APPROXIMATION FORMULATIONS FOR THE SINGLE
PRODUCT CAPACITATED LOT SIZE PROBLEM*

We consider two approximation formulations for the single product capacitated lot size problem. They correspond respectively to a restriction of the number of production policies and to the rounding of demands up to multiples of a constant. After briefly reviewing the literature within a new framework, we discuss the relations between these approximation formulations. Next, we provide relative error bounds and algorithms for solving the approximation problems. We demonstrate that these approximation formulations require a significantly smaller number of calculations than the original formulation, and that the relative error bounds are satisfactory for practical purposes.
1. Introduction

In this paper we study the following single product capacitated lot size problem:

\[
\begin{align*}
    &\text{(P)} \quad v(P) = \min \sum_{t=1}^{T} [h_t(I_t) + p_t(X_t)] + f(X_1, X_2, \ldots, X_T) \\
    \text{s.t.} \quad &I_{t-1} + X_t - I_t = d_t & t=1, 2, \ldots, T \\
    &0 \leq X_t \leq m_tK \quad t=1, 2, \ldots, T \\
    &l_t \leq I_t \leq u_t \quad t=1, 2, \ldots, T \\
    &I_0 = 0
\end{align*}
\]

where:

- \(X_t\) = production in period \(t\)
- \(I_t\) = inventory at the end of period \(t\),
- \(h_t(I_t)\) = inventory holding cost for \(0 \leq I_t \leq u_t\), and shortage cost for \(l_t \leq I_t < 0\) if \(l_t < 0\), in period \(t\),
- \(p_t(X_t)\) = variable production cost to produce \(X_t\) units in period \(t\),
- \(d_t\) = demand in period \(t\),
- \(m_tK\) = capacity available in period \(t\); \(m_t\) is a given non-negative integer and \(K\) is a known constant,
- \(l_t\) = lower bound on inventory in period \(t\) (-\(l_t\) is the upper bound on the number of backorders in period \(t\) if \(l_t < 0\)),
- \(u_t\) = upper bound on inventory in period \(t\), and
- \(f(X_1, \ldots, X_T)\) = cost penalty usually associated with changes in production quantities. In section 2 we will discuss several forms of \(f(\cdot)\).

Problem (P) is of interest for several reasons. In practice, it is useful in situations where similar items share the same productive resources and can be aggregated into a single product. From a theoretical point of
view, the analysis of the single item problem has been used to study the computational complexity of more general production problems and to gain insight for developing algorithms for such problems. References [1] to [4], [8], [10] to [17], [19], and [22] provide exact algorithms for a variety of single item capacitated lot size problems.

In this paper we concentrate on approximation formulations to (P) because the latter has been shown to be NP-hard ([5]) except for very special instances ([2] and [4]). We provide fast algorithms to solve the approximation problems and show that the worst case error bounds should be acceptable for most practical instances.

**Approximation Problems**

We analyze two approximation problems. The first is inspired by practical situations where production in any period is restricted to be equal to a multiple of K. That is, in period $t$, $X_t$ can only assume a value in the set $\{0, K, 2K, \ldots, m_t K\}$. This is the case, for example, when there are n machines, numbered 1 to n, whose capacities are multiples of K; in each period, machine i can be used only if machine j, for $j < i$, is being fully utilized. The restricted production policy problem is written as follows:

$$\text{Min} \sum_{t=1}^{T} \left[ h_t(I_t) + p_t(X_t) + f(X_1, X_2, \ldots, X_T) \right]$$

s.t. $I_{t-1} + X_t - I_t = d_t$ \quad $t=1, 2, \ldots, T$

$l_t \leq I_t \leq u_t$ \quad $t=1, 2, \ldots, T$

$X_t \in \{0, K, 2K, \ldots, m_t K\}$ \quad $t=1, 2, \ldots, T$

$I_0 = 0$

We provide in section 5, $O(m^2 T^2)$, $O(m T^2)$, $O(m m^3 T^2)$, and $O(m^2 n^2 T^2)$ algorithms
to solve (RPP) depending on the functional forms of the objective function, where \( m \) and \( n \) are respectively the maximum of \( m_t \) for \( t=1,2,...,T \) and the total number of machines available. Note that \( n \leq m \) and that if the capacity of each machine is \( qK \), then \( m = qn \).

The second approximation formulation is based on the "softness" of the demand constraints. That is, if the standard deviation of the forecast errors is large enough to justify rounding the demands up to the nearest multiple of \( K \) then the resulting problem (RUD), described below, can be interpreted as an approximation of (P).

Let \( d'_t = \left\lfloor \sum_{\tau=1}^{t} d_{\tau} \right\rfloor - \left\lfloor \sum_{\tau=1}^{t-1} d_{\tau} \right\rfloor \) for \( t=1,2,...,T \), where \( \sum_{\tau=1}^{t} d_{\tau} = 0 \) and \( \left\lfloor a \right\rfloor \) denotes the smallest multiple of \( K \) greater than or equal to \( a \). The approximation formulation with demands rounded-up to the nearest multiple of \( K \) is written as follows:

\[
(RUD) \quad v_{RUD} = \min \left\{ \sum_{t=1}^{T} \left[ h_t(I_t) + p_t(X_t) \right] + f(X_1, X_2, ..., X_T) \right\}
\]

s.t. \( I_{t-1} + X_{t} - I_{t} = d'_t \quad t=1,2,...,T \)

\( \ell_t \leq I_t \leq u_t \quad t=1,2,...,T \)

\( 0 \leq X_t \leq m_t K \quad t=1,2,...,T \)

\( I_0 = 0 \)

If \( K \) is smaller than or is of the same magnitude as the standard deviation of the forecast error in every period, to solve (RUD) may be as meaningful as to solve (P). As we show in section 3, (RUD) and (RPP) are equivalent under mild assumptions. Therefore, the same fast algorithm to solve (RPP) can be used to derive a solution to (RUD).

The plan of this paper is as follows. In section 2 we briefly review the literature categorized in terms of the different functional forms of \( f(\cdot) \).
and present a list of assumptions and measures of computational complexity of the existing algorithms. In particular we introduce a unified functional form of \( f(\cdot) \) that subsumes the three forms previously used in the literature. In section 3 we establish the desired relations between (RPP) and (RUD). In section 4 we compute the worst case error bound when (RPP) is used as an approximation to (P). Finally, in section 5 we provide algorithms to solve (RPP) and compute a measure of their computational complexity. Concluding this section, we make the following assumptions that will hold throughout the paper:

\[ p_t(X_t) \text{ is non-decreasing for } t=1,2,...,T; \]

\[ h_t(I_t) \text{ is non-decreasing for } I_t \geq 0 \text{ and non-increasing for } I_t \leq 0 \text{ for } t=1,2,...,T. \]
2. Brief Review of the Literature

In this section we review and classify a representative sample of the research done on problem (P) in terms of the functional form of \( f(\cdot) \). Four categories are identified. They are not necessarily mutually exclusive; rather, they reflect an increase in generality.

(i) Sequence-independent Set-up Costs

\[
\text{(Fl)} \quad f(X_1, X_2, \ldots, X_T) = \sum_{t=1}^{T} s_t \delta(X_t)
\]

where

\[
\delta(X_t) = \begin{cases} 
1 & \text{if } X_t > 0 \\
0 & \text{otherwise}
\end{cases}
\]

and \( s_t \) is the set-up cost in period \( t \).

Problems in this category are formulated by using in (P) the form (Fl) of \( f(\cdot) \). Florian and Klein [3] characterized the optimal solutions of problems in this class assuming \( \lambda_t = 0, u_t = \infty, \) and \( p_t(\cdot) \) and \( h_t(\cdot) \) concave. For \( m_t = 1 \), i.e. constant capacity, they derived an \( O(T^4) \) algorithm. For the same class of problems, but with \( m_t \neq 1 \), Lambert and Luss [12] presented an \( O(m^2T^4) \) algorithm (where \( m = \max_{t=1,\ldots,T} m_t \)).

Jagannathan and Rao [8] derived an \( O(m^2T^4) \) algorithm to solve (P) with \( p_t(\cdot) \) piecewise concave, reflecting the difference in costs between regular and overtime labor, where the breakpoints are multiples of a constant. Also, for a piecewise concave \( p_t(\cdot) \) arising out of the use of multiple identical machines, Lipman [15] reported an \( O(T^5) \) algorithm for (P) with \( \lambda_t = 0 \) and \( u_t = K = \infty \). Assuming \( h_t(\cdot) \) is concave on \((-\infty,0] \) and \([0,\infty) \), Florian and Klein [3] and Jagannathan and Rao [8] showed that their algorithms with no backorder allowed can be easily extended for the case where backorders must be satisfied within \( \alpha \) periods. This condition has been previously used by Zangwill [22] for (P) with \( \lambda_t = 0 \) and \( u_t = K = \infty \). Further, for \( h_t(\cdot) \) concave on \((-\infty,0] \) and \([0,\infty) \),
K = ∞ and either $u_t = ∞$ and $l_t = 0$ or $u_t = 0$ and $l_t = ∞$, Love [16] provided a characterization of optimal solutions and an $O(T^3)$ algorithm. Swoveland [19] generalized Love's characterization to the capacitated lot size problem with piecewise concave $p_t(\cdot)$ and $h_t(\cdot)$. When the breakpoints of $p_t(\cdot)$ are written as multiples of a constant, Swoveland showed that the computational complexity of his algorithm is $O(m^2Q^2T^4)$, where $Q$ is the maximum number of breakpoints of $h_t(\cdot)$.

When the production capacities are neither constant nor multiples of a constant, problem (P) is usually NP-hard. Florian et al [4] discussed the computational complexity of this problem. Bitran and Yanasse [2] studied several cases with $p_t(\cdot)$ and $h_t(\cdot)$ linear and proposed polynomial algorithms when the parameters of problem (P) satisfied certain special conditions.

Exponential algorithms have also been developed for the problem with general capacity constraints on production. Baker et al [1] provided an $O(2^T)$ branch and bound algorithm for $l_t = 0$, $u_t = ∞$, $p_t(X_t) = pX_t$, $h_t = hI_t$, $X_t ≤ C_t$, $t=1,2,...,T$. A similar type of algorithm was developed by Lambrecht and Vander Eeken [13] with almost identical conditions except that $p_t(X_t) = p_tX_t$ and $h_t(I_t) = h_tI_t$.

(ii) Single Machine/Sequence-dependent Set-up Costs

Problems of type (P) in this category assume the existence of a single machine and have the following form of $f(\cdot)$ which incorporates sequence-dependent as well as sequence-independent set-up costs:

\[(F2) \quad f(X_1, X_2, \ldots, X_T) = \min_{Y_t \in \{0,1\}} \sum_{t=1}^{T} (s_tY_t + e_tZ_t)\]

s.t. $Y_t ≥ δ(X_t)$

$Z_t ≥ Y_t - Y_{t-1}$

$Y_t$ and $Z_t \in \{0,1\}$

$Y_0 = 0$
where
\[
Y_t = \begin{cases} 
1 & \text{if the machine is on in period } t, \\
0 & \text{otherwise},
\end{cases}
\]
\[
Z_t = \begin{cases} 
1 & \text{if the machine state changes from off to on in period } t, \\
0 & \text{otherwise},
\end{cases}
\]
e_t = \text{sequence-dependent start-up cost in period } t, \text{ and}
\]
s_t = \text{cost of having the machine on in period } t; \text{ this is a sequence-independent cost. For example, } s_t \text{ may represent a rental fee.}

Karmarkar et al. [10] introduced this model and pointed out two advantages of defining \( Y_t \leq \delta(X_t) \) rather than \( Y_t = \delta(X_t) \) in (F2). First, in this formulation, the machine may be on whether or not there is production. This strategy can be more economical in some cases since the company need not incur the sequence-dependent costs. Second, unlike the case where \( Y_t \) is required to be equal to \( \delta(X_t) \), \( f(X_1, X_2, \ldots, X_T) \) is concave.

(iii) Production Smoothing

Instead of considering sequence-dependent set-up costs, the third category of functions \( f(\cdot) \) incorporates a penalty for changes in the production level. (F3) is written as follows:

\[
(F3) \quad f(X_1, X_2, \ldots, X_T) = \sum_{t=1}^{T} [s_t \delta(X_t) + f_t(X_t - X_{t-1})]
\]

If \( X_t \) is measured in labor hours, \( f_t(\cdot) \) penalizes variations of the labor force. Usually, such costs are associated with training, hiring and firing.

Problems of type (P) with the functional form (F3) for \( f(\cdot) \) are extensively studied in the literature. Authors have frequently assumed linear objective functions. Readers are referred to Silver [18] for a tutorial on this problem category.

For concave objective functions, Zangwill [23] addressed the production
smoothing problem with $e_t = 0$ and $u_t = K = \infty$. He characterized optimal solutions when $f_t(\cdot)$ is concave on $(-\infty,0]$ and $[0,\infty)$ and demands are non-decreasing, and provided a dynamic programming algorithm using a penalty function of the form

$$f_t(x_t-x_{t-1}) = \begin{cases} a_i & \text{if } x_t > x_{t-1} \\ 0 & \text{if } x_t = x_{t-1} \\ b_i & \text{if } x_t < x_{t-1} \end{cases}$$

Korganker [11] extended Zangwill's results for problem (P) to the case with constant production capacities, non-decreasing demands, $e_t = -\infty$ and $u_t = \infty$, and presented an exponential time algorithm.

(iv) **Multiple Machines/Sequence-dependent Set-up Costs**

Lasdon and Terjung [14] formulated problem (P) assuming the existence of multiple identical machines and sequence-dependent set-up costs. In their model, they used the following functional form for $f(\cdot)$:

$$(F4') f(x_1,x_2,\ldots,x_T) = \sum_{t=1}^{T} c_t \max(x_t-x_{t-1},0)$$

where $c_t$ is the cost of starting a machine in period $t$, $x_0 = 0$, and $x_t$ is an integer quantity representing the number of machines utilized in period $t$.

Schrage [17] provided an $O(m^3T^2)$ algorithm to solve that problem.

In this paper we consider a more general form of $f(\cdot)$, designated as (F4), and defined below; (F4) is more general in the sense that its feasible set contains those of (F1), (F2), and (F4') and that of (F3) whenever the production quantities are restricted to integral numbers. It allows for fractional production and for keeping the machines on even if they are not being used. It is useful to note that this type of formulation does not preclude the shut off of a machine, if it is not being used, in case such strategy is more economical.
(F4) \( f(X_1, X_2, \ldots, X_T) = \min \left[ \sum_{t=1}^{T} \sum_{i=1}^{n} s_{tit} + \sum_{t=1}^{T} f_t \left( \sum_{i=1}^{T} Y_{t-1,i} + \sum_{i=1}^{n} Y_{tit} \right) \right] \)

s.t. \( \sum_{i=1}^{n} q_{iK} Y_{tit} \geq [X_t] \quad t=1,2,\ldots,T \)

\( Y_{t1} \geq Y_{t2} \geq \cdots \geq Y_{tn} \quad t=1,2,\ldots,T \) \hfill (2.1)

\( Y_{tit} \in \{0,1\} \quad i=1,2,\ldots,n; \quad t=1,2,\ldots,T \)

where

\( n = \) number of machines, \( n \leq m \),

\( q_{iK} = \) capacity of the \( i \)th machine where \( q_i \) is a positive integer,

\( Y_{tit} = \begin{cases} 1 & \text{if machine } i \text{ is on in period } t, \text{ and} \\ 0 & \text{otherwise} \end{cases} \)

\( s_{tit} = \) sequence-independent cost of keeping machine \( i \) on in period \( t \), and

\( f_t(a,b) = \) cost of changing the number of machines on from \( a \) to \( b \).

Note that constraints (2.1) require machines 1,2,\ldots,i to be on whenever machine \( i+1 \) is on for \( i=1,2,\ldots,n-1 \).

The functional form (F4) of \( f(\cdot) \) will be used in sections 3 and 4. The following proposition will be useful in our development. Let \( J_j \) denote the interval \( \left[ \sum_{i=1}^{j} q_{iK}, \sum_{i=1}^{j-1} q_{iK} \right] \) for \( j = 1,2,\ldots,n \) and \( t=1,2,\ldots,T \), where \( \sum_{i=1}^{n} q_{iK} = 0 \). By using an argument similar to the one used by Karmarkar et al in [10] we can prove that:

**Proposition 2.1:** The functional form (F4) of \( f(\cdot) \) is concave on \( \prod_{t=1}^{T} J_j \) for \( j=1,2,\ldots,n \) and \( t=1,2,\ldots,T \).

Assume that \( \ell_t = 0 \), \( u_t = \infty \) for \( t=1,2,\ldots,T \), and the objective function of (P) is given by \( \sum_{t=1}^{T} s_t \delta(X_t) + \sum_{t=1}^{T} v_t X_t + \sum_{t=1}^{T} h_t I_t \) where the \( v_t \)'s are non-increasing, then there is an optimal solution which satisfies \( I_{t-1} X_t (m_{K-X_t}) = 0 \).
for $t=1,2,...,T$ (see [1] and [2]). The following proposition is an extension of this theorem to problem (P) where $f(X_1,X_2,...,X_T)$ takes the functional form (F4).

Proposition 2.2: Assume that for $t=1,2,...,T$, $\lambda_T = 0$, $\gamma_T = \infty$, $P_t(X_t) = v_t X_t$, the $v_t$'s are non-increasing, and $f(X_1,X_2,...,X_T)$ takes the functional form (F4) in (P). Then there is an optimal solution which satisfies:

$$\sum_{t=1}^{T} X_t \prod_{j=1}^{n} (\sum_{i=1}^{j} q_i X_i - X_t) = 0 \quad \text{for } t=1,2,...,T.$$ 

To conclude this section we summarize in Table 2.1 the main characteristics of the problems addressed and the algorithms presented in this paper and in those cited in our brief review of the literature.

(a) The breakpoints are integers.
(b) g_t: non-decreasing concave; f_t: non-negative piecewise linear convex and continuous and the breakpoints occur at equal interval K.
(c) The breakpoints are multiples of K.
(d) Q: maximum number of inventory breakpoints.
(e) Lagrangean relaxation method.
(f) The algorithm is not specified.
(g) Demands are assumed to be non-decreasing. The number of calculations is exponential.
(h) The algorithm is not specified. X_t is integer for t=1,2,...,T.
(i) The number of calculation is \( O(m^2T^2) \) if set-up times are incorporated.
(j) Approximation algorithm. n: the number of machines.
(k) Demands are multiples of K.
3. **Relation Between (RPP) and (RUD)**

In this section we explore relations between (RPP) and (RUD). In particular, we show that under mild assumptions the two problems have common optimal solutions. Throughout this section and the next we assume that the functional form of $f(\cdot)$ is given by (F4).

As a vehicle to study the relation between (RPP) and (RUD) we introduce the following problem which is the restricted-production version of (RUD):

$$
\begin{align*}
(RUD')_{t,RUD'} &= \min \left\{ \sum_{t=1}^{T} \left[ h_t(I_t) + p_t(X_t) \right] + f(X_1, \ldots, X_T) \right\} \\
\text{s.t.} & \quad I_{t-1} + X_t - I_t = d'_t \\
& \quad t, I_t \leq u_t \\
& \quad X_t \in \{0, K, 2K, \ldots, m_t K\} \\
& \quad I_0 = 0
\end{align*}
$$

For convenience of notation we assume that the following substitutions have been made

$$
\begin{align*}
I_t &= \sum_{\tau=1}^{t} (X_\tau - d_\tau) \text{ in (P) and (RPP) and} \\
I_t &= \sum_{\tau=1}^{t} (X_\tau - d'_\tau) \text{ in (RUD) and (RUD').}
\end{align*}
$$

Hence, the feasible set $S$ of (RUD) can be written as

$$
S = \{X \in \mathbb{R}^T \mid \sum_{\tau=1}^{t} d'_\tau + \ell_t \leq \sum_{\tau=1}^{t} X_\tau \leq \sum_{\tau=1}^{t} d'_\tau + u_t, X_t \leq m_t K, X_t \geq 0 \text{ for } t=1,2,\ldots,T \}.
$$

Assume that $\ell_t$ and $u_t$ are multiples of $K$ for $t=1,2,\ldots,T$ and let
\[ W = \{ w \in \mathbb{R}^{2T} \mid w = (a_1, a_2, \ldots, a_T, b_1, b_2, \ldots, b_T) \text{ where } a_t \in \{1, 2, \ldots, m_t\}, \]

\[ b_t \in \{1, 2, \ldots, (u_t - \ell_t)/K\} \text{ if } u_t > \ell_t, \text{ and } b_t = 0 \text{ if } u_t = \ell_t \text{ for } t = 1, 2, \ldots, T \}

\[ S_w = \{ x \in \mathbb{R}^T \mid K(a_t - 1) \leq x_t \leq Ka_t, \]

\[ \sum_{\ell=1}^{t} d_{t}^\ell + \ell_{t} + K(b_{t} - 1) \leq \sum_{\ell=1}^{t} x_{t} \leq \sum_{\ell=1}^{t} d_{t}^\ell + \ell_{t} + Kb_{t} \]

if \( b_{t} \geq 1 \), and \( \sum_{\ell=1}^{t} x_{t} = \sum_{\ell=1}^{t} d_{t}^\ell + \ell_{t} \) if \( b_{t} = 0 \) for \( t = 1, 2, \ldots, T \)

and \( (a_1, a_2, \ldots, a_T, b_1, b_2, \ldots, b_T) = w \).

Therefore, \( S = \bigcup_{w \in W} S_w \). The next proposition will play an important role in establishing the relationships between (RUD), (RUD'), and (RPP).

**Proposition 3.1:** If \( \ell_t \) and \( u_t \) are multiples of \( K \) for \( t = 1, 2, \ldots, T \), then the extreme points of \( S_w \) are multiples of \( K \).

**Proof:** Let \( S'_w = \{ x' \in \mathbb{R}^T \mid x' = x/K \text{ for } x \in S_w \} \). \( S'_w \) can be written as \( S'_w = \{ x' \in \mathbb{R}^T \mid Ax \leq b, x' \geq 0 \} \). It is not difficult to show that \( A \) is a totally unimodular matrix and \( b \) is an integer vector. Therefore the extreme points of \( S_w \) are multiples of \( K \) (see [6], [7], and [21]). Since there is a one to one correspondence between the extreme points of \( S'_w \) and \( S_w \) the desired results follows.

**Proposition 3.2:** Assume that \( \ell_t \) and \( u_t \) are multiples of \( K \) and that \( h_t(I_t) \) and \( p_t(X_t) \) are piecewise concave functions whose breakpoints are multiples of \( K \). Then, \( v_{\text{RUD}} = v_{\text{RUD'}} \), and the optimal solutions of (RUD') are also optimal in (RUD).

**Proof:** Problem (RUD) can be written as:

\[ \min_{w \in W} \min_{x \in S_w} \{ \sum_{t=1}^{T} h_t[\sum_{t=1}^{T} (X_t^t - d_t^{t})] + \sum_{t=1}^{T} p_t(X_t) + f(X_1, X_2, \ldots, X_T) \} \]
By proposition 2.1, \( f(X_1, X_2, \ldots, X_T) \) is concave on \( S_w \). Therefore, the objective function of (RUD) is concave on \( S_w \). This fact together with proposition 3.1 implies that there is an optimal solution \( X \) in (RUD) whose components are multiples of \( K \). Hence, \( X \) is feasible in (RUD') and since both problems have the same objective function, and the feasible set of (RUD') is contained in the feasible set of (RUD), it follows that \( v_{RUD'} = v_{RUD} \); hence the optimal solutions of (RUD') are also optimal in (RUD).

In order to establish the relation between (RPP) and (RUD) we first prove the following result that relates (RPP) and (RUD').

**Proposition 3.3:** Assume that \( h_t(I_t) = h_t I_t \), \( \ell_t \) is a multiple of \( K \) and \( u_t = \infty \) for \( t = 1, 2, \ldots, T \). Then, \( X \) is optimal in (RUD') if and only if it is optimal in (RPP). Moreover,

\[
v_{RUD'} = v_{RPP} - \sum_{t=1}^{T} h_t \left( \sum_{t=1}^{T} d_t - \sum_{t=1}^{T} d_t \right).
\]

**Proof:** Suppose that \( X \in \mathbb{R}^T \) is feasible in (RUD'). Then \( \sum_{t=1}^{T} X_t \geq \sum_{t=1}^{T} d_t' + \ell_t \).

By the definition of \( d_t' \), \( \sum_{t=1}^{T} X_t \geq \sum_{t=1}^{T} d_t' + \ell_t \geq \sum_{t=1}^{T} d_t + \ell_t \). Hence, \( X \) is feasible in (RPP). Conversely, suppose \( X \) is feasible in (RPP). Then,

\[
\sum_{t=1}^{T} X_t = \sum_{t=1}^{T} d_t' + \ell_t.
\]

By the definition of \( d_t' \), \( \sum_{t=1}^{T} d_t' + \ell_t \leq \sum_{t=1}^{T} d_t + K + \ell_t \leq \sum_{t=1}^{T} X_t + K.
\]

Since \( X_t, d_t', \) and \( \ell_t \) are multiples of \( K \) for \( t = 1, 2, \ldots, T \),

\[
\sum_{t=1}^{T} X_t = \sum_{t=1}^{T} d_t' + \ell_t.
\]

Therefore, \( X \) is feasible in (RUD') and the feasible set of (RPP) and (RUD') are the same. Since the objective function values of (RPP) and (RUD') differ by the constant \( \sum_{t=1}^{T} h_t \left( \sum_{t=1}^{T} d_t - \sum_{t=1}^{T} d_t \right) \) for any given feasible solution, the desired result follows.

**Corollary 3.1:** Assume that for \( t = 1, 2, \ldots, T \), \( \ell_t \) is a multiple of \( K \), \( u_t = \infty \), \( h_t = h_t I_t \), and \( p_t(X_t) \) is a piecewise concave function whose breakpoints are multiples of \( K \). Then, if \( X \in \mathbb{R}^T \) is optimal in (RPP), \( X \) is optimal in (RUD)
and

\[ v_{\text{RUD}} = v_{\text{RPP}} - \sum_{t=1}^{T} \left( \sum_{t=1}^{T} d_{t1} - \sum_{t=1}^{T} d_{t} \right) h_{t}. \]

The results of this section show that under mild conditions, (RUD), (RUD') and (RPP) are essentially equivalent. Therefore, if the forecast errors of the demand are of the same magnitude as \( K \), the practitioner may opt to solve one of these three approximation problems instead of (P). We show in the next section that even when this is not the case, these problems are good approximations to (P).
4. Error Bounds for Approximations to Problem (P)

In this section we relate the optimal values of (RPP), (RUD'), (RUD) to the optimal value of (P). Suppose $\ell_t$ and $u_t$ are multiples of $K$ for $t=1,2,\ldots,T$. Let $H_t (P_t)$ be the maximum value of the differences in $h_t(\cdot)$ ($p_t(\cdot)$) for two consecutive multiples of $K$, i.e.,

$$H_t = \max\{|h_t(Kq_t+K) - h_t(Kq_t)| \text{ for } q_t \in \{\ell_t/K, (\ell_t+K)/K, \ldots, (u_t-K)/K\}\}$$

$$P_t = \max\{p_t(Kq_t+K) - p_t(Kq_t) \text{ for } q_t \in \{0,1,\ldots,m_t-1\}\} \text{ for } t=1,2,\ldots,T$$

and let

$$Q = \max\{\sum_{t=1}^{T} [p_t(X_t)-p_t(X_t-Y_t)] \text{ for } X_t \in \{K,2K,\ldots,m_tK\} \text{ for } t=1,\ldots,T \text{ and } \sum_{t=1}^{T} Y_t < K\}$$

Denote by $v(X)$ the objective function value of (P) or (RPP) when that function is expressed in terms of the production quantities.

The next proposition provides an error bound when an optimal solution of (RPP) is used as a solution to (P).

Proposition 4.1: Assume that (P) is feasible, and that $\ell_t$ and $u_t$ are multiples of $K$ for $t=1,2,\ldots,T$. Then, if $X^*_RPP$ is an optimal solution to (RPP), $v(X^*_RPP) - v_P \leq \sum_{t=1}^{T} (H_t+P_t)$.

Proof: Since (P) is feasible and has a bounded feasible set, it follows that (P) has an optimal solution, say $X$. Let

$$X'_t = \left[\sum_{t=1}^{T} X_t\right] - \left[\sum_{t=1}^{t-1} X_t\right] \text{ for } t=1,2,\ldots,T.$$

It suffices to show that $X' = (X'_1,\ldots,X'_T)$ is feasible in (RPP) and that

$$v(X') \leq v_P + \sum_{t=1}^{T} (H_t+P_t) \text{ since } v(X^*_RPP) \leq v(X') \text{ trivially implies that } v(X^*_RPP) \leq v_P + \sum_{t=1}^{T} (H_t+P_t).$$

We first prove that $X'$ is feasible in (RPP). Note that, for $t=1,2,\ldots,T$,

$$\sum_{t=1}^{T} X'_t = \sum_{t=1}^{T} \left[\sum_{t=1}^{T} X_t\right] - \sum_{t=1}^{T} \left[\sum_{t=1}^{t-1} X_t\right] \geq \sum_{t=1}^{T} X_t > \sum_{t=1}^{T} d_t + \ell_t.$$
of $K$, $\sum_{t=1}^{T} X'_t > \sum_{t=1}^{T} d'_t + \ell_t$, $\sum_{t=1}^{T} X'_t = \sum_{t=1}^{T} d'_t + \ell_t - K$. To show that $\sum_{t=1}^{T} X'_t < \sum_{t=1}^{T} d'_t + u_t$, suppose that $\sum_{t=1}^{T} X'_t > \sum_{t=1}^{T} d'_t + u_t + K$. Then,

$$\sum_{t=1}^{T} X'_t > \sum_{t=1}^{T} X_t - K = \sum_{t=1}^{T} X'_t - K > \sum_{t=1}^{T} d'_t + u_t > \sum_{t=1}^{T} d'_t + u_t,$$

contradicting the feasibility of $X$ in (P). Since $\sum_{t=1}^{T} X'_t$, $\sum_{t=1}^{T} d'_t$ and $u_t$ are multiples of $K$, it follows that $\sum_{t=1}^{T} X'_t < \sum_{t=1}^{T} d'_t + u_t$. It remains to show that $X'_t \leq K m_t$ for $t=1,2,...,T$. Suppose that $X'_t > K (m_t + 1)$ for $t=1,2,...,T$. Then,

$$X'_t = \sum_{t=1}^{t-1} X'_t - \sum_{t=1}^{t-1} X_t > \sum_{t=1}^{t-1} X'_t - K > \sum_{t=1}^{t-1} d'_t + u_t > \sum_{t=1}^{t-1} d'_t + u_t,$$

contradicting the feasibility of $X$ in (P).

Therefore, $X'$ is feasible in (RPP).

It remains to show that $v(X') \leq v_p + \sum_{t=1}^{T} (H + P_t)$. By construction of $X'$, $\sum_{t=1}^{T} X'_t \leq \sum_{t=1}^{T} X_t$ for $t=1,2,...,T$. Hence, by (P4), $f(X'_1,X'_2,...,X'_T) \leq f(X_1,X_2,...,X_T)$. Since $p_t(\ast)$ is non-decreasing and $X'_t \leq X_t + K$ with $X'_t$ being a multiple of $K$,

$$p_t(X'_t) \leq p_t(X_t) + P_t$$

holds for $t=1,2,...,T$. Still by construction of $X'$,

$$\sum_{t=1}^{T} X'_t \leq \sum_{t=1}^{T} X_t + K$$

implying that $h_t(\sum_{t=1}^{T} X'_t - \sum_{t=1}^{T} d'_t) \leq h_t(\sum_{t=1}^{T} X_t - \sum_{t=1}^{T} d'_t + H_t)$. Therefore, $v(X') \leq v_p + \sum_{t=1}^{T} (H + P_t)$.

Proposition 3.3 and Proposition 4.1 imply the following corollary.

**Corollary 4.1:** Assume that (P) is feasible and that $h_t(I_t) = h_t I_t$, $\ell_t$ is a multiple of $K$ and $u_t = \infty$ for $t=1,2,...,T$. Then if $X^*_{RUD'}$ is an optimal solution of (RUD'),
The error bound for the case when an optimal solution to (RUD) is used as a solution to (P) can be computed as follows. Let $X^*_\text{RUD}$ be an optimal solution to (RUD).

**Proposition 4.2:** If (P) is feasible, $\ell_t$ is a multiple of $K$, $u_t = \infty$, and $h_t(I_t - t^t_t) = h_t^t t$ for $t=1,2,...,T$, then $v(X^*_\text{RUD}) - v_p \leq K( \sum_{t=1}^{T} h_t ) + Q$ and the bound is tight.

**Proof:** Since (P) is feasible and its feasible set is bounded, it has an optimal solution $X$. To prove the result we will construct a feasible solution $X'$ to (RUD) from $X$ and show that $v(X') - v_p \leq K( \sum_{t=1}^{T} h_t ) + Q$. Since $h_t(I_t)$ is linear for $t=1,2,...,T$ and $X'$ is feasible in (RUD), $v(X^*_\text{RUD}) \leq v(X')$. Hence, it will follow that $v(X^*_\text{RUD}) - v_p \leq K( \sum_{t=1}^{T} h_t ) + Q$.

Let $(X^t_{t_1}, X^t_{t_2},...,X^t_{t_q})$ be the sequence of positive production quantities of $X$. Set $X^t_{t_1} = 0$ if $t \not\in \{t_1,t_2,...,t_q\} \Delta R$. Determine $X'_t, X'_{t_1},...,X'_{t_q}$ by the following recursion equations.

1. $a_{t_1}^t = K$
2. $X'_{t_1} = \min\{X^t_{t_1} + a_{t_1}^t, [X^t_{t_1}]\}$ and
3. $a_{t_1+1}^t = a_{t_1}^t - (X'_{t_1} - X^t_{t_1})$ for $i=1,2,...,q$.

Then, the following relations hold for $t=1,2,...,T$.

1. $X'_t \geq X_t$
2. $[X'_t] = [X_t]$
3. $0 \leq X'_t \leq m_t K$,
4. $\sum_{t=1}^{t} X'_t \leq \sum_{t=1}^{t} X_t + K$, and
5. If $\sum_{t=1}^{t} X_t + K > \sum_{t=1}^{t} X'_t$, then $[\sum_{t=1}^{t} X'_t] = \sum_{t=1}^{t} X'_t$. 

\[ v(x^*_\text{RUD}) - v_p \leq \sum_{t=1}^{T} (H_t + P_t). \]
(i) through (iv) are easy to show. To prove (v), suppose that 
\[ \sum_{t=1}^{t} X_{t} + K > \sum_{t=1}^{t} X'_{t} \] for some \( t \). Let \( i = \max\{j | t_j \leq t\} \). Since \( X'_{t} = X_{t} = 0 \) 
for \( t \not\in \mathbb{R} \), it suffices to show that \( \sum_{j=1}^{i} X_{j} = \sum_{j=1}^{i} X'_{j} \). By (a) and (c), 
\[ a_{t, i+1} = a_{t, i} - (X'_{t} - X_{t}) = K - \sum_{j=1}^{i} (X'_{j} - X_{j}) > 0. \] By (c) and (i), 
\[ 0 < a_{t, i+1} \leq a_{t, i} \leq \ldots \leq a_{t, i} \]. (c) and \( a_{t, i} > 0 \) imply \( X'_{i} < X_{i} + a_{t, i} \) for \( j=1,2,\ldots,i \). Therefore, (b) implies \( X'_{j} = [X_{j}] \) for \( j=1,2,\ldots,i \). Note that 
\[ \sum_{j=1}^{i} X_{j} + K > \sum_{j=1}^{i} X'_{j} = \sum_{j=1}^{i} [X_{j}]. \] Since \( K > \sum_{j=1}^{i} [X_{j}] - \sum_{j=1}^{i} X_{j} > 0 \), 
\[ \sum_{j=1}^{i} X_{j} = \sum_{j=1}^{i} [X_{j}] = \sum_{j=1}^{i} X'_{j}. \] 

Next, we prove that \( X' \) is feasible in (RUD). Since (iii) holds, it 
\[ t \sum_{t=1}^{t} X_{t} + K = \sum_{t=1}^{t} X'_{t}. \] Since \( \sum_{t=1}^{t} X_{t} \geq \sum_{t=1}^{t} d_{t} + l_{t} > \sum_{t=1}^{t} d'_{t} + l_{t} - K \) 
for \( t=1,2,\ldots,T \). Hence, two cases are possible:

**Case 1:** \( \sum_{t=1}^{t} X_{t} + K = \sum_{t=1}^{t} X'_{t}. \) Since \( \sum_{t=1}^{t} X_{t} \geq \sum_{t=1}^{t} d_{t} + l_{t} > \sum_{t=1}^{t} d'_{t} + l_{t} - K \) 
holds, \( \sum_{t=1}^{t} X'_{t} = \sum_{t=1}^{t} X_{t} + K > \sum_{t=1}^{t} d'_{t} + l_{t} \) for \( t=1,2,\ldots,T \). 

**Case 2:** \( \sum_{t=1}^{t} X_{t} + K > \sum_{t=1}^{t} X'_{t}. \) By (v), \( \sum_{t=1}^{t} X'_{t} = [\sum_{t=1}^{t} X_{t}] \). Since 
\[ \sum_{t=1}^{t} X_{t} = \sum_{t=1}^{t} d_{t} + l_{t} \text{ and } l_{t} \text{ is a multiple of } K, \] 
\[ \sum_{t=1}^{t} d'_{t} + l_{t} = \sum_{t=1}^{t} d'_{t} + \sum_{t=1}^{t} l_{t}. \] Therefore, \( \sum_{t=1}^{t} X'_{t} > \sum_{t=1}^{t} d'_{t} + l_{t}. \) 

It remains to show that \( v(X') - v_{p} \leq K(\sum_{t=1}^{t} h_{t}) + Q. \) (ii) implies
\( f(X'_1, X'_2, \ldots, X'_t) = f(X'_1, X'_2, \ldots, X'_t). \) (iv), the linearity of \( h_t(*) \) and the
definition of \( H_t \) imply \( h_t(\sum X'_t - \sum d_t) \leq h_t(\sum X'_t - \sum d_t) + K_h_t. \)

Also, (i), (ii), (iv), the monotonicity of \( P_t(*) \) and the definition of \( Q \)
imply that \( \sum P_t(X'_t) \leq \sum P_t(X_t) + Q. \) Therefore, \( v(X') \leq v_p + K(\sum h_t) + Q. \)

The following example shows that this bound is tight. Suppose that

\[ p_t(X_t) = vX_t, \quad \text{for } t = 1, 2, \ldots, T, \quad d_1 = \varepsilon, \quad \text{and } d_t = 0 \quad \text{for } t \neq 1. \]

Then, \( Q = Kv. \) Suppose \( \varepsilon \) is less than \( K. \) Then, \( X_1 = \varepsilon, X_t = 0 \) for \( t \neq 1 \) is optimal to (P) while \( X_1 = K, X_t = 0 \) for \( t \neq 1 \) is optimal to (RUD).

\[
v(X^*_\text{RUD}) - v_p = \sum_{t=1}^{T} h_t(K - \varepsilon) + v(K - \varepsilon) \leq K(\sum h_t) + Q - \varepsilon(\sum h_t + v). \]

As \( \varepsilon \to 0, \) \( v(X^*_\text{RUD}) - v_p \to K(\sum h_t) - Q \) tends to zero.

If \( Q \) is hard to calculate, then a weaker bound can be computed as

\[
v(X^*_RPP) - v_p \leq K(\sum h_t) + Q. \]

**Proposition 4.3:** Assume that for \( t = 1, 2, \ldots, T, \) \( \ell_t \) is a multiple of \( K, \) \( u_t = \infty, \)
\( h_t(I_t) = h_t \ell_t, \) and \( P_t(X_t) \) is a piecewise concave function with breakpoints which
are multiples of \( K. \) Then

\[
v(X^*_\text{RPP}) - v_p \leq K(\sum h_t) + Q. \]

**Proof:** The proposition follows immediately from Corollary 3.1 and
Proposition 4.2.

It is important to note that the error bounds described do not depend
on set-up related costs. This means that the approximations are particularly
good if the set-up costs are significant.

The relative error bound implied by proposition 4.3 can be fairly tight in practical settings. Assume that for \(t=1,2,\ldots,T\), \(\lambda_t = 0\), \(u_t = \infty\), \(m_t = m\), \(h_t(I_t) = h_t I_t\), \(p_t(X_t) = v_t X_t\). \(f(X_1, X_2, \ldots, X_T)\) takes the form of \((F')\), and denote the capacity utilization rate, \(\sum_{t=1}^{T} d_t / mTK\), by \(q\). In practice it is common to compute the holding costs as a fraction of \(v_t\), i.e., \(h_t = iv_t / T\) where \(i\) is the inventory carrying factor over the planning horizon \(T\). It reflects the opportunity cost of the capital tied up in inventory as well as other costs like handling, insurance, pilferage, etc. We have that

\[
V_{\text{P}} \geq \left( \min_{t=1,\ldots,T} \frac{v_t}{h_t} \right) \sum_{t=1}^{T} d_t = \left( \min_{t=1,\ldots,T} \frac{h_t T}{i} \right) \sum_{t=1}^{T} d_t = (\min_{t=1,\ldots,T} h_t) qaKT^2 / i.
\]

By proposition 4.3,

\[
v(X_{RPP}^*) - v_{\text{P}} \leq K \sum_{t=1}^{T} h_t + Q = K \sum_{t=1}^{T} h_t + K \max_{t=1,\ldots,T} v_t \leq KT(1+1/i) \max_{t=1,\ldots,T} h_t.
\]

Therefore

\[
\frac{v(X_{RPP}^*) - v_{\text{P}}}{v_{\text{P}}} \leq \frac{\max_{t=1,\ldots,T} h_t}{\min_{t=1,\ldots,T} h_t} \frac{KT(1+1/i)}{qmKT^2} = \frac{\max_{t=1,\ldots,T} h_t}{\min_{t=1,\ldots,T} h_t} \frac{1 + i}{qmT}.
\]

Typically \(i = 0.3\), \(T = 12\), and \(Q = .8\). In this case

\[
\frac{[v(X_{RPP}^*) - v_{\text{P}}]}{v_{\text{P}}} \leq (\max_{t=1,\ldots,T} h_t / \min_{t=1,\ldots,T} h_t) 0.14/m.
\]

Note that, if \(h_t = h\) for \(t=1,2,\ldots,T\), then the relative error bound is proportional to \(1/T\). If the planning horizon is partitioned into months, then the relative error bound is given by \(14/m\). However, if the planning
horizon is partitioned in weeks, then the relative error bound becomes $0.031/m$. Therefore, the finer the partition of the planning horizon, the tighter the bound will be.
5. **Algorithms to Solve (RPP)**

To simplify the explanation we first provide an algorithm to solve (RPP) with the functional form (F2) for \( f(s) \).

Let a point \((t,y,w)\) correspond to a state where the time period is \( t \), the cumulative production is \( Ky \) and

\[
w = \begin{cases} 
1 & \text{if the machine is on in period } t, \\
0 & \text{otherwise.} 
\end{cases}
\]

In the following algorithm \( S_t \) denotes the set of feasible points, in period \( t \), and \( g(t,y,w) \) denotes the cumulative costs from \((0,0,0)\) to \((t,y,w)\). Consider the following layered network \((N,A)\) where \( N = \bigcup_{t=1}^{T} S_t \) and \( A \) consists of the following arcs:

(i) from \((t,y,0)\) to \((t+1,y',1)\) if \( y < y' \leq y + m_{t+1} \),

(ii) from \((t,y,0)\) to \((t+1,y,0)\),

(iii) from \((t,y,1)\) to \((t+1,y',1)\) if \( y \leq y' < y + m_{t+1} \),

(iv) from \((t,y,1)\) to \((t+1,y,0)\),

where the origin of each arc must be in \( S_t \) and the destination in \( S_{t+1} \). Note that arc \(((t,y,1),(t+1,y,1))\) corresponds to the alternative that there is no production in period \( t+1 \) but the machine is on. The costs associated with the arcs defined in (i) - (iv) are, respectively:

(i) \[ h_{t+1}(Ky' - \sum_{\tau=1}^{t+1} d_{\tau}) + p_{t+1} [(y'-y)K] + s_{t+1} + e_{t+1} \]

(ii) \[ h_{t+1}(Ky - \sum_{\tau=1}^{t+1} d_{\tau}) \]

(iii) \[ h_{t+1}(Ky' - \sum_{\tau=1}^{t+1} d_{\tau}) + p_{t+1} [(y'-y)K] + s_{t+1} \delta(y'-y) \]

(iv) \[ h_{t+1}(Ky - \sum_{\tau=1}^{t+1} d_{\tau}) \]

The following algorithm solves a shortest path problem in \((N,A)\).
Step 0. Set $S_0 = \{(0,0,0)\}$, $g(0,0,0) = 0$ and $h_0 = p_0 = s_0 = e_0 = 0$. Let $S_t = \{(t,y,w) \mid 0 \leq y \leq \sum_{\tau=1}^{T} m_{\tau}, \ y \leq Ky - \sum_{\tau=1}^{T} d_{\tau} \leq u_t, \ y \text{ integer and } w \in \{0,1\} \}$ for $t=1,2,...,T-1$. Also, let $S_T = \{(T,y,w) \mid y \in \{0,1\}, \ y \leq Kg + T/K\}$ and $w \in \{0,1\}$ if $K_T < 0$ and $S_T = \{(T, y,w) \mid y \leq Kg + T/K, \ w \in \{0,1\} \}$ if $K_T > 0$.

Step 1. For $t = 0$ to $T-1$, compute
\[
g(t+1,y',w') = \min \{g(t,y,w) + h_{t+1}(Ky - \sum_{\tau=1}^{T} d_{\tau}) + p_{t+1}[(y'-y)K] + \sum_{\tau=1}^{T+1} s_{t+1} (y'-y) + e_{t+1}(1-w)w' \}
\]
\[\text{s.t. } (t,y,w) \in S_t \text{ and } y' - m_{t+1} \leq y \leq y', \]
for any $(t+1,y',w') \in S_{t+1}$.

It is not difficult to show that
\[
v_{RPP} = \min_{(T,y,w) \in S_T} g(T,y,w)
\]

The number of nodes in graph $(N,A)$ is at most $1 + \sum_{t=1}^{T} [2 \cdot (\sum m_{\tau}) + 1] \leq 1 + mT(T+1) + 2T$. The number of arcs incident to a node is at most $m+1$.

Therefore, the total number of steps in the above algorithm is $O(m^2 T^2)$.

Assume that $f(X_1,X_2,...,X_T)$ takes the functional form (F4). Essentially, the algorithm for this case is the same as the one just described for (F2). Let $w$ represent the number of machines kept on in period $t$, i.e. $w=0,1,2,...,n$. Then, the number of nodes is $O(nmT^2)$. Since the number of arcs incident to a node is $O(mn)$, the total number of calculation is $O(m^2 n^2 T^2)$. Note that if there are no sequence-dependent set-up costs in (F4), $w$ can be dropped from the description of the state in the dynamic recursions. Therefore, the number of calculations for this case is $O(m^2 T^2)$.

Assume that for $t=1,2,...,T$, $l_t = 0$, $u_t = \infty$ and $p_t(X_t) = v_t X_t$ and the $v_t$'s are non-increasing. Then, by proposition 2.2, there is an optimal solution
which satisfies 

\[ \prod_{t=1}^{n} \left( \sum_{j=1}^{J} q_{i,j} K - X_{t} \right) = 0 \quad \text{for} \quad t=1,2,\ldots,T \]

for the functional form (F4) and

\[ \prod_{t=1}^{n} \left( m_{t} K - X_{t} \right) = 0 \quad \text{for} \quad t=1,2,\ldots,T \]

for the functional form (F2).

Since we need to consider only \( O(n^2) \) arcs incident to a node for (F4) and two arcs for (F2), the total number of calculations is reduced to \( O(mn^3T^2) \) and \( O(mT^2) \) for (F4) and (F2), respectively.

Assume the sequence-dependent set-up costs are zero in (F4). For \( t=1,2,\ldots,T \), let \( C_t(X_t) \) be the cost associated with \( X_t \) and let \( C'_t(X_t) \) denote the piecewise linear function whose breakpoints occur on multiples of \( K \) with

\[ C'_t(X_t) = C_t(X_t) \quad \text{for any} \quad X_t \quad \text{which is a multiple of} \quad K. \]

If \( C'_t(X_t) \) is convex for \( t=1,2,\ldots,T \), we can use the algorithm proposed by Johnson [9] and Veinott [20] to solve (RPP) optimally. The algorithm takes \( O(mT^2) \) calculations if \( \lambda_t \geq 0 \) and \( O(mT^3) \) calculation if \( \lambda_t < 0 \).
6. **Conclusions**

The proposed approximation formulations cover a large class of problems and require a significantly smaller number of calculations than those required to solve optimally the original problem. The approximation formulation (RUD) is motivated by fluctuations and inaccuracy of demand forecasting. We claim that if the standard deviation of demands is larger than a scaling constant, to solve (RUD) is as meaningful as to solve the original problem (P). Since (RUD) and the other approximation formulation (RPP) are equivalent under mild conditions, (RUD) can be solved by the same algorithms provided for (RPP). We provide a validation of the approximation formulations (RPP), (RUD), and (RUD') through worst case analysis of the error bounds under the assumption that all inputs are accurate. Note that the algorithms for (RPP) are pseudopolynomial in the sense that they are polynomial with respect to a constant $m$ which is closely related to the scaling of the unit of demand quantities. A point to observe is that the relative error bound is proportional to $1/m$ while the order of calculations is proportional to $m$ or $m^2$. For practical purposes, we showed that there exists a satisfactory trade-off between them. This suggests that the combination of pseudopolynomial algorithms and the worst case analysis is fairly effective for the single product capacitated lot size problem. Our current research indicates that this approach can be extended to other practically important problems such as the multiple product capacitated lot size problem and the multistage lot size problem.
