also thought

of it as intractable and impractical.

Interviewees discussed how safety factors can lead a design to be incorrectly seen as infeasible. One talked in particular about electric airplanes, much of whose mass rests in their battery. Putting a safety factor on total airplane weight increases the amount of battery needed, which increases the total airplane weight; the process converges, but often leaves a design looking impossible. Therefore, instead of weight safety factors, this interviewee accounted for excess weight by making the allowable payload a maximized free variable, even though this makes it more difficult to design for an exact payload.

Deciding on a model's objective function (the parameter it optimizes for) was described as the "single most important choice" of modeling. In robust optimization, uncertainty can be the optimized parameter. This allows for different conceptualizations of a design problem. With the electric aircraft above, instead of calculating the battery size required to handle 20% extra weight, designers might use robust optimization to calculate the maximum level of uncertainty allowable for an airplane capable of carrying a specific payload.

That our interviewees used GPkit primarily during conceptual design stages made the detailed accounting for uncertainty of robust optimization seem less necessary to them. In order to use robust optimization, they would have to create models with increased complexity in both concept and form, more difficult to interpret and to code. Some practitioners were additionally skeptical that doing so would significantly improve conceptual designs, as the uncertainties known at such an early stage felt more "made up" than other design parameters. While they found current uncertainty accounting practices to be more arbitrary, they felt that the specific uncertainty values they would choose in robust optimization might be just as arbitrary without the benefit of following industry standards. This formed the question for our human-subjects experiment: can robust optimization be useful (in comparison to current practices) even with guessed parametrizations of uncertainty?

Chapter 4

Human-Subjects Experiment

This experiment was held to provide a direct comparison between methods of accounting for uncertainty with different computational models. We wanted in particular to see how additional uncertainty information mathematically encapsulated in models might shape designer's practices.

4.1 Methods

Forty-three graduate and undergraduate students in science and engineering at a US university were recruited to individually participate in a design challenge using a custom built graphical interface for a GPkit design model. Participants were prompted to choose parameters for an airplane design which led to designs with both as low a failure rate and as low a fuel consumption as possible. They were tasked with finding designs in three "reward regions" and to find designs on the final combined Pareto frontier; participants received greater compensation depending on their performance on these metrics. Each participant was given a ten minute tutorial, thirty minutes to complete the design challenge, and ten minutes to complete a short survey about their experience using the tool after the experiment.

Table 4.1: Participant Demographics (self-reported)
Each participant was randomly assigned to an experimental condition upon arrival; no stratification was used to split participants.

4.1.1 Experimental Interface

The graphical interface shown in Figure 4-1 allowed users to directly modify a small set of parameters with sliders (A), then optimized a design based on those parameters and presented its fuel consumption (performance) and simulated failure rate. Participants kept track of the history of their designs with a plot of each design's fuel consumption and failure rate (B), a list of parameter combinations they'd tried that led to infeasible designs (C). The three reward regions were also shown on (B), providing a visual reminder of their goals. Additionally, participants saw the planform of their most recent airplane design (D). Fuel consumption was evaluated by solving the GPkit design model for the input slider values, while failure rate was determined by checking the model's feasibil-

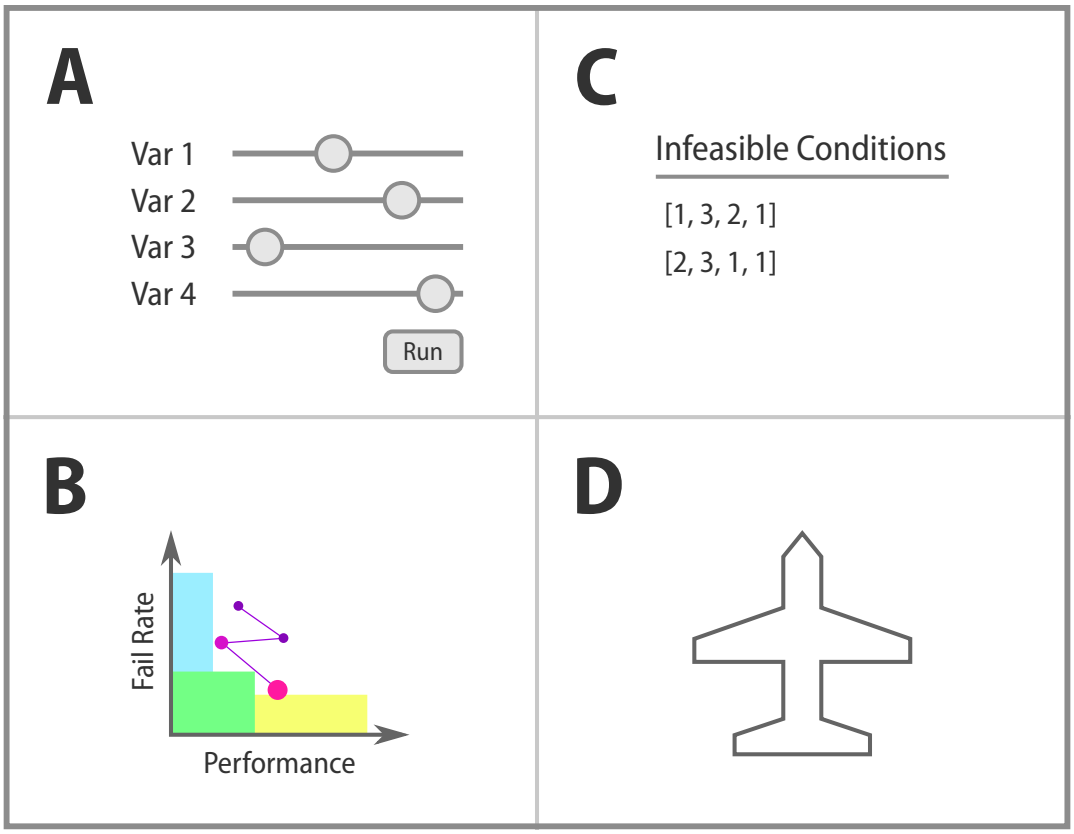

Figure 4-1: Diagram of Experimental UI
The three reward regions highlighted in the plot are designs with a fuel consumption below 1100 lbs (in blue), designs with failure rate below 10% (in yellow), and designs with both a fuel consumption below 1200 lbs and a failure rate below 30% (in green). The ordering of participant's designs was tracked through a line, with the most recent points in bright pink and older points in dark purple.

ity across a set of one hundred randomized conditions; conditions were sampled from a multivariate truncated Gaussian probability distribution. A fixed set was used for all participants to enable comparability between the failure rates of various designs. This method of determining failure rates is similar to best-practices Monte Carlo simulations. The design model underlying this graphical interface was based on the "SimPleAC" GPkit model for passenger aircraft, [40] itself a condensed version of previous GPkit models for commercial aircraft [19, 38] that had been co-developed with the robust optimization library [41].

4.1.2 Experimental Conditions

Subjects were randomly partitioned into the four experimental conditions: two conditions similar to existing practices (Control and Margin), and two using robust optimization (Gamma Slider and Performance Slider). A breakdown of participant demographics can be found in Table 4.1. Participants using Control chose design parameters such as wing size; those using Margin chose safety factors, those using Gamma Slider chose the precise shape and scale of the uncertainty region they were optimizing for, while those using Performance Slider, chose the shape of that region and a desired performance, letting the optimizer maximize the scale of the uncertainty region. The uncertainty region was set to be elliptical, which represents a percentage of combined uncertainty being accounted for. Both Control and Margin represent current design practices: Control simulates common practices with non-optimizing design models, while Margin simulates common practices with GPkit models. Gamma Slider and Performance Slider represent the intended design practices Robust enables. We expected to see improvements to design space exploration coverage and quality with these uses of robust optimization.

More specifically, Control users directly manipulated four physical design parameters of the airplane (wing length, wing area, fuel volume available, and lift coefficient). Margin, Gamma Slider, and Performance Slider users directly manipulated parameters which accounted for uncertainty (margins or percentages of uncertainty on wing weight, fuel quality, takeoff speed, and range). Control users saw the fuel consumption of their designed airplane in the context it was optimized for, while users of the other design models saw performances which "priced in" uncertainty. Since the reward regions were identical across conditions, a larger fraction of possible designs Control users were able to find appeared in these regions. This kind of biased comparison is common in robust optimization practice. To compare performance across conditions during the analysis, designs made in non-Control conditions were "nominalized" by recalculating performance of each design in the nominal conditions Control designs had seen.

4.2 Results

Prior to analyzing the quantitative data of the experiment, we assessed our overall impressions of each of the conditions from piloting and from post-experimental conversations with participants. Participants in the Control condition seemed to have the most direct understanding of how or why their parameter changes affected performance and failure rate, especially if they had some experience with airplane design. Participants in the Margin condition found their designs highly sensitive to even small parameter changes; it seemed easy to accidentally go to extremes with this tool. For both Performance Slider and Gamma Slider participants it seemed difficult to find designs far away from the Pareto frontier. Performance Slider participants could, by keeping the performance slider consistent, constrain their motion on the results plot to a single vertical line, allowing them to separate dimensions inextricably linked for other users. Gamma Slider participants could, by keeping their standard deviations constant and only modifying the size of their uncertainty set, move along a single curve. Being able to act in only one "dimension" in these ways seemed to make the challenge less stressful for both Gamma Slider and Performance Slider participants.

To see if these impressions were validated by our data, we analyzed qualitative results from the post-experiment survey, which gave participants a set of statements and asked them to rate how much they agreed or disagreed with each on a six point Likert scale (Figure 4-2). Comparisons between Control and other conditions were biased by Control's easier access to the goal regions; given this, the fact that Control felt less stressed and frustrated than most other conditions is unsurprising. Between other conditions, we saw differences in the amount participants felt like they "had a plan", were "in control", were "frustrated", or were "stressed". As expected, robust optimization conditions were mildly less stressful and frustrating than Margin. However, Gamma Slider participants felt *the least* like they had a plan and were in control. This may indicate confusion about the "Gamma" parameter, which, as a robust optimization specific term, was unfamiliar. Despite this, Gamma Slider participants had the highest quality solutions of all conditions. Even without feeling they understood what they were doing, Gamma Slider

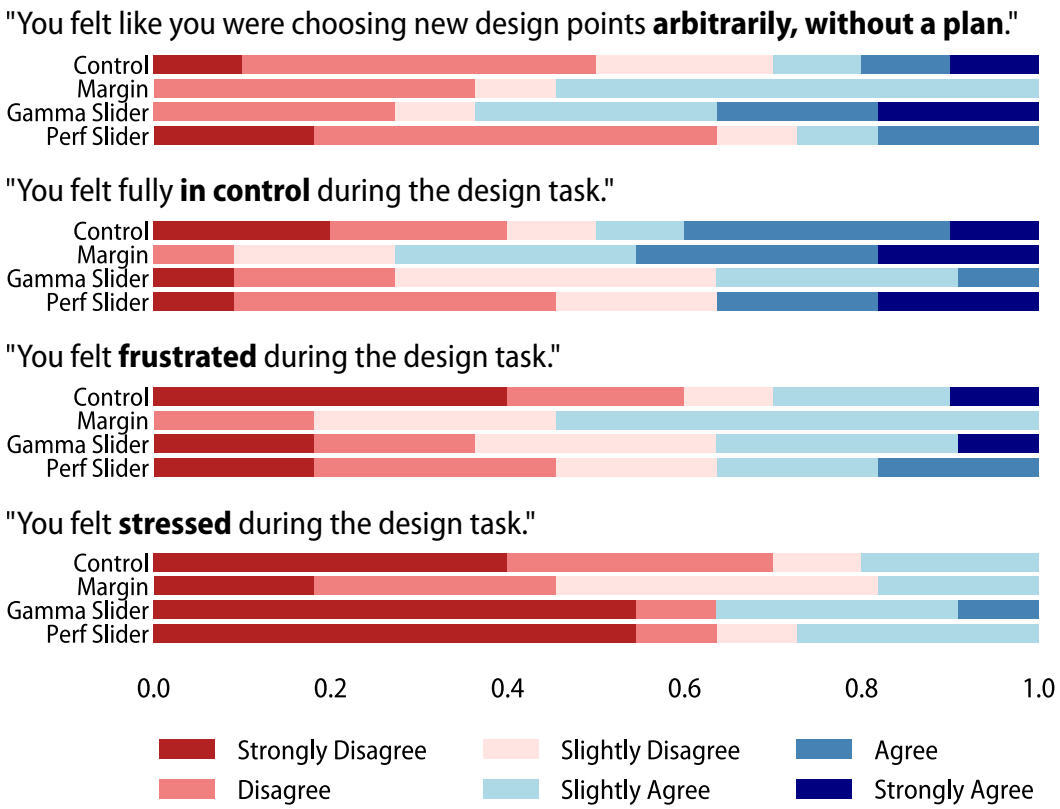

Figure 4-2: Results from Post-Experimental Survey
A six point Likert scale was used to evaluate the emotional reaction of participants to the experimental set up. Participants filled out the post-experimental survey immediately after finishing the experiment.

participants were able to find high quality designs.

The rest of this section quantitatively compares solutions across all four conditions. The design challenge incentivized participants not to find an optimal solution given a single goal, but rather to find a Pareto frontier of optimal solutions in terms of two goal parameters, performance and failure rate. To statistically analyze the influence conditions had on design outcomes, we compare the quantity of high quality points found in Figure 4-3. The metrics of Pareto points and combined Pareto points serve as proxies for how much of the space was covered; the percent inside reward regions serves as a proxy for design quality. We see significant differences between robust optimization methods and standard methods in these metrics, providing evidence for the hypothesis that robust optimization encourages more exploration of optimal designs and increases

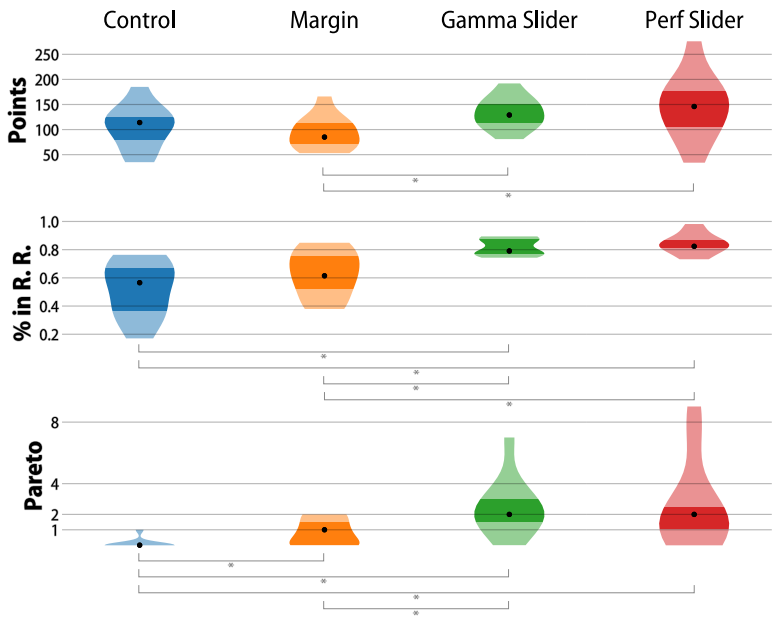

Figure 4-3: Summary Statistics
Significant differences (Welch's t-test) indicated by an asterisk (significance defined as $p < 0.05$). "Points" refers to the number of feasible designs generated by each participant within thirty minutes. "% in R.R." refers to the percent of nominalized designs per participant that were in any of the regions with financial incentive. "Pareto" refers to the average number of points found by each participant in each condition that were on the combined experimental Pareto frontier across all conditions. $n = 11$ for all conditions except Control, in which $n = 10$. Shaded region shows the distribution for each condition, darker between the 25th and 75th percentiles. Black dots show medians.

the quality of each design explored.

The number of points metric is an indication of how much exploration participants were willing to do given specific tools; the large number of points in robust conditions indicates that exploration was faster and/or participants more willing to explore. To disambiguate this, we looked at the average time between points for each condition. We did see a statistically significant difference here, but this was likely due to the abundance of points produced decreasing the threshold required for significance. As the overall end times did not show significant differences, the number of points produced may be best explained by participants' willingness to explore under each condition. Robust optimization is not the sole factor here: the Control condition, in which the reward regions were the easiest to achieve, provided less financial incentive to explore, which

may have discouraged exploration. However, the Margin condition was rated as slightly more stressful and frustrating, and participants may have been disincentivized to explore by their stress and frustration. One of the benefits of robust optimization might be a reduction of this stress and frustration, leading to increased exploration.

We parametrize a design's quality with two dimensions: the improvement in failure rate that could have been achieved for that design's performance (vertical distance on the following plots), and the improvement in performance that could have been achieved for its failure rate (horizontal distance). In both cases, designs were compared to the final combined Pareto frontier achieved by other participants. Figures 4-4 and 4-5 show the distribution of these distances across participants' Pareto frontiers. Because we used the same reward regions across conditions, the difficult central region became therefore a focal point for some participants, as can be seen in the compression of their distribution at that point. With normalized performance, Control and the least-performant half of Margin participants are clearly separated from the combined frontier, while other participants are quite close.

To see the differences between the Pareto frontiers achieved by participants under condition, we summarize each individual frontier by its average vertical distance (Figure 4-6) and horizontal distance (Figure 4-7). We consider individual's frontiers all together instead of each of their points because such frontiers are the primary output of design model use, not a particular design point. That is, our simplified framework for the use of these models in a design process is 1) a condition is selected, 2) a Pareto frontier created, and 3) a condition is chosen from that Pareto frontier based upon the whole frontier.

Figure 4-6 shows the distributions of excess failure rates (average vertical distance) across the frontiers made with each condition. There is a clear distinction between Control and Margin, and between both of them and the two robust conditions. Figure 4-7 shows the distribution of excess fuel consumption (average vertical distance) across conditions. The frontiers of median users of the robust models perform better by this metric than the best users of Margin and Control, and every user of robust models performs better than three quarters of Control users.

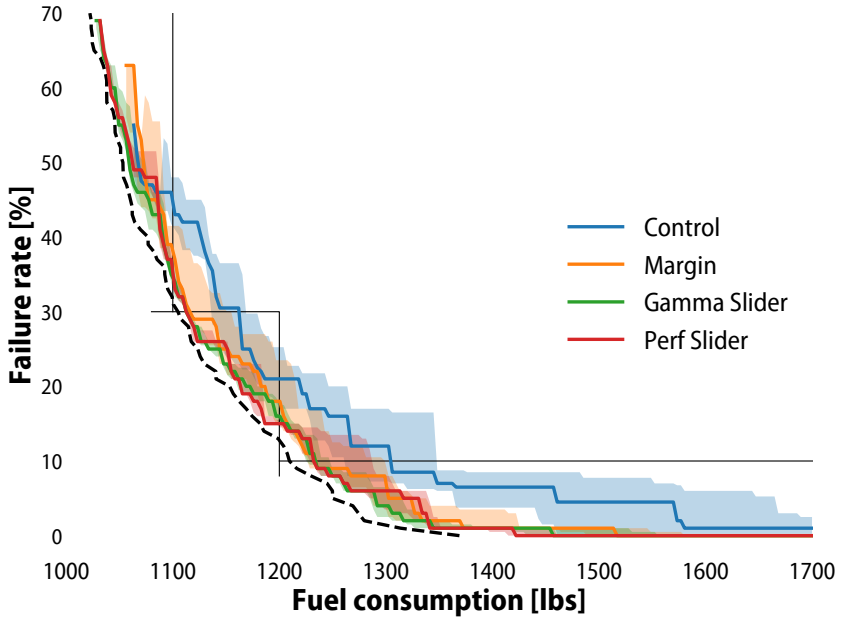

Figure 4-4: Distribution of Fuel Consumptions
Solid lines show median of participants' Pareto frontiers after nominalization. Shaded regions extend above it to the 75th percentile and below to the 25th. The black dashed line shows the combined final Pareto frontier, while solid black lines indicate reward regions.

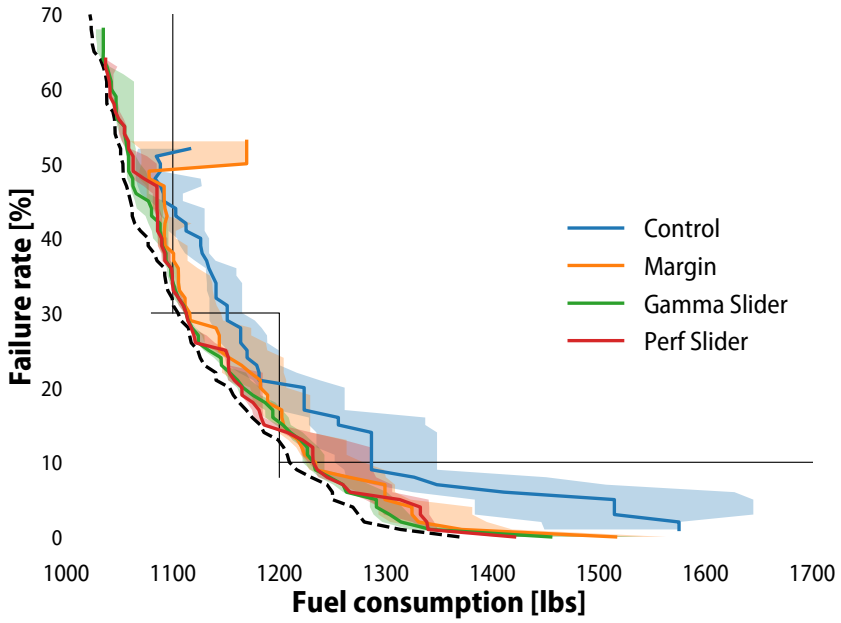

Figure 4-5: Distribution of Failure Rates
Solid lines show median of participants' Pareto frontiers after nominalization. Shaded regions extend to its right to the 75th percentile and to its left to the 25th. The black dashed line shows the combined final Pareto frontier, while solid black lines indicate reward regions.

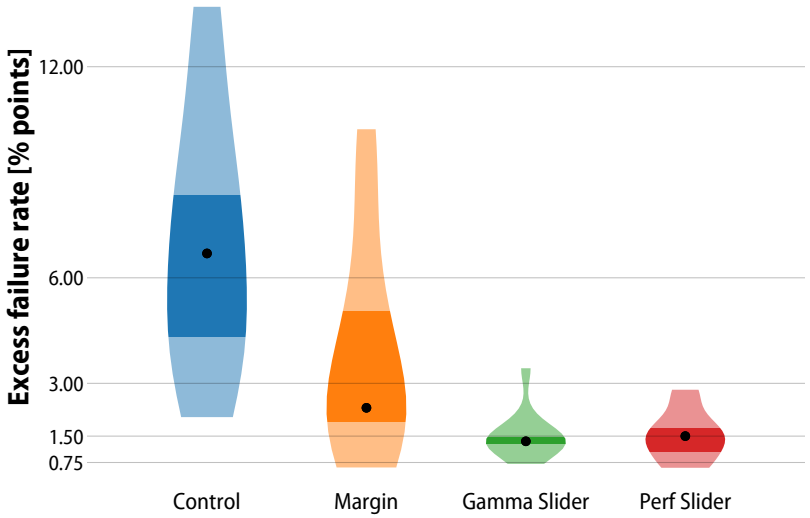

Figure 4-6: Average Excess Failure Rates
Shaded region shows the distribution for each condition, darker between the 25th and 75th percentiles. Black dots show medians.

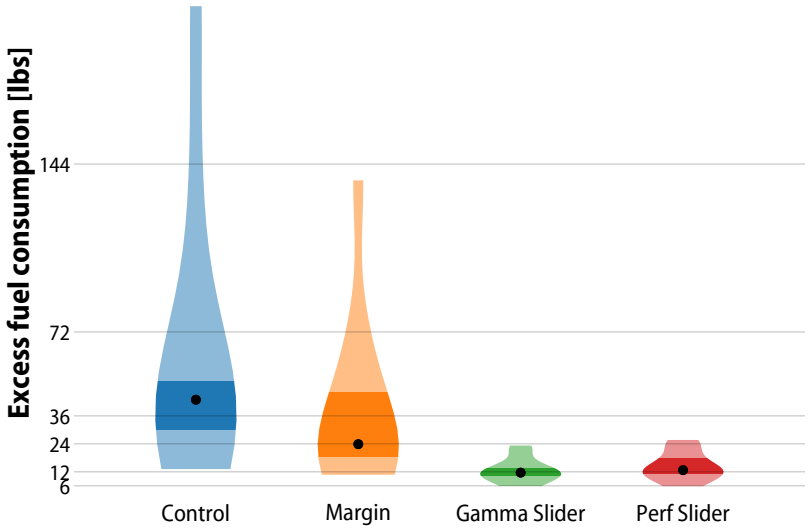

Figure 4-7: Average Excess Fuel Consumptions
Shaded region shows the distribution for each condition, darker between the 25th and 75th percentiles. Black dots show medians.

Chapter 5

Discussion

These results are evidence that robust optimization can increase design quality. Returning to our fundamental research questions, what do they imply about the effects of conceptualizations and formulations of uncertainty, and what current design practices might robust optimization alter or automate?

5.1 RQ1: Conceptualization of Uncertainty

From practitioner interviews we found that uncertainty conceptualization in the early stages of airplane design is minimal, partly because uncertainty is considered fruitless to estimate by our interviewees when the overall design is rapidly changing. However, we found two types of uncertainty were being mixed together: 1) uncertainty related to changes that were part of the design process, and 2) uncertainty related to the range of possibilities the final design might face. The conceptual merging of these meant that designers who did not think they could account for the first type, also thought they could not account for the second. For robust optimization to be used in conceptual design, it must make clear it is formulated for the second type.

Given that designers at this stage do not often conceptualize this second type of uncertainty, how might they adopt robust optimization? Experimental participants in the robust Performance Slider condition felt most like they "had a plan"; Gamma Slider participants felt least like they had a plan. This implies that, for non-expert users, the termi-

nology of robust optimization (present in Gamma Slider as the "Gamma" factor, but absent in Performance Slider) may be a barrier to entry. However, the concept of optimizing for uncertainty, present in both conditions, did not seem to hinder understanding (using "felt like they had a plan" as a proxy). For GPkit users trying robust optimization, we would expect the transition to be eased by parallels between the conceptualization of uncertainty in robust optimization and uncertainty questions already asked later in the design process. The Performance Slider condition is analogous to finding the most robust design possible for a certain performance; the Gamma Slider condition is analogous to finding the most performant design possible for a specific uncertainty set. The additional complexity of design models in practice and the lack of GUI-based abstraction may limit the generality of these results.

5.2 RQ2: Formulation of Uncertainty

The current process of GPkit model creation does not encourage a rigorous formulation of uncertainty. Practitioners discussed multiplying uncertain fixed variables with industry-standard safety factors, but this method seemed more of a default practice rather than one engaged with a conceptualization of uncertainty.

In our experiment, the Control condition had no formulation of uncertainty, the Margin condition encapsulated uncertainty in safety factors, and the robust optimization conditions encapsulated uncertainty in relative standard deviations. Results showed participants in Control and Margin were far worse at finding Pareto optimal points than participants in robust optimization conditions: 75% of robust optimization frontiers were better than the median frontier of the other conditions. Additionally, formulating uncertainty as a directly controllable variable seems to have reduced the quantity of suboptimal designs explored.

In this simplified design challenge, the model's formulation was abstracted away from the participants. In practice, users of GPkit would need to understand robust optimization well enough to create these models on their own. While Robust was designed to only require a small amount of additional code, the mathematical increase in un-

derstanding needed to create such syntax was not accounted for within this study. It remains to be investigated as a possible obstacle to usage of robust optimization in GPkit.

5.3 RQ3: Automated Design Processes

Our experiment was designed to represent both designers' present design exploration processes and the potential processes of robust optimization. Our failure rate simulation was meant to mimic a designer testing their design, either through Monte Carlo simulation, more complex computational modeling, or prototype creation. In this study, this failure rate simulation formed the "ground truth" of the participants involved; in practice, the ground truth could not be so easily discovered at this stage. A simulation similar to ours would serve as an early check in the design process, rather than the final one.

Current design processes were emulated by the Control and Margin conditions. Control emulated the process of manually setting design parameters without use of optimization, as is common in conceptual aerospace design. Our results find that, while it is possible to find high quality solutions this way, it is difficult to do so consistently. Our Margins participants emulated the process of specifying safety factors within an optimization framework such as GPkit. Margins are not so flexibly set in practice. Instead, they are generally fixed at an industry-standard value. Similarly, simulations to check failure rates are more generally performed after a solution has been decided upon, not during a single designer's rapid iteration through designs. Both the Margin and Control conditions of our experiment put current practices on a much faster timescale; caution should be taken equating these results with current design practices. The optimization involved in Margin, as well as the ability to control uncertainty parameters, led to higher quality designs than those of Control participants, though Margin participants were still able to find poor quality designs far away from the Pareto frontier.

Judging just by what participants saw on their screen, the Control case had an easier time reaching the reward regions. However, this is due to the method in which uncer-

tainty is incorporated into the mathematical model—since the uncertain variables are directly modified to be in their worst case of the uncertainty accounted for, the performance given by the model is the performance under worst case conditions. We presented this performance to participants to better simulate how designers would view each tool. To be able to compare the underlying data however, we needed to "nominalize" the data, which meant rerunning the model with optimized fixed design parameters with uncertainty parameters set to the nominal values used by the Control condition. This workflow on the experimenter's part implies the need for an automated functionality to compare designs optimized for various conditions; practitioners also noted the need to easily test performance on "off-design" cases.

The Gamma Slider and Performance Slider conditions mimic two ways designers could use robust optimization to explore the design space, and the consistent quality of their Pareto frontiers implies that the methods can produce a high likelihood of Pareto optimality without requiring much skill. Given the mathematical formulation of robust optimization, this is no surprise. A random sample of conditions is an approximation of the bounds robust optimization is designed to optimize for; the failure rate returned by the random sample is a less accurate representation of how much uncertainty is accounted for than the robust optimization's own parameter bounds. This turns the experiment into a game of finding uncertainty parameters that overfit the controlled set of one hundred random samples. A designer mimicking this process in practice would set the bounds of both the Monte Carlo simulation and the uncertainty parameters of robust optimization; however, a probabilistic simulation analysis does not make sense if the designer can choose the space of uncertainty optimized for. Robust optimization automates away the mathematical necessity of performing Monte Carlo simulations over direct design parameters. In practice, we would expect Monte Carlo simulations to still be used to provide additional legitimacy to designs for stakeholders with less familiarity with robust optimization practices, and for uncertain parameters not representable within a convex model.

Robust optimization's most apparent advantage becomes clearer later in the design process—the expressivity it provides designers to build models that are detailed mir-

rors of their project-specific conceptions of uncertainty. However, this potential benefit would require a change in how GPkit is used; while some designers wanted to continuously update GPkit models as their designs proceeded past the conceptual stage, they felt little ability or incentive to do so, as their coworkers usually trusted more complex "high-fidelity" to be more legitimate.

Trust in GPkit models of various designs does need to be built; not many designers would be willing to use the values determined as optimal directly from a GPkit solve without first validating the model in other software. However, late-stage GPkit models have been able to accurately predict the performance of an airplane prototype, such as with the Jungle Hawk Owl [11, 10], whose designers built a plane fully modelled in GPkit, and found their built performance remarkably close to model estimates. However, to encourage adoption of robust optimization in GPkit, improvements in design quality must be evident even at early conceptual stages. This study provides evidence that robust optimization can have a dramatic effect, even with a simple conceptual model.

Chapter 6

Conclusions

This study provides evidence for the importance of accounting for uncertainty early in the design process. A lack of uncertainty formulation within a design model can require external, imperfect metrics of uncertainty testing, such as Monte Carlo simulations, and the iteration modeling process is thus less likely to produce high quality designs. Simple uncertainty formulation within a design model, such as multiplying a variable by a safety factor, can create overly conservative designs or make worthwhile designs appear infeasible. However, most designers do not know alternative methods of accounting for uncertainty, or consider those methods to be impractical for conceptual design.

Robust optimization provides stronger protections against uncertainty than safety factors, making it difficult for even inexperienced users to create non-robust designs. This is seen through the high quality of almost all our experimental participants' final designs relative to the combined Pareto frontier. We also provide two conceptualizations of uncertainty GPkit users could use robust optimization to represent. The first, represented by Performance Slider, is optimizing for the largest scaled uncertainty, creating an airplane that is as robust as possible for a particular performance. The second, represented by Gamma Slider, is optimizing for performance, creating an airplane that maintains a particular level of robustness while spending little on fuel. GPkit users who already consider uncertainty via Monte Carlo simulations of their designs will find robust optimization essentially automates the function of Monte Carlo simulation within it, reducing the necessity of running additional simulations on designs.

The human-subjects experiment was a game for novices, and so does not allow us to draw conclusions about how designers in practice might behave. However, even though robust optimization uncertainty parameters were difficult to understand conceptually, this barrier did not prevent novice participants from finding high quality solutions. The experiment also provides questions for future field studies: Do explicit formulations of uncertainty enable better conversations about it during conceptual design? How do multiple stakeholders interact with these tools and solutions to reach an agreement? Do the benefits found in this study extend to more complex solutions? How difficult is it for designers to transition from formulating uncertainty as safety factors to skillfully using robust optimization? Answering these questions will allow us to understand the potential of robust optimization as a method for accounting for uncertainty.

Appendix A

Questionnaire for Interviews

Questions were grouped into three broad categories:

(A) Background/General

(B) Integration/Communication

(C) Robustness

Questions were given approximately in this order, allowing for flexibility given the natural flow of conversation.

1. Tell me about the projects you are working on and your role within them. **(A)**
2. How and why did you start using GPkit? **(A)**
3. Think about a project you did that could have used GPkit, but didn't.
   (a) Why did the project not use GPkit? **(A)**
   (b) How did you integrate and optimize your systems? What tools did you use to integrate and optimize your systems? **(B)**
   (c) How long did the design process take? How many early stage iterations (i.e. early simulations) did you go through? How many late stage iterations (i.e. more detailed simulations, built objects) did you go through? **(C)**

(d) How closely did early simulations match the final object? **(C)**

(e) How many people were involved? How were they organized? **(B)**

(f) How did you evaluate the quality of your design during the process? After it was complete? **(C)**

4. Think about the last project you did with GPkit.

   (a) What stages of the project did you use GPkit during? **(B)**

   (b) How did you use GPkit to integrate and optimize your systems? What processes did GPkit replace, and which ones did it not replace? **(B)**

   (c) What tools did you use in addition to/before/after GPkit? **(B)**

   (d) How long did the design process take? How many early stage iterations (i.e. early simulations) did you go through? How many late stage iterations (i.e. more detailed simulations, built objects) did you go through? **(C)**

   (e) How closely did early simulations match the final object? **(C)**

   (f) How many people were involved? How were they organized? **(B)**

   (g) How did you evaluate the quality of your design during the process? After it was complete? **(C)**

5. Of the differences in the two projects we mentioned, which ones were related to GPkit? **(A)**

6. If you haven't used GPkit in major projects, why? **(A)**

7. What do you view as benefits of GPKit? **(A)**

8. What do you find to be lacking in GPkit? What features would you like to be added? **(A)**

9. What qualities of a project do you find make it better suited for GPkit? **(A)**

10. How do you moderate uncertainty? (i.e. do you prioritize accuracy in measurements of certain components versus others?) **(C)**

11. How do you encode uncertainty information into GPkit? **(C)**

12. How does your initially designed model translate into the final built structure? What things change? How often are you re-solving your model/modifying the design? **(C)**
