The crystal structures of some phases of silica.

by

Wayne A. Dollase

Submitted to the Department of Geology and Geophysics on May 13, 1966, in partial fulfillment of the requirement for the degree of Doctor of Philosophy.

New crystallographic and structural data are presented on four polymorphs of silica. A refinement of low cristobalite, which required correction of the data for the effects of twinning, has confirmed Nieuwenkamp's proposed structure. The refined Si-O distances are 1.601 and 1.608 Å, both  $\pm .004$  Å. The intertetrahedral angle, Si-O-Si, is  $146.8^\circ \pm 0.3^\circ$ .

Tridymite from the Steinbach and two other meteorites, and from a silica brick, has an apparent  $30 \times 49$  Å pseudo-hexagonal cell at room temperature. This cell is shown to be the twin composite cell, the true cell being monoclinic  $C2/c$  or  $Cc$  with  $a = 18.54$ ,  $b = 4.99$ ,  $c = 23.83$  Å and  $\beta = 105.65^\circ$ ,  $Z = 48$   $SiO_2$ . The six individuals of the twin are related by a six-fold twin axis parallel to  $[201]$  of the monoclinic cell.

Above about  $107^\circ$  C the Steinbach tridymite transforms reversibly to transitional tridymite which is identified by a characteristic dynamic superstructure. The supercell translation of this superstructure decreases continuously from about  $105$  Å to about  $65$  Å as the temperature is raised from  $107^\circ$  to  $180^\circ$  C. This behavior is similar to that observed at the ferroelectric transition in  $NaNbO_3$ .

At about  $180^\circ$  C the Steinbach tridymite transforms reversibly to a third phase, namely, orthorhombic high tridymite, which exists at least up to  $250^\circ$  C. In this temperature range the space group is  $C222_1$  with  $a = 8.74$ ,  $b = 5.05$ , and  $c = 8.24$  Å. A crystal structure determination has shown regular tetrahedra connected as in the Gibbs ideal high tridymite structure. The lowering of the symmetry is brought about by a twisting of the tetrahedra relative to each other. The average tetrahedral distance, uncorrected for thermal motion, is  $1.56$  Å. The rms amplitudes of thermal vibration of the oxygen atoms normal to the Si-O bonds are as high as  $0.4$  Å which partly accounts for the apparent short Si-O distances.

The transitional tridymite subcell shows monoclinic  $P2_1$  symmetry. A refinement based upon the substructure reflections only, has given nearly the same positional and thermal parameters as found for orthorhombic high tridymite. The only statistically significant deviations from the higher symmetry are very small shifts of the silicon atoms.

## Chapter I

### Background and plan of thesis

#### The problem

The silica system, composed of the polymorphous forms of  $\text{SiO}_2$ , is perhaps the most fundamentally important system in mineralogy. As an end member of all silicate systems, its structures and properties form a norm against which the parameters of a multicomponent silicate system may be compared. In their own right, most of the phases of silica occur naturally, some in great abundance. Furthermore, the structures of many of the phases have been adopted by other silicates and non-silicates thus forming an extensive family of derivative structures. Finally, due to the large number of different structure types displayed by this one compound, it has become a model and type case in the study of polymorphic transformations.

For all these reasons it might be expected that silica would be one of the most studied of chemical compounds; and that its crystal structures would be among the best known. The two very recent volumes of Frondel (1962) and of Sosman (1965), each devoted entirely to this compound, show the large amount of work that has been done. It is, however, somewhat surprising to find that although the general framework of each of the silica structures is

believed known, their exact structures are poorly known or entirely unknown. In fact, the only silica structure which is well known by modern standards is that of low quartz. The symmetries and locations of some of the atoms in high quartz are disputed. The entire tridymite group is unknown except for the original very rough qualitative structure proposed by Gibbs. Different investigators have proposed different symmetries and structures for the cristobalites, both high and low. The symmetry of coesite is at least open to question. The structure has not been refined and the proposed symmetry constrains a Si-O-Si bond to be  $180^\circ$ , (the existence of such bonds, at room temperature, has not been well authenticated, and is doubted by some authors). Lastly, as pointed out by Wyckoff (1963), the published structure of keatite leads to  $\text{SiO}_4$  tetrahedron with three bonds of normal length (ca.  $1.6 \text{ \AA}$ ) and a fourth bond of  $3.7 \text{ \AA}$ . This is almost surely incorrect.

The reasons for these uncertainties are two-fold: the difficulty of obtaining good single-crystal intensity data, and the difficulty in determining the true symmetries. The first problem stems from the frequent lack of good single crystals, the apparent ubiquitous twinning of every one of the phases, and in some cases the occurrence of a weak superstructure. The second problem is due also to the twinning and to the fact that the required symmetry is expressed only by relatively small deviations from a strong

pseudosymmetry. The lack of knowledge of the true symmetry does not prevent the determination of the general mode of tetrahedral linkage, but does prevent the determination of the details, namely the bond distances and angles, the rotations, tilting, or distortions of the tetrahedra, the thermal vibrations, etc., all of which are dictated or strongly restricted by the symmetry.

#### Scope of the thesis

Because of the importance of the system and because of its crystallographic complexity, the silica system poses an interesting problem. A crystallographic re-study of the system was, therefore, undertaken, and the first group of new results comprises this thesis. The individual topics, insofar as they are separable, are treated in the five succeeding chapters and an appendix. The second chapter is concerned with the structure of cristobalite at room temperature. A procedure had to be developed to obtain the true structure factors from the superposed diffraction data measurable from twinned material. Once this was done the refinement, confirming an earlier structure proposal, proceeded smoothly.

The largest unknown segment of the silica system, the tridymite group, was then studied. The first result was the establishment of the existence of at least two fundamentally different tridymites. The tridymite of ceramic silica brick and of meteorites is distinctly different from

all presently known natural, terrestrial tridymites. The symmetry and twinning of the first type are reported in Chapter 3. The next chapter describes the most unexpected finding of the study, a remarkable dynamic superstructure which seems to occur in all tridymites at their high-low transformation. This superstructure shows a temperature-dependent translation that changes continuously from about  $60 \text{ \AA}$  to over  $100 \text{ \AA}$ , as the temperature is raised through a  $70^\circ \text{ C}$  interval. The superstructure appears to be due to an ordering of thermal vibrations in the form of waves, and is only the second reported example of this phenomenon, and the first known example in a mineral. Similar superstructures may be a general accompaniment to such transformations.

Chapters 5 and 6 report complete crystal-structure determinations of tridymite from the Steinbach meteorite in two different structural states, at  $220^\circ \text{ C}$  and at  $120^\circ \text{ C}$ . Both structures are found to be related to the ideal high tridymite structure by slightly different distortions. The unusually large thermal vibrations found for the oxygen atoms, even at as low a temperature as  $120^\circ \text{ C}$ , help explain the behavior of the tridymite group.

The appendix describes the construction and operation of the furnace used in making most of the x-ray diffraction measurements above room temperature. This furnace was specifically designed for the single-crystal counter diffractometer, and represents several improvements over previous designs.

It was hoped at the outset that an intensive study restricted to a few of the phases of this system would point out the general procedures required in the eventual solution of all of the structures. This hope is now believed to have materialized. The main crystallographic obstacles standing in the way of solution of this group of structures have been overcome. The procedure for obtaining the structure factors from twinned crystals should have application in most of the other structure solutions. The single-crystal counter diffractometer has been shown to be capable of determining the small deviations in symmetry that occur in this system provided proper precautions are observed. And finally, the insight gained from the present structural studies should prove valuable in deciding what to look for and how to interpret what is observed in the studies of the remaining phases of silica.

## Chapter II

## Reinvestigation of the structure of low cristobalite

## Abstract

Twinned crystals of low cristobalite from Ellora, Hyderabad, India were found to have space group  $P4_12_1$  (or  $P4_32_1$ ) and cell dimensions  $a = 4.978$  and  $c = 6.948$  Å. A three-dimensional full-matrix least-squares refinement based upon 110 integrated intensities which were corrected for the effects of twinning, confirmed Nieuwenkamp's original structure and reduced the final  $R$  value to 4.4%. The refined set of four positional parameters are;  $u = .30004 \pm .00033$ ,  $x = .23976 \pm .00089$ ,  $y = .10324 \pm .00085$ ,  $z = .17844 \pm .00052$ . These refined parameters lead to Si-O distances of  $1.601 \pm .004$  and  $1.608 \pm .004$  Å.

## Introduction

High cristobalite is the polymorph of  $\text{SiO}_2$  whose stability range occurs between  $1470^\circ$  and the melting point of  $1728^\circ$ . Upon cooling, it tends to exist metastably down to a variable inversion temperature of about  $268^\circ$  where it inverts to low cristobalite. The exact structures of the cristobalites are necessary to the understanding of the silica system, silica polymorphism, and the large field of silicates having related structures. Accordingly, the cristobalite structures have received considerably attention. Besides the early direct crystal-structure determinations, which are reviewed below, there have been a number of later, less direct studies which have yielded structural implications. The results of this latter group have been included, in the main, in the recent compilation of Frondel (1962).

### Previous structural studies

The first structural study of high cristobalite was made by R. W. G. Wyckoff (1925) using powder photographs taken at  $290^\circ$  and  $430^\circ$ . The proposed structure belonged to the isometric space group  $\underline{\text{Fd}3\text{m}}$ . The agreement between the 16 observed and calculated intensities, some of which were the sum of superposed powder lines, was fair, and could be improved somewhat by increasing the scattering power of the silicon atom relative to that of the oxygen atom. This structure, as well as all following cristobalite-structure proposals, showed an infinite three-dimensional

network of more or less regular  $\text{SiO}_4$  tetrahedra with all corners shared. The silicon-oxygen distance in Wyckoff's structure was 1.54 Å and the Si-O-Si angle between joined tetrahedra was  $180^\circ$ .

Tom F. W. Barth (1932a) suggested a high-cristobalite structure belonging to space group  $\underline{P2}_13$  on the basis of some extra lines in the powder photographs (taken at temperatures up to  $500^\circ$ ) which are not allowed by Wyckoff's space group. The agreement between the 17 observed and calculated intensities was rather poor. Two-thirds of the intensities actually observed were the sums of two or more nonequivalent reflections. The Si-O distances ranged from 1.58 to 1.69 Å.

Later in the same year Barth (1932b) made the first structural study of low cristobalite. Reasoning that it must belong to a subgroup of  $\underline{P2}_13$ , and ruling out, on optical grounds, systems more symmetrical than orthorhombic, he arrived at space group  $\underline{P2}_12_12$ . With this space group and with the pseudoisometric cell dimensions, nearly all the lines of the powder photographs he used were the sums of two or three nonequivalent reflections. The agreement between the 13 observed and calculated intensities was fair. The Si-O distances for this model ranged from 1.50 to 1.75 Å.

W. Nieuwenkamp (1935) reinvestigated low cristobalite and suggested a structure belonging to the tetragonal space group  $\underline{P4}_12_1$ . The structure determination was made by

qualitative estimation of intensities from rotation photographs made with twinned material. Due to the fortuitous cell dimensions many of the reflections were superposed on the photographs making it possible to estimate only the combined intensities of these pairs. The two Si-O distances of this model were both 1.59 Å, and the Si-O-Si angle was  $146^\circ$ .

Nieuwenkamp (1937) also reinvestigated high cristobalite and proposed a third structure. From rotation photographs taken at  $270^\circ$ , using the same crystals as in the low-cristobalite study, he determined the space group to be  $Fd\bar{3}m$ , the same as that proposed by Wyckoff. The best fit of the 25 observed and calculated intensities was with the oxygen atom disordered around the circumference of a circle of radius 0.4 Å. This circle was oriented normal to the Si-Si axis of joined tetrahedr. Nieuwenkamp's model gave fair agreement of intensities and could account for Wyckoff's observation of the low scattering power of the oxygen atom. The Si-O distance in this model was 1.59 Å and the Si-O-Si angle was  $151^\circ$ .

On the basis of these several structure determinations, which are characterized by meager, ambiguous data leading to conflicting results, the structures of the cristobalites are, at best, somewhat uncertain and merit reinvestigation. It is the purpose of this paper to report the results of the reinvestigation of the low-cristobalite structure.

### Unit cell and space group

Crystals of low cristobalite from Ellora, Hyderabad, India were kindly made available from the Harvard Museum collection by Professor Clifford Frondel. A description of the material from this locality is given by Frondel (1962, page 282), and by Valkenburg and Buie (1945).

The cell dimensions and systematic absences were determined from precession photographs, taken into account the twinning which is discussed below. The diffraction symbol is  $4/\underline{mmm}P4_1/-2_1-$ , which determines the space group as  $\underline{P}4_12_1$  or its enantiomorph,  $\underline{P}4_32_1$ . The cell dimensions,  $\underline{a} = 4.978$  and  $\underline{c} = 6.948$  Å, compare well with the values given by Frondel (1962, page 276).

When dealing with a primitive tetragonal lattice it is possible, though unconventional to choose a  $\underline{C}$  - centered cell. The relationship between the two cells is shown in Fig. 1A. For the particular case of low cristobalite this  $\underline{C}$  - centered cell is pseudoisometric. The discrepancy between the  $\underline{c}$ -axis translation and  $\underline{t}_{110}$  ( $=\underline{a} \sqrt{2}$ ) of the primitive cell, is only 1.3%. This pseudoisometric cell is dimensionally equivalent to the high-cristobalite cell.

### Description of the twinning

X-ray examination of the few available crystals from this locality showed that each of them was twinned. The pattern of reflections given by  $\underline{c}$ -axis precession photographs is illustrated in Fig. 2A. Besides the reflections attributable to the  $\underline{P}4_12_1$  cell described by Nieuwenkamp

a)

b)

**Fig. 1**

Fig. 2

(large circles), there were observed additional weak reflections (small circles) falling between the Nieuwenkamp-cell reflections. A possible supercell origin for these additional reflections can be discarded for the following reason. Their very low intensity would require a structure only slightly distorted from  $P4_12_1$  symmetry, whereas the new diffraction symbol (obtained when the additional reflections are treated as superstructure reflections) would require drastic deviation from this symmetry.

Although not observable on the precession photographs, further examination of the crystals on a counter diffractometer showed additional weak reflections satellitic to some of the Nieuwenkamp-cell reflections, as shown exaggerated in Fig. 2B. The location and number of the satellitic reflections as well as the extra reflections mentioned above can be accounted for by twinning. The twin operations may be chosen as  $90^\circ$  rotations about the  $[110]$  and  $[\bar{1}\bar{1}0]$  directions of the primitive tetragonal cell (see Fig. 1A). These two operations relate a reference twin individual with two other twin individuals, the three comprising the composite twin as shown in Fig. 1B.

On the basis of the relationship between the twin individuals the indices of the additional reflections may be tentatively assigned. The intensity of a reflection from one individual may then be plotted against the

intensity of the same reflection from a second individual for all the single, non-superposed reflections which are individually measureable. The linearity of such plot confirms the indexing of the additional reflections and thus confirms the relationship between the twin individuals. Figure 3 shows such plots made with the crystal used for intensity measurements. The precision of measurement of the additional reflections is low due to their weak intensities. Taking this into consideration, the plots are satisfactorily linear.

#### Collection of intensity data

A small pseudooctahedron, 0.15 mm on a side, was selected for intensity measurements. An equi-inclination diffractometer employing a proportional counter was used to collect integrated intensities with nickel-filtered  $\text{CuK}$  radiation. The  $\lambda/2$  harmonic was removed by pulse-height analysis.

The single, nonsuperposed reflections presented no problem in their measurement. On the other hand, the composite, superposed reflections are somewhat spread out as can be seen from Fig. 2B. To ensure collection of the entire composite intensity an extended  $\omega$  scan, as well as a large counter aperture, was used.

About 200 reflections, including a number of the same reflections from the different twin individuals,

Figure 3. Graphs of the integrated intensity of non-Superposed reflections from one twin individual plotted against the integrated intensity of the same nonsuperposed reflections from a second twin individual.  $\underline{I}$ ,  $\underline{I}'$  and  $\underline{I}''$  represent the integrated intensity of reflections from the first, second, and third twin individuals, respectively.

were collected. The data were corrected in the usual way. Since  $\mu_r=0.6$ , no absorption correction was applied.

#### Correction of the data for twinning

It is possible to extract a set of individual intensities from the composite reflections if the volumes of the twin individuals are not all equal. In order to obtain a sufficiently large and random set of intensities for least squares refinement it is desirable to use this extracted set of intensities as well as the intensities of the nonsuperposed reflections. Since the lattices of the twin individuals in the twinned position mismatch appreciably, it may be assumed that there is negligible coherence of the diffracted beam and that the intensity of the composite reflections is the sum of the intensities of the contributing individual reflections. Taking into consideration the volumes of the twin individuals, this relation between the composite and individual reflections is

$$\frac{C}{\underline{HKL}} = \underline{t} \frac{I}{\underline{hkl}} + \underline{u} \frac{I}{\underline{h'k'l'}} + \underline{v} \frac{I}{\underline{h''k''l''}} \quad (1)$$

where  $\underline{t}$ ,  $\underline{u}$  and  $\underline{v}$  are the volumes of the twin individuals. Using the orientation of the largest individual of the twin as the reference orientation, the indices of the individual reflections are found by operating on the indices of the composite reflection with the matrices

$$\begin{pmatrix} 100 \\ 010 \\ 001 \end{pmatrix} \quad \begin{pmatrix} \bar{1}\bar{1}\bar{1} \\ \bar{1}\bar{1}\bar{1} \\ 1\bar{1}0 \end{pmatrix} \quad \begin{pmatrix} \bar{1}\bar{1}\bar{1} \\ \bar{1}\bar{1}\bar{1} \\ \bar{1}\bar{1}0 \end{pmatrix}$$

These are respectively the unit matrix and the matrices representing the twin operations given above. In practice, the volumes  $\underline{t}$ ,  $\underline{u}$  and  $\underline{v}$  are difficult to determine directly, so the volume ratios,  $l=t/t$ ,  $\mu=u/t$ , and  $\nu=v/t$ , are used. These may be accurately estimated from the intensity ratios of the nonsuperposed reflections plotted in Fig. 3. The upper plot gives  $\mu = 0.094$  and the lower plot gives  $\nu = 0.064$ .

Although the individual intensities may be obtained by the normal methods of solving a set of simultaneous equations, for computer solution an iterative method is advantageous and was employed. The recursive formula used was

$$\underline{i} + \underline{1} \underline{I}_{\underline{hkl}} = \underline{C}_{\underline{HKL}} \mu \underline{I}'_{\underline{h'k'l'}} + \underline{C}_{\underline{H''K''L''}} \nu \underline{I}''_{\underline{h''k''l''}} \quad (2)$$

where the left superscript refers to the  $\underline{i}$ th approximation of the term which bears the superscript. The starting approximation

$$\underline{1} \underline{I}_{\underline{hkl}} = \underline{C}_{\underline{HKL}} - \frac{\mu}{1+\mu+\nu} \underline{C}_{\underline{H'K'L'}} - \frac{\nu}{1+\mu+\nu} \underline{C}_{\underline{H''K''L''}} \quad (3)$$

was employed. This method has the disadvantage that the convergence rate depends upon the ratios of the individual intensities, but in this case, due to the very small magnitude of  $\mu$  and  $\nu$ , uniform convergence was reached in five cycles.

### Refinement

After correcting for the effects of twinning, a total of 110 reflections with  $F_o > 0$  were available for least-square refinement. The number of observations per variable is greater than 15. The full-matrix least-squares refinement program written by C. T. Prewitt was used. Scattering curves for both neutral and half-ionized atoms were tried without any significant change in the results. An equal-weighting scheme was employed. The original atom coordinates of Nieuwenkamp, together with the best fit of scale factor and isotropic temperature factors, yielded an  $R$  value of 13%. Six cycles of refinement varying all parameters led to convergence and a final  $R$  value of 4.4%. The final observed and calculated structure amplitudes are given in Table 1. During the refinement the silicon atom oscillated to both sides of the Nieuwenkamp value but finally settled within one standard deviation of his value.

The final atomic parameters are given in Table 2 along with those of Nieuwenkamp. The silicon atom occupies the position with site symmetry 2 in space group  $P4_12_1$  while the oxygen atom lies in the general position. The magnitudes of the temperature factors should not be regarded as very significant as the correlation factors between these values and the scale factor are 0.82 and 0.64. The usual interaction of these dependent variables is further aggravated in this case by the small number

\*The subscript, N, refers to Nieuwenkamp's original values

of temperature factors and the rather narrow range of  $(\sin \theta)/\lambda$  values. The correlation factor between the two temperature factors is smaller, implying that the ratio of the temperature factors is more meaningful than their individual magnitudes. The value of this ratio for low cristobalite is similar to those observed in other silicate refinements.

There are two independent silicon-oxygen distances and four independent oxygen-silicon-oxygen angles in the tetrahedron. The refined coordinates yield the values given in Table 3. The silicon-oxygen-silicon angle between joined tetrahedra is also included. The difference between the Si-O distances is not statistically significant. The deviations of the angles from the ideal tetrahedral angle are as much as three standard deviations and may be significant.

Acknowledgements. The author is indebted to Professor M. J. Buerger for having suggested this study and for his council during the course of the investigation. The computations were carried out at the M. I. T. Computation Center. This work was supported by a grant from the National Science Foundation.

## Chapter III

Symmetry and twinning of tridymite from the Steinbach,  
Crab Orchard, and Esterville meteorites.

## Abstract

Single-crystal x-ray examination of tridymites from those meteorites mentioned in the title and of an artificial tridymite from silica brick, show them all to be identical. At room temperature the symmetry is monoclinic,  $Cc$  or  $C2/c$  with  $a = 18.54$ ,  $b = 4.99$ ,  $c = 23.83 \text{ \AA}$ , and  $\beta = 105.65^\circ$ . The cell contains 48  $SiO_2$  formula units. The  $[20\bar{1}]$  direction of this cell is a pseudo-hexagonal axis and all crystals examined were multiply twinned with this axis as the six-fold twin axis. The pseudo-hexagonal composite cell has dimensions;  $A = 30.0$  and  $C = 49.3 \text{ \AA}$ .

Tridymite is an accepted and not infrequent constituent of meteorites.<sup>1,2</sup> With the exception of a set of cell dimensions proposed for one meteoritic tridymite<sup>3</sup>, no crystallographic data have been reported which would allow comparison of meteoritic tridymites with each other or with artificial and natural, terrestrial occurrences of tridymite. As a part of a crystallographic study of the phases of silica, this note reports such new data for the two mesosiderites: Esterville and Crab Orchard and the siderophyre: Steinbach.

#### Identification as tridymite

Tridymite specimens from the three meteorites were kindly made available from the Harvard Museum collection by Professor Clifford Frondel. A thorough characterization of these tridymites, including refractive indices, specific gravity and x-ray powder patterns, as well as a complete wet chemical analysis of the Steinbach tridymite (J. Ito, analyst) is reported by Dr. Raymond Grant.<sup>4</sup>

As part of this study it was confirmed that the Steinbach material is tridymite on the basis of its reversible transformation to high tridymite whose crystal structure was determined on the same material. In addition a spectrographic analysis, kindly run by Professor Wm. H. Dennen, confirmed the unusually low impurity content of this tridymite. (See Table 1.)

### Determination of the apparent cell

Using single-crystal methods some two dozen crystals from the three samples were studied. In all cases the apparent cell found was pseudohexagonal with the same dimensions reported for the Grimma meteorite tridymite<sup>3</sup> (part of the same fall as Steinbach). A very similar cell has been reported for tridymite from a gas-retort silica brick<sup>5</sup>, "which had been heated for about 1900 working days at an average temperature of 1380° C".

To substantiate the apparent equality of the meteoritic and silica-brick results, a similar study was made of a silica-brick tridymite kindly provided by Dr. Helmut Stützel of Heinrich Koppers G.M.B.H. This tridymite has a somewhat similar history to that described above, being from a tunnel oven brick that had been heated for many years at 1400° C. The apparent cell of this material was found to be identical to that shown by the meteoritic tridymites. These cells are compared in Table 2.

### Twinning

This apparent cell is, however, the twin-composite cell, twinning being suggested by the observations:

- 1) That all grains, including the (few) cases where twinning was optically readily apparent, showed the same  $30 \times 49 \text{ \AA}$  cell (hereafter called the composite cell).

Table 2

Comparison of apparent room-temperature cells  
of tridymite from various sources.

<u>This study</u>	<u>Grimm</u>	<u>Gas-retort silica brick</u>
$\underline{a} = 30.056 \text{ \AA}$	30.05 $\text{ \AA}$	30.08 $\text{ \AA}$
$\underline{c} = 49.32_7$	49.56	49.08
pseudo-hexagonal	(cell given as orthohexagonal)	"appeared to be hexagonal"

- 2) That the composite cell shows systematic extinctions which do not correspond to any possible symmetry element (so called "non-crystallographic extenctions"). Of each 54 composite reciprocal-lattice nodes, only seven are present and 47 are systematically extinct. The present reflections are given by the conditions  $\underline{H}$  and/or  $\underline{K} = 6\underline{n}$  and  $\underline{H} + \underline{K} + \underline{L}$  and/or  $\underline{H} + \underline{K} - \underline{L} = 6\underline{n}$ . (Following convention, capital letters refer to the composite cell.)
- 3) That although there is strong hexagonal pseudo-symmetry and, within the limit of measurement, exact hexagonal dimensionality, the composite intensities show no true symmetry at all, except for the center added by Friedel's law.
- 4) That the intensity ratios of pairs of reflections vary from grain to grain.

A typical precession photograph taken in one of the A-axis directions is shown in Figure 1. The obvious twinning seen in this direction may be described by a two-fold rotation about the C axis. Examination of the other two A-axis directions showed the same twinned pattern but with uniformly subdued or enhanced intensities implying similar twinning in these directions, and thus a total of six twin individuals in all. The two individuals seen in any A-axis photo are related to the pair seen in any other A-axis photo by the operation of a three-fold twin axis parallel

Fig. 1. Sixth-level, A-axis precession photograph (referred to composite cell) of Steinbach tridymite, taken with filtered copper radiation. The C axis of the composite cell is horizontal.

to C. The six individuals of the twin can be equivalently related by the operations of a six-fold (twin) axis parallel to the pseudohexagonal axis of the composite cell.

#### Proposed true cell

From a knowledge of the twin operations, the collection of reflections due to one twin individual may be extracted from the composite. Figures 2 and 3 are projections along the twin axis of the reflections present in the composite cell and in one of the twin individuals, respectively. Figure 4 shows the reflections of one twin individual plotted in the direction of the composite A axis (as seen in Figure 1). The zero, first, and second reciprocal-lattice levels normal to this direction are shown, as well as the superposition of all three levels. This collection of reflections shows diffraction symmetry  $2/m \underline{C} -/c$  and no non-crystallographic absences. The space group is therefore  $\underline{C} 2/c$  or  $\underline{C}c$  depending on the presence or absence of a symmetry center, respectively. The reduced monoclinic cell has dimensions  $\underline{a} = 18.53_5 \text{ \AA}$ ,  $\underline{b} = 4.99_3 \text{ \AA}$ ,  $\underline{c} = 23.83_2 \text{ \AA}$ ,  $\beta = 105.65^\circ$ . The cell volume is  $2124 \text{ \AA}^3$  which yields a cell content of  $48 \text{ SiO}_2$  formula units when the published<sup>2</sup> value of 2.26 is used for the density.

The unique monoclinic axis b coincides with the A axis of the composite cell. The relations of the other axes to those of the composite cell axes can be seen in

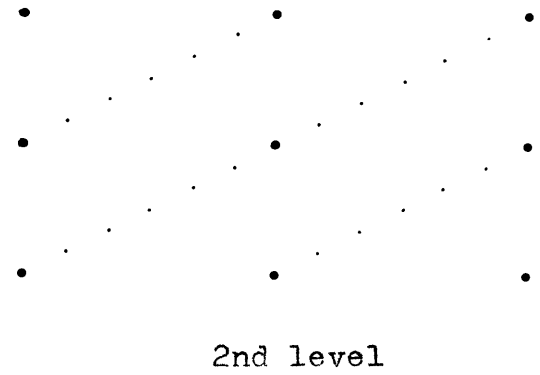

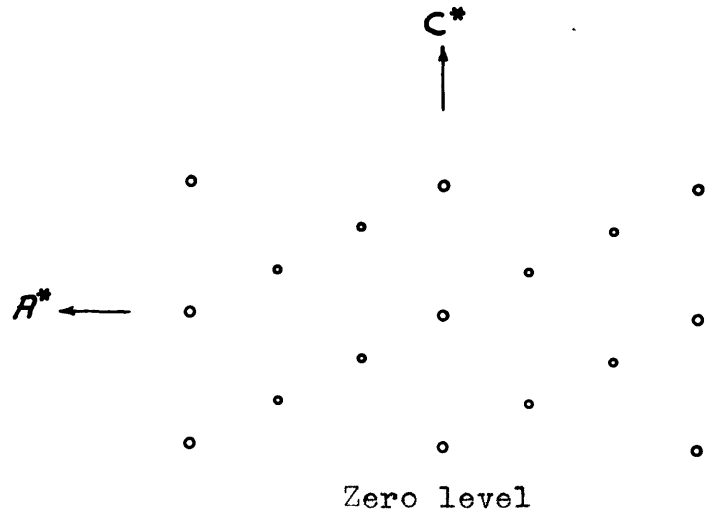

Figure 4. The matrix,  $T$ , relating the true cell with the composite cell is  $1, T, 2/\sqrt{3}, \sqrt{3}, 1/1, T, T$ , i.e.  $A = aT$ .

#### Check of monoclinic symmetry

A set of diffraction intensities from a twinned grain was collected with a single-crystal diffractometer out to a value of  $\sin \theta/\lambda = .5$  for purposes of a crystal structure determination which is in progress. Due to the twinning some, but not all of the reflections are identically superposed. For the general case, assuming no coherence in the diffracted beams from different twin individuals, the  $h$ 'th composite measured intensity is given by

$$C_h = \sum_{i=1}^6 v_i I_{hT_i}$$

where  $T_i$  is the  $i$ 'th twin operation matrix,  $v_i$  is the volume of the twin individual related to a reference individual by the operation  $T_i$  and  $I$  is the true intensity.

Then the  $j$ 'th member of the twin-equivalent set of composite intensities is given by

$$C_{hT_j} = \sum_{i=1}^6 v_i I_{hT_jT_i}$$

This set of equations can then be solved for the true intensities according to the matrix equation

$$I_h = v_{hk}^{-1} C_k$$

if the volumes of the twin individuals are not all equal. The volumes (relative to one individual taken as unit volume) are easily determined by measurement of equivalent, non-superposed reflections from each of the individuals.

As noted above, the composite cell has Friedel symmetry  $I$ , whereas the true cell has Friedel symmetry  $2/\underline{m}$ . Thus half of the extracted true intensities must equal the other half by the additional symmetry element of the true cell. In general, the agreement between such pairs is a function of the seventeen variables of the last equation. The average agreement,  $\sum |I-I'| / \sum (I+I')$ , for all of the intensities collected that were affected by twinning was 0.032, which strongly substantiates the previous conclusions in regard to the cell and symmetry.

#### Relation to the high tridymite structure

At about  $107^\circ \text{C}$  this tridymite transforms rapidly and reversibly to another polymorph whose structure was found to be only a slightly distorted version of the ideal high-tridymite structure<sup>6</sup>. Thus, it can be expected that the room-temperature form will also be similar in structure to high tridymite. When the atom locations of the high-tridymite cell are transformed to their corresponding locations in the room-temperature cell, it can be seen that, if the symmetry is centrosymmetric ( $C2/c$ ), there are six  $\text{SiO}_2$  formula units per asymmetric unit; in this case three oxygen atoms are constrained to inversion centers. This, of course, constrains their Si-O-Si bonds to be  $180^\circ$ . If the symmetry is acentric ( $Cc$ ), there are twelve formula units per asymmetric unit, with all atoms in the general position.

### Summary

Tridymite from three meteorites and a silica brick were found to be identical and to show the same apparent cell as had previously been reported separately for a meteoritic tridymite and a silica brick tridymite. Twinning, however, seems to be universally present and the apparent cell is actually the twin composite cell. The twin is composed of six individuals related by the operations of a six-fold twin axis. The true symmetry is monoclinic with a cell volume twelve times that of the classical high tridymite cell.

## Chapter IV

A dynamic superstructure associated  
with the high-low transformation in tridymite

## Abstract

A weak superstructure has been observed in a 70° C range directly above the low-to-high transformation in tridymite. The supercell reflections lie in, or very nearly in one of the  $[[110]]$  directions of the high-tridymite (pseudo)hexagonal subcell. The intensities of the supercell reflections fall off very rapidly away from the subcell reflections, giving the appearance of satellites. As the temperature is increased, the "satellites" move away from their respective subcell reflections and decrease in intensity. Over the 70° C range in which they are visible, the variable satellite spacing represents, in real space, an apparently continuous decrease in supercell period from about 105 Å down to about 65 Å.

The high-low (beta-alpha) transformation in tridymite has the characteristic of a distortional transformation, (Buerger, 1961). This low-energy, non-quenchable phase transformation takes place rapidly and reversibly within a small temperature range at slightly above 100° C. As a part of a structural study of the phases of silica, this transformation was studied by single-crystal x-ray diffraction methods. This paper reports observations made of an unusual superstructure which appears to be associated with the distortional transformation, and which is characterized by a supercell translation that varies remarkably with temperature.

#### Film observations

The high-low transformation of a tridymite crystal from the Steinbach meteorite was monitored with Laue photographs taken at small temperature intervals from room temperature to 250° C. The transformation is marked by the sudden disappearance of the reflections characterizing the low-temperature supercell. Along with the disappearance of these reflections, many of the remaining "subcell" reflections develop a series of very weak satellite maxima, whose intensities decline rapidly away from the strong subcell reflection, somewhat similar in aspect to the secondary maxima of optical diffraction described by the  $(\sin x/x)^2$  function.

As the temperature is increased the satellites are observed to decrease in intensity and to increase their separation from their respective main peaks. These changes appear to occur continuously from the transformation point at about  $107^{\circ}$  C up to about  $170^{\circ}$  C. At this point the satellites have decreased in intensity until they are no longer discernable above the background. The regularity of the directions and spacings of the satellitic reflections indicates that they form a periodic superstructure whose cell changes greatly in size with temperature.

This behavior was entirely reversible with temperature (although the transformation itself shows hysteresis), and could be repeated at will on other crystals of the same tridymite sample. Similar studies were made with tridymite crystals from several terrestrial, volcanic occurrences which are characterized by different low-temperature supercells. Except that their low-to-high transformations occurred at a higher temperature (about  $125^{\circ}$  C) the appearance of satellites and their behavior with temperature was analogous with the meteoritic tridymite.

To obtain the orientation of the supercell relative to the normal high-tridymite cell, oscillation and precession photographs were taken in this temperature range. The oscillation photographs taken about the pseudohexagonal axis of the high tridymite cell showed that the satellites were restricted to the reciprocal lattice levels normal to this axis. Iron-radiation precession photographs made of these

levels gave the pattern schematically reproduced in Figure 1. An enlarged section of one of the actual photographs is shown in Figure 2.

The large spots of Figure 1 outline the normal high-tridymite reciprocal cell, whose axes have been designated by lower case labels. Referred to this cell the satellites can be seen to lie in (or approximately in) the direction of one of the  $a^*$  axes. Thus in direct space the variable period repeat of the supercell occurs in one of the  $[[110]]$  directions of the high-tridymite cell. Measurements from precession photographs taken in the temperature range of  $110^\circ$  to  $170^\circ$  C, gave supercell translations of about 65 to 95 Å.

The furnace employed in heating the crystal during the film observations was of the type described by Wuench (1963). With this type of furnace, and the use of long-wavelength radiation (necessary to resolve the closely spaced satellites) only a very limited range of diffraction angle,  $\theta$ , was observable. In addition, the rather open nature of the furnace allowed the temperature to vary slightly and thus to change the diffraction effects during their observation. For these reasons an improved furnace was constructed (See appendix) based largely upon a design due to Buerger, et.al. (1943) This furnace was designed for use with an equi-inclination counter diffractometer so as to allow a range of  $\psi$  up to  $135^\circ$ , and  $\mu$  up to  $45^\circ$ , to be explored. In practice the furnace also provided the desired constancy of temperature,

Figure 1. Schematic representation of a reciprocal lattice level normal to the  $c$  axis, showing superstructure.

Figure 2. Enlarged section of an unfiltered, g-axis, zero-level precession photograph taken with iron radiation. The reflection showing satellites in 010, while that without satellites is 100. Beta reflections are also seen. 3X.

such that during the measurements at any given setting no temperature variation effect could be noticed, after allowing a short time for the furnace to come to equilibrium.

#### Single-crystal diffractometer observations

The diffraction effects observed with an equi-inclination counter diffractometer can be understood by reference to Figure 3 which shows an enlarged part of the standard  $n$ th level, equi-inclination geometry. (See for example, Buerger, 1942, p. 255). The dashed lines represent three successive positions of a single reciprocal-lattice line passing through the sphere of reflection. The reciprocal-lattice line, which lies in the plane of the figure, contains a main reflection and two satellitic supercell reflections. The three positions shown are those where successively, one satellite, the main reflections, and the other satellite are in the reflections position.

During such a scan the difference in the rotation angle,  $\Delta\phi$  between the reflecting positions of the satellites on either side of the main peak, may be measured directly from a strip chart recording. In principle, the difference in the diffraction angle,  $\Delta\tau$ , between this pair of satellites could also be measured directly, for example, by means of a variable detector aperture. From these two measurements it is possible to calculate the superstructure parameters of direct interest, namely, the magnitude and direction of the superstructure translation. For

Figure 3.

this purpose it is convenient to specify the orientation of the superstructure translation by the angle it makes with a radial to the main reflection, as shown in Figure 3. An equation relating these variables may be derived from Figure 3. Since the measurements on the weak satellites cannot easily be made with high precision, it is sufficient to derive an approximate equation.

If the superstructure period is very large, i.e. if the separation,  $t^*$ , of a satellite from its main reflection is small, then:

$$\Delta\phi \approx \tan^{-1} \left( \frac{QQ''}{Q'O} \right) \quad (1)$$

where  $QQ'' \approx 2(t^* \sin \psi + t^* \cos \psi \tan(OQ'P))$ .

From equi-inclination geometry (Buerger, 1942, p. 255).

$$OQ'P = \mathcal{T}/2$$

$$Q'O = 2\cos \nu \sin(\mathcal{T}/2).$$

Substituting these values in (1),

$$\Delta\phi \approx \tan^{-1} \left[ \frac{2t^*(\sin \psi + \cos \psi \tan(\mathcal{T}/2))}{2\cos \nu \sin(\mathcal{T}/2)} \right] \quad (2)$$

Multiplying the numerator and denominator of the arctan argument by  $\cos(\mathcal{T}/2)$  gives,

$$\Delta\phi \approx \tan^{-1} \left[ \frac{2t^*(\cos(\mathcal{T}/2)\sin \psi + \cos(\mathcal{T}/2)\cos \psi \tan(\mathcal{T}/2))}{\cos(\mathcal{T}/2)2\cos \nu \sin(\mathcal{T}/2)} \right] \quad (3)$$

which can be simplified to

$$\Delta\phi \approx \tan^{-1} \left[ \frac{2t^*\sin(\mathcal{T}/2 + \psi)}{\sin \mathcal{T} \cos \nu} \right] \quad (4)$$

Similarly,

$$\Delta\mathcal{T} \approx \tan^{-1} \left( \frac{PR''}{O'S} \right) \quad (5)$$

where

$$PR'' \approx 2\cos \psi t^*/\cos(OQ'P).$$

Again from Buerger (1942),

$$\begin{aligned}\frac{OQ'P}{Q'S} &= T/2 \\ Q'S &= \cos \nu.\end{aligned}$$

With these values substituted in (5),

$$\Delta_T = \tan^{-1} \left[ \frac{2t^* \cos \psi}{\cos \nu \cos (T/2)} \right]. \quad (6)$$

In practice the parameter  $\psi$  was known from films and could be confirmed by scanning several equivalent reflections on the diffractometer. Equation (4) may then be solved for the superstructure translation which, converted to direct space, is:

$$t = \frac{\lambda}{t^*} = \frac{2\lambda \sin(T/2 + \psi)}{\tan \Delta_T \sin T \cos \nu}. \quad (7)$$

It can be noted from Figure 3 that, although (7) is based upon a number of approximations, they tend to be self-cancelling as long as the pair of satellites are considered rather than the difference in the rotation angle between a satellite and the main peak.

A large number of scans were made on the single-crystal counter diffractometer at temperatures between 20° and 250° C using several different crystals. A typical scan showing the satellites is reproduced in Figure 4. The main peak has been cut off due to the scaling necessary to show the satellite detail. The envelope shown in Figure 4 may be decomposed into its constituent main peak and satellites. The decomposed group is shown in Figure 5 with the main peak represented by the dashed line for clarity. As mentioned above, with an increase in temperature

Figure 4. Diffractometer scan thru the  $\bar{3}30$  reflection of the Steinbach tridymite, showing satellites.

Figure 5. Decomposition of Figure 4 into its components.

the satellites spread away from the main peak and decrease in intensity. This effect is shown in Figure 6 by the superposition of two recordings made at two different temperatures. The greater value of  $\Delta_{\phi}$  for the higher-temperature recording (dashed lines) is obvious.

Using equation (7) the observed  $\Delta_{\phi}$  values were converted to the supercell translation,  $\underline{A}$ . The results for two reflections of the Steinbach tridymite are shown in Figure 7. The relationship between the temperature and the translation thus seems to inverse and linear. By slow reduction of the temperature it was found possible to undercool the transformation to the low form by about  $15^{\circ}$  C. The supercell translations found in the undercooled region seem to obey the same linear relationship. Furthermore, similar measurements made on several crystals of a terrestrial tridymite (from Plumas Co. California) showed that, although the transformation from the low form took place at a higher temperature (ca.  $125^{\circ}$  C), when the satellites did appear their spacing was also that given by the relation shown in Figure 7.

The low-form structures of the terrestrial and meteoritic tridymites are definitely different and, since they transform reversibly to themselves, their structures in the satellite range are probably also different. It seems therefore that the satellite spacing is independent of the actual transformation temperature and of the small differences in the structures of the tridymites.

Figure 6. Superposition of the 330 scans at two different temperatures.

Figure 7. Relation between temperature and supercell period for two reflections of the Steinbach tridymite.

Previous observations and origin of the  
superstructure.

Although the observations reported above were made independently, it was pointed out to the author by Dr. M. L. Canut-Amorós and Professor J. L. Amorós that strikingly similar phenomena have been observed at the ferroelectric transition in  $\text{NaNO}_2$ . Tanisaki (1961, 1963) discovered that just above the Curie point the normal x-ray reflections of  $\text{NaNO}_2$  showed a pair of sharp satellites. These satellites, which occur in the direction of the a axis, are visible only over a  $3^\circ$  C range. Above this temperature they become diffuse. The repeat period represented by the satellite spacing decreases from  $9.4x \text{ \AA}$  to  $8.6x \text{ \AA}$  as the temperature is increased over this  $3^\circ$  range. These observations were confirmed by Canut and Mendiola (1964).

An exact explanation of these effects in tridymite (and  $\text{NaNO}_2$ ), in terms of the changes in the atomic structure, will require a quantitative study of the satellite intensities and their change with temperature. The present information does, however, allow some speculative conclusions to be drawn.

It seems likely that the dynamic superstructure is a result of correlation or interdependence between the thermal vibrations of neighboring atoms (probably one or more of the oxygen atoms in the case of tridymite). Such correlation normally gives rise to thermal diffuse scattering,

that is, the correlations are non-periodic. See for example the t. d. s. studies of Arnold (1965) on quartz where he has quantitatively related the t. d. s. intensity with correlated motion between chains of atoms.

At a distortional transformation the loose changing structure evidently allows the correlations to become so strong that the thermal displacements become more-or-less ordered and periodic. Such superstructures may therefore be generally found associated with distortional transformations.

## Chapter V

The Crystal Structure at 220° C of high tridymite  
from the Steinbach meteorite

## Abstract

Tridymite from the Steinbach meteorite has been examined at 220° C and found to be orthorhombic, space group  $C222_1$ , with  $a = 8.74 \text{ \AA}$ ,  $b = 5.04 \text{ \AA}$ , and  $c = 8.24 \text{ \AA}$ . The crystal-structure has been determined and refined using single-crystal counter-diffractometer data, to  $R = 8.6\%$ . The resulting structure is distorted in comparison with the ideal high tridymite structure. The tetrahedra remain nearly regular but are twisted relative to each other. The magnitudes of the thermal displacements, especially of the oxygen atoms normal to their bonds with silicon atoms, are unusually large.

Tridymite from the Steinbach meteorite was found, from film and single-crystal diffractometer observations, to exist in three well defined structural states between room temperature and 250° C. Each of the phases is characterized by a different cell and symmetry. The highest-temperature polymorph of the three, existing from about 180° C up to the 250° limit of the investigated temperature range, is here termed high tridymite since it has the same small cell that has previously been reported for high tridymite<sup>1</sup>. This paper reports the results of a study of its crystal structure at 220° C. The details of the transformations and of the structures of the lower-temperature phases, as well as the relationship of the Steinbach tridymite to other tridymites, is considered elsewhere<sup>2</sup>.

#### Previous structural studies of high tridymite

The first structural study of tridymite was that of high tridymite made by R. E. Gibbs in 1927. The source of the tridymite was not given. The unit-cell parameters were measured from Laue and oscillation photographs taken at an undetermined temperature "well above the transition point". Gibbs concluded that at this temperature the Laue symmetry was  $\bar{6}mm$ , and that the reflections of the type  $h\bar{h}l$ ,  $l = 2n + 1$  were absent. This symmetry and extinction rule restricted the possible space groups to a small number. The observed density and cell size require

the cell to contain four formula units of  $\text{SiO}_2$ . By further requiring the structure to be composed of regular  $\text{SiO}_4$  tetrahedra, the space group could be limited to  $\underline{P6}_3/\underline{mmc}$ . As noted by Gibbs, this fixed the structure as essentially identical with that of ice.

The only other structural investigation made of tridymite above room temperature has been a powder-diffractometer study of a natural volcanic tridymite by Sato<sup>3</sup>. He reported that he observed a "good agreement" between 23 intensities measured on a powder diffractometer at  $500^\circ \text{C}$ , and the values calculated from the model proposed by Gibbs.

#### Symmetry of high tridymite

A specimen of tridymite from the Steinbach meteorite was kindly provided by Professor Clifford Frondel from the Harvard Museum collection. A previously reported study<sup>2</sup> has shown this material to be invariable twinned. The proportion of a grain in each of the possible twin orientations is easily measureable from the relative intensities of x-ray reflections not superposed by the twinning. By examining several dozen grains it was possible to select one with 3% of its volume in a twinned position relative to the main part of the grain. Precession and oscillation photographs were taken of this grain and of other less favorably twinned grains at temperatures in the range of  $200^\circ$  to  $250^\circ \text{C}$ , using a heating device similar to that described by Wuensch<sup>4</sup>.

The photographs revealed strong hexagonal pseudosymmetry and a cell which is dimensionally hexagonal within the error of measurement. The true symmetry in this temperature range appeared to be orthorhombic as was later verified from diffractometer measurements. The parameters of the C-centered orthorhombic unit cell are given in Table 1. The only reflections found to be extinct were the odd orders of the  $00\lambda$ -type reflections. All other reflections were actually measurable on the diffractometer. The space group is therefore uniquely determined to be C222<sub>1</sub>.

The C-centered cell has twice the volume of the ideal hexagonal cell and thus contains eight formula units of  $\text{SiO}_2$ . Since the multiplicity of the general position in space group C222<sub>1</sub> is eight-fold, the asymmetric unit must contain one formula unit.

#### Data collection

Intensity measurements were made on a single-crystal counter-diffractometer employing equi-inclination geometry. The furnace used in heating the crystal was especially designed to hold the temperature constant over the data-collection period and to allow the maximum possible volume of reciprocal space to be explored. In this design the primary and diffracted beams each pass through a .0005 inch thick nickel foil which serves as a heat radiation barrier and as a beta filter for the copper x-radiation employed A xenon-

Table 1

$$\underline{a} = 8.74$$

$$\underline{b} = 5.05$$

$$\underline{c} = 8.24$$

$$\underline{V} = 363.69 \text{ \AA}^3$$

$$\underline{Z} = 8 \text{ SiO}_2$$

filled proportional counter was used with pulse-height analysis to eliminate electrical noise and also the  $\lambda/2$  and shorter wave-length harmonics.

Integrated intensities were collected by the normal fixed-counter, rotating-crystal method. The background was estimated by fixed-time counts at each end of the scan. Approximately 300 reflections were measured in all. This included all independent reflections within the range of the instrument, as well as about 125 additional reflections used to verify the proposed symmetry and to determine the precision of the measurements.

The data were corrected for Lorentz and polarization factors, for absorption by the crystal, and for absorption by the nickel-foil shield of the furnace. The programs used in this data reduction are described by Onken<sup>5</sup>, except for the correction program for the nickel-foil shield, which was written by the author.

After correcting for these effects, the symmetry-related reflections were compared and found to show an average deviation of only 3.3% ( in intensity, or  $F^2$ ) from mmm symmetry. This corresponds to an average error of less than 2% in the structure factors; and so provides an excellent confirmation of the orthorhombic symmetry.

#### Determination and refinement of the structure

It was considered likely that the actual structure of the high form would be similar to the ideal high tridymite

structure proposed by Gibbs. In order to verify this a Patterson function was first calculated<sup>5</sup>. The positions of the maxima in the resulting maps confirmed the similarity of the general linkage of the ideal high-tridymite structure but showed that the atoms must be shifted from their ideal locations. The strong smearing of the silicon-oxygen and oxygen-oxygen maxima on the maps also showed that the oxygen atoms were strongly affected by thermal motion or disorder. The problem of the structure determination then became one of finding the directions and magnitudes of the distortion.

The transformation matrix relating the cell of the ideal hexagonal high-tridymite cell with the actual C-centered orthorhombic cell is  $\underline{a}_{\text{orthe}} = S \underline{a}_{\text{hex}}$ , where  $S = 210/010/001$ . The atom locations of the hexagonal cell may then be transformed to their "ideal" locations in the orthorhombic cell by  $\underline{x}_{\text{orthe}} = \underline{x}_{\text{hex}} S^{-1}$ . It should be noted that using this relationship between the two cells results in an interchange of the a and b axes of the orthorhombic cell relative to the cell given in International Tables. For this reason the equivalent positions of space group C222<sub>1</sub>, in the orientation used in this study, are listed in Table 2.

The transformed locations of the atoms in the true space group are given in Table 3. It can be seen that, as mentioned above, there is one SiO<sub>2</sub> formula unit to be specified. The silicon atom and one of the oxygen atoms are in

the general position. Two oxygen atoms occur in the special positions,  $4a$  and  $4b$ , which are positions on two-fold axes.

A structure-factor calculation<sup>5</sup> was made using the values given in Table 3. The agreement between the observed and calculated structure amplitudes, in terms of the usual  $R$  factor was 42%. A least-squares refinement was then carried out of the positional and thermal parameters, in that order. The refinement converged to  $R = 13.4\%$ , in five cycles. In the isotropic refinement the ratio of observation to variables is more than 13:1. As was expected, the apparent isotropic temperature factors of all the oxygen atoms were found to be very high, averaging about  $7 \text{ \AA}^2$ .

At this point an electron-density function and difference map were computed. The electron-density map clearly indicated that the oxygen atoms were elongated normal to direction of their bonds with the silicon atoms. Similarly, the difference map showed maxima corresponding to as much of 0.7 electrons near some of the oxygen-atom locations. With such evidence of anisotropic thermal motion, refinement was continued with anisotropic temperature factors. The restrictions to the thermal ellipsoids of the atoms lying on the two-fold axes is that, for  $O(1)$ ,  $B_{12} = B_{23} = 0$ , and for  $O(2)$ ,  $B_{12} = B_{23} = 0$ . The refinement converged in two cycles to  $R = 8.6\%$ . In the case of anisotropic temperature factors the ratio of observations to variables is 6:1.

Another electron-density map and difference map were then calculated. The electron-density map was essentially identical with the previous one, showing that few, if any, signs had changed in the anisotropic refinement. The difference map, however, was quite changed from the previous map, and showed no anomalies near any of the atom locations, indicating that the anisotropic thermal motion was well described by the six-parameter ellipsoids.

Table 4 lists the final refined positional parameters and their estimated standard deviations. Table 5 lists the final refined thermal parameters in terms of the usual anisotropic temperature factors,  $B_{1j}$ , and their estimated standard deviations. A comparison of the observed structure amplitudes and those calculated from the final model is given in Table 6.

A measure of the statistical significance of the differences between the starting parameters of Table 3, and the final parameters of Table 4 can be made by comparing these differences with the final standard deviations. It can be seen that the shifts amount to as much as forty standard deviations, in the case of silicon.

#### Description of the structure

The final refined structure is illustrated in Figure 1. Also shown are those symmetry elements of the orthorhombic cell that are not hidden by the structure. In this view the tetrahedra joined in the direction of the  $c$  axis are

Figure 1. Projection of orthorhombic high tridymite structure in c axis direction.

seen to be slightly offset from each other in the direction of the b axis. This should be compared with the ideal structure where these same tetrahedra would project, in this view, directly on top of one another. Figure 2 focuses attention on a smaller fragment of the structure as seen looking along the a axis. In the ideal structure these tilted pairs of tetrahedra would stand vertically along the c axis. The observed tilt, relative to the c axis, amounts to about  $8^\circ$ . From the two figures it can be seen that the distortion results in a slight flexure of joined tetrahedra at O(2) and O(3), but that the tetrahedra joined at O(1) are essentially as in ideal high tridymite.

Bond distances, bond angles, and their standard deviations were computed using the program MGEOM<sup>5</sup>. The results are listed in Table 7. In view of the large thermal motion, the standard deviations are surprisingly low. The weighted average Si-O distance in the tetrahedron,  $\bar{d}_w = (\sum \frac{d_i}{\sigma_i} / \frac{1}{\sigma_i})$ , is 1.56 Å. This should be compared with the distances found in quartz<sup>7</sup>; 1.603 and 1.616, and in low cristobalite<sup>2</sup>; 1.601 and 1.608. The deviations of the individual bonds from this weighted average is, in each case, less than one standard deviation, implying that the tetrahedron is regular in regard to distances.

The average of the tetrahedral angles listed in Table 7 is  $109^\circ 27'$  which is almost exactly that of a regular tetrahedron. The deviations of the individual angles from the average, however, are as much as four times the individual

Figure 2. View of part of structure of high tridymite along a-axis showing tilt of tetrahedra.

Table 7

## Interatomic distances and angles in high tridymite

	Bond distances	$\sigma$
Si-O(1)	1.563 Å	.006 Å
Si-O(2)	1.561	.005
Si-O(3)	1.542	.017
Si-O(3')	1.554	.018

	Bond angles	$\sigma$
O(1)-Si-O(2)	108.7	1.4
O(1)-Si-O(3)	108.6	0.8
O(1)-Si-O(3')	110.7	1.2
O(2)-Si-O(3)	105.9	0.8
O(2)-Si-O(3)	111.9	0.9
O(3)-Si-O(3')	110.0	1.5
Si-O(1)-Si	178.7	0.9
Si-O(2)-Si	171.2	2.7
Si-O(3)-Si	165.2	1.4

bond-angle standard deviations. This suggests that the tetrahedra do depart slightly from perfect regularity.

The Si-O-Si bond angles are all unequal. In the ideal high-tridymite structure these bonds are constrained by symmetry to be exactly  $180^\circ$ . In the actual structure the bond across O(1) does not depart significantly from this value. The bonds across O(2) and O(3), are significantly different from  $180^\circ$  and from each other, but both are still large compared to the "normal" values found in quartz<sup>7</sup>,  $143.5^\circ$ , and in low cristobalite<sup>2</sup>,  $146.8^\circ$ .

The anisotropic temperature-factor tensors were interpreted using the program THELOR<sup>8</sup>. Table 8 gives the root-mean-square amplitudes of thermal vibration in the directions of the principle axes of the thermal ellipsoids. The angles given are those between the respective principle axes and the crystallographic axes. The principle axis of the ellipsoid which most nearly parallels the crystallographic a axis is termed a' and so forth. For comparison the rms amplitudes found for quartz, at room temperature, are about .08 for Si and .09 to .14 for oxygen. The thermal ellipsoids given in Table 8 are shown plotted in Figure 2. It can be readily seen that the silicon atom is nearly spherical but that the oxygen atoms are highly elliptical. The most important point to notice is that the vibration amplitudes of the oxygen atoms normal to their bonds with the silicon atoms are almost twice that of their vibrations along the bonds.

Table 8

Root-mean-square amplitudes along principle axes of the thermal ellipsoids, and orientation of ellipsoids with respect to crystallographic axes.

Atom		rms amplitude	$\sigma$	angles (in $^{\circ}$ ) between axes of ellipsoid and crystal		
				<u>a</u>	<u>b</u>	<u>c</u>
Si	a'	.215 Å	.005	8±10	14±6	9. ±14
	b'	.182	.006	96±5	12±8	80±9
	c'	.203	.011	85±14	100±9	11±9
O(1)	a'	.394	.028	0	90	90
	b'	.324	.27	90	11±11	80±11
	c'	.238	.047	90	101±11	11±11

	b'	.419	.036	90	0	90
	c'	.323	.035	87±6	90	3±6
O(3)	a'	.408	.015	16±4	75±4	96±5
	b'	.240	.018	106±4	27±9	111±11
	c'	.301	.024	91±5	68±10	22±10

Figure 3. Orientation and rms amplitudes of thermal ellipsoids in  $\text{SiO}_4$  tetrahedron of high tridymite, projected along b (top view), and c (lower view).

Figure 3.

The effect of this large-amplitude motion normal to the silicon oxygen bond is seen by considering the instantaneous position of the oxygen atom. If, for example, O(2) is considered as displaced from its time average position in the direction of the b axis, by its rms amplitude, the instantaneous Si-O(2) distance increases to 1.605 Å and the instantaneous Si-O(2)-Si angle decreases to about 156°. Both of the instantaneous values are close to those observed in room temperature structures. This model of thermal motion is somewhat similar to that proposed by Nieuwenkamp<sup>9</sup> for high cristobalite except that he considered the oxygen atom to be rotating about the circumference of a circle of radius .4 Å.

#### Summary

In summary the true structure is seen to be distorted relative to the ideal high-tridymite structure. The distortion is a twisting of pairs of tetrahedra about the a axis such that tetrahedra joined in the c axis direction are alternately displaced in the plus and minus direction of the b axis. The amount of the twist is about 8° which causes the centers of the tetrahedra to be displaced by about 0.2 Å. The atoms show strong thermal motion, and particularly the oxygen atoms in the directions normal to the silicon oxygen bonds. The tetrahedra are very nearly regular and the interatomic distances and angles are not too different from those reported for room temperature structures, provided the thermal motion is taken into account.

## Chapter VI

The crystal structure at 120° C of transitional tridymite from the Steinbach meteorite.

## Abstract

Transitional tridymite is the phase of the Steinbach tridymite which exists between 107° C and 80° C and is characterized by a weak variable superstructure. The subcell of the phase is monoclinic  $P2_1$  with  $a = 5.04$ ,  $b = 5.04$ ,  $c = 8.23 \text{ \AA}$ , and  $\gamma = 120^\circ$ . The subcell reflections deviate only slightly from the orthorhombic  $C222_1$  symmetry of high tridymite.

The refined structure is almost identical with that found for high tridymite at 220° C. The only definite deviations from the higher symmetry are very slight shifts of the silicon atoms in the  $[1\bar{1}0]$  direction of the monoclinic cell. The apparent thermal motion is as large as that found in high tridymite although it is probably due in part to the regular deviations from the subcell positions which cause the superstructure.

Tridymite from the Steinbach meteorite has been shown in three previous chapters to exist in three distinct structural states between room temperature and  $250^{\circ}$  C. The intermediate-temperature phase, which is here termed transitional tridymite, occurs between about  $107^{\circ}$  C and about  $180^{\circ}$  C. This phase is characterized by the presence of a weak variable superstructure whose unusual behavior has been more fully described elsewhere. The supercell period of this weak superstructure varies between  $65 \text{ \AA}$  and  $105 \text{ \AA}$  over the temperature limits of this phase. Because of size of the supercell, and its variability with temperature, it was not considered feasible to collect the data or solve the complete (supercell) structure. Instead, in the nature of a preliminary investigation of the structure of this phase, this paper reports the averaged subcell structure of the transitional phase at  $120^{\circ}$  C.

#### Previous studies

In the temperature range under consideration (roughly  $105 - 180^{\circ}$  C) no structural studies have been reported although a few papers have yielded structural implications and the presence of additional reflections has been noted. Buerger and Lukesh (1942) took Weissenberg photographs of two naturally occurring tridymites at temperatures just above their inversions from the low cells, and found, in addition to the reflections of high tridymite, a "pattern

of satellite reflections which varied in their distribution in a definite manner with temperature". Hill and Roy (1958) have schematically represented powder patterns of synthetic tridymites taken at about  $130^{\circ}$  C which show additional lines relative to both the room-temperature pattern and the pattern of high tridymite. The behavior of reflections of a natural tridymite were studied by Sato (1964) on a powder diffractometer at temperatures up to  $500^{\circ}$  C. He noted the essentially continuous change in both the shape and the intensities of various reflections throughout the transitional-temperature range and at least up to  $260^{\circ}$  C.

#### Unit cell and twinning

Precession photographs were taken of several crystals of tridymite from the Steinbach meteorite at various temperatures throughout the range of the transitional phase using  $\text{MoK}$  and  $\text{FeK}$  radiation. The heating device employed was similar to that constructed by Wuensch (1964). As described previously, the subcell of the transitional phase is dimensionally the same as the hexagonal high-tridymite cell reported by Gibbs (1927). The symmetry is, however, definitely lower and somewhat problematic. From films, the substructure reflections taken by themselves seemed to show orthorhombic symmetry. Later single-crystal diffractometer measurements revealed slight deviations from this apparent symmetry, as is described in detail below, and showed the true symmetry of the subcell reflections to be

monoclinic. The dimensions of this monoclinic cell were measured from the precession photographs, and the resulting parameters are listed in Table 1. There are thus four  $\text{SiO}_2$  formula-units per unit cell, as in ideal high tridymite.

All the tridymites of this type that have been examined have proved to be twinned. The twin law and a method of determining the proportion of a grain in each of the twin orientations have been given previously. The actual grain used in the data collection was the same one used in the room-temperature phase-data collection and was selected as one of the most favorable grains found up to that time. In the transitional phase this grain was determined to have only 9.6% of its volume in twinned orientation relative to the main part of the grain. Because of this small value, and larger errors from other sources, the small effect of this twinning on the reflection intensities could be ignored.

#### Determination of the symmetry

In order to determine the true symmetry of the transitional phase, the intensities of a large number of reflections from several different crystals were measured at various temperatures between 20° C to 250° C on a single-crystal counter diffractometer. The behavior of the transitional-phase satellites has already been described (see Chapter 4). The substructure reflections were also noted to change in intensity in this region, as had been reported by Sato, but

Table 1

Subcell parameters at 120° C of tridymite  
from the Steinbach meteorite

$$a = 5.04 \text{ \AA}$$

$$b = 5.04$$

$$c = 8.23$$

$$\alpha = 90^\circ$$

$$\beta = 90^\circ$$

$$\gamma = 120^\circ$$

the magnitude of the changes are not nearly as drastic as those of the supercell reflections. Typically, the subcell reflections were observed to have their maximum value at a temperature just above the transition from the low-temperature form, and to decrease in intensity, more-or-less continuously, throughout the transitional-phase temperature range. Near the transition of the high phase the changes were seen to level off to the normal slow decrease of intensity with temperature that is expected.

Examination of the intensity measurements made just above the transition from the low-temperature form suggested that the symmetry at this temperature was monoclinic. Previous studies had shown that above  $180^{\circ}$  C the symmetry was orthorhombic. Thus it would appear that the observed intensity changes are involved with this symmetry change, and that certain pairs of reflections which are unequal in intensity at about  $110^{\circ}$ , must converge to equal intensity by about  $180^{\circ}$  C. This indicated behavior was then confirmed on the diffractometer by following pairs of equivalent reflections as the temperature was decreased from the high form, and noting a slight but real divergence in many of the cases.

Accepting the symmetry then as monoclinic, the diffraction symbol was determined to be  $2/mP2_1/-$ . The space group must therefore be  $P2_1/m$  if the crystal is centrosymmetric but  $P2_1$  if it is noncentric. In the former case there would

be one formula unit of  $\text{SiO}_2$  in the asymmetric unit of the space group, and in the latter case, there would be two formula units.

#### Data collection and correction

The intensities of the substructure reflections were then measured on the single-crystal diffractometer out to  $\sin \theta/\lambda = 0.4$ . The procedures employed were the same as have been previously described except that molybdenum radiation was used with NaI(Tl) scintillation counter. About two hundred independent reflections were collected. For control, a few reflections were remeasured a number of times during the course of the data collection to ensure a constancy of conditions. The reflections were corrected for Lorentz and polarization factors. Absorption of the molybdenum radiation by the crystal was negligible.

#### Determination and refinement of the structure

A three-dimensional Patterson function was computed. For the space group  $\underline{P2}_1/\underline{m}$ , the Patterson map has a Harker line at  $00z$ , and a Harker section at  $\underline{xy}\frac{1}{2}$ . (See Buerger, 1959) Since there would be only one independent silicon atom in this space group, this Harker line should contain a silicon-silicon peak. If, alternatively, the symmetry is  $\underline{P2}_1$ , there must be two independent silicon atoms in the cell, and these need not, in general, give rise to a peak at  $00z$  in the Patterson map; the Harker section should,

in general, show two separate silicon-silicon peaks.

Examination of the Patterson map showed peaks of appropriate height for silicon-silicon peaks: one of these occurred near, but definitely off, the line  $00z$ , and two such well resolved peaks occurred in the Harker section. The space group is therefore  $P2_1$ .

Trial locations for the two silicon atoms were taken from the Patterson map and used to calculate structure factors. The agreement between observed and calculated structure factors, in terms of the usual  $R$  factor was 34%. An electron-density map was then computed using the phases determined by the two silicon atoms. The resulting map showed the locations of the oxygen atoms, but also showed that these atoms were highly smeared out.

Starting with the parameters obtained from the electron-density map, and employing isotropic temperature factors, the structure was refined to  $R$  11.7%. The ratio of observations per variable was 8:1. The final refined positional and thermal parameters are given in Table 2. The comparison of observed and calculated structure amplitudes is given in Table 3.

As was expected from the electron-density map, the refined oxygen-atom temperature factors are very high. The apparent magnitude of the thermal vibrations could probably be decreased by continued refinement with anisotropic temperature factors. In this case, however, such refinement is not warranted. The ratio of observations per variable

would drop to only  $3\frac{1}{2}:1$ , which begins to allow errors in the data to be absorbed by the refinement. In addition, anisotropic thermal motion is probably not, in itself, the cause of these high values, as is discussed below.

A final electron-density map was computed after the refinement. The oxygen atoms could be seen to be definitely elongated in the directions normal to their bonds with silicon atoms.

#### Interpretation of the refinement model

Positional parameters. As was noted above, the substructure reflections of the transitional phase show only relatively small deviations from orthorhombic symmetry. The first test of the validity of the refinement is therefore whether or not the refined structure deviates significantly, in a statistical sense, from the symmetry of the orthorhombic high phase.

In passing from monoclinic symmetry to the orthorhombic symmetry of the high phase Si(1) becomes equivalent to Si(2), O(3) becomes equivalent to O(4), and O(1), and O(2) are required to move to special positions on the two-fold axes. Table 4 lists in the first column the deviation of these pairs of atoms from such equivalence, or for the case of the single atoms, the deviation from such special position. The second column lists the standard deviations of the parameters as determined from the monoclinic refinement. The last column gives the magnitudes of the deviations from

Table 4

Statistical significance of deviations of transitional tridymite  
from high tridymite, based upon the present refinement.

Atom	orthorhombic coordinate	deviation from $C222_1$	standard deviation	significance
Si(1,2)	$\underline{x}$	.018 Å	.002 Å	9
	$\underline{y}$	.004	.002	2
	$\underline{z}$	.002	.001	2
O(3,4)	$\underline{x}$	.020	.008	2.5
	$\underline{y}$	.018	.008	2.3
	$\underline{z}$	.015	.008	1.9
O(1)	$\underline{x}$	-	-	-
	$\underline{y}$	.007	.009	0.8
	$\underline{z}^*$	-	-	-
O(2)	$\underline{x}$	.016	.009	1.8
	$\underline{y}$	-	-	-
	$\underline{z}$	.013	.008	1.6

\* This parameter is taken as origin-determining, and may be set arbitrarily.

orthorhombic symmetry in the form of the number of standard deviations of this parameter. It can be seen that on the basis of this refinement, the only atoms which deviate significantly from the symmetry of the high phase, are the silicon atoms.

The significance of the deviations of the silicon atoms indicate that these atoms are in different positions in the two phases. The non-significance of the oxygen-atom shifts does not imply that these atoms have identical positions in the two phases, but merely means that the refinement has not furnished any meaningful evidence of a difference in position.

Figure 1 shows the refined positions of the atoms in the monoclinic unit cell. As could be expected from the above remarks, this figure is almost identical with the corresponding view of the high-tridymite structure illustrated in that paper. The interatomic distances and angles were calculated from the refined positions and are listed in Table 5.

The average Si-O tetrahedral distance is 1.56 Å, the same value found in high tridymite at 220° C. The range of distances is only slightly more than one standard deviation. The tetrahedral angles also do not depart significantly from those of a regular tetrahedron. Finally, the silicon-oxygen-silicon bond angles are within one or two standard deviations of the same values found in high tridymite at 220° C.

Table 5

Interatomic distances and angles in transitional tridymite  
at 120° C.

Si(1)-O(1)	1.59 Å
Si(1)-O(2)	1.58
Si(1)-O(3)	1.54
Si(1)-O(4)	1.60
Si(2)-O(1)	1.53
Si(2)-O(2)	1.52
Si(2)-O(3)	1.58
Si(2)-O(4)	1.57
e. s. d. (Si-O)	.03 Å
O(1)-Si(1)-O(2)	107.6°
O(1)-Si(1)-O(3)	108.3
O(1)-Si(1)-O(4)	112.7
O(2)-Si(1)-O(3)	108.4
O(2)-Si(1)-O(4)	110.7
O(3)-Si(1)-O(4)	109.0
O(1)-Si(2)-O(2)	111.2

O(3)-Si(2)-O(4)	110.3
e. s. d. (O-Si-O)	1 - 2°
Si(1)-O(1)-Si(2)	178.0°
Si(1)-O(2)-Si(2)	168.5
Si(1)-O(3)-Si(2)	164.2
Si(1)-O(4)-Si(2)	167.8
e. s. d. (Si-O-Si)	2 - 3°

Figure 1. Projection of transitional tridymite along g axis.

Thermal parameters. Due to the overall similarity of the transitional-phase structure with that of the structure of the high-temperature phase similar large amplitude thermal vibration is expectable. The observations of elongated atoms in the electron-density maps and large isotropic temperature factors may then be interpreted in the same way as in the structure of the high-temperature phase (see previous chapter). There is, however, a contributing factor to the apparent thermal motion in the case of transitional tridymite. This is due to the fact that only the substructure reflections of the transitional-phase superstructure were considered. The refined model thus represents the averaged structure, and any deviation of an atom from the averaged position appears in the form of a larger temperature factor for that atom (in the refinement model) or as an elongated atom (in the electron-density maps). The actual observations then probably represent a combination of true thermal motion and small deviations of the atoms from their subcell averaged position. Such small, ordered, deviations from the subcell average position would be in keeping with the model proposed in Chapter 4 to explain the dynamic superstructure.

#### Summary

The symmetry of the transitional-tridymite subcell at 120° C is monoclinic,  $P2_1$ . The substructure reflections

deviate only slightly from orthorhombic  $C_{222}_1$  symmetry. The average positions of the atoms in the subcell, as determined by a least-squares refinement, do not deviate significantly from  $C_{222}_1$  symmetry, except in the case of the silicon atoms. The refinement shows that the two-fold axes of the high-tridymite orthorhombic cell are lost in the transformation to the transitional phase. The change of the structure appears to be a very slight twist of the tetrahedra about the  $c$  axis, but shifts in the positions of corners of the tetrahedra (the oxygen atoms) could not be proved from the refinement. The observed thermal-vibration amplitudes seem to be similar to those found in high tridymite at  $220^\circ \text{C}$ , and are doubtlessly augmented by the (ordered) atomic displacements from the subcell positions which give rise to the transitional-phase superstructure.

## Appendix

### An improved furnace for use with a single-crystal counter diffractometer.

The heating attachment employed in most of the single-crystal diffractometer measurements was expressly designed for this study and has proved to be quite useful. Since it has not been described elsewhere, this appendix provides the details of its design and construction necessary to allow a copy to be made, if desired. Figures 1-4 are reproductions of the actual working drawings from which the furnace was constructed at the Electronics Systems Laboratory, at M.I.T.

The design of the furnace was based largely upon similar designs by M. J. Buerger, N. W. Buerger, and others, although their instruments were constructed for film studies at high temperatures. Prior to the construction of the furnace described below, initial film and diffractometer studies were made by the author using a heating device of the type described by Wuensch. The drawbacks of this type of furnace, and the experience gained in its use, influenced the design of the new furnace.

### Design

For use with a single-crystal counter diffractometer a heating attachment should ideally satisfy the following

major requirements; for a given setting, the temperature in the furnace should remain constant indefinitely, the heating attachment should not decrease the volume of reciprocal space which may be explored by the diffractometer, and the temperature should be variable continuously from room temperature to the melting point of the substance under investigation. Subsidiary requirements of the ideal heating attachment are that it should allow the crystal to be reoriented at high temperatures and that any absorption of the x-ray beam by the diffractometer, be of a correctable form.

The final practical design must, of course, be a compromise between the several desired characteristics, and in addition, depends upon the materials available, the space available on the diffractometer, the cost, etc. It was found that, by choosing the desired diffraction geometry and by optimizing the most desired characteristics, the design was essentially fixed.

The equi-inclination geometry of data collection was considered preferable since it allowed all of reciprocal space (out to a certain limit) to be explored without re-mounting the crystal, and since it led to a simple correction for absorption by the furnace. In order to maintain the temperature constant it was decided that the furnace should be as enclosed as possible. The only opening needed was that required to admit the crystal and its supporting

glass fiber. In order to support the enclosure as well as the heating element itself it was necessary to restrict the angular range of the diffractometer. The furnace was then designed to allow a maximum equi-inclination angle of  $45^{\circ}$ .

#### Materials and construction

The individual components of the furnace are numbered in the working drawings shown in Figures 1-4. The heating element is a coil of resistance wire which is allowed to expand within the supports (1) and (2). These supports are fired pyrophyllite turnings, which should withstand a furnace temperature of  $1000^{\circ}$  C. The heating element and its supports slide into a cylindrical brass cartridge (3) and are held in place by caps (4) and (5). One end of the heating coil is grounded to the cartridge, and the other end is passed through the body of support (1), to a screw threaded into the end serving as a binding post.

The cartridge is wrapped with a single layer of nickel foil .0005-inches thick which serves as the furnace enclosure. The foil easily passes copper or molybdenum x-radiation but forms a barrier to the escape of heat radiation. The wrapped cartridge is inserted into the furnace cooling jacket (6) and held in place by the cap (7). The water cooling jacket (6) is constructed of two coaxial brass cylinders that have been heat-fitted and silver-soldered together at the ends. The channels through which the cooling

water circulates are cut into the cylinders prior to their being joined. The water jacket (6) is silver-soldered to the support arm (9) which is a bent brass bar held in place on the diffractometer by means of an aluminum dovetail assembly (10), (11) and (12). The dovetail is attached with screws to the crystal-rotation-axis support of the diffractometer.

With the crystal in place, the support arm of the assembled furnace is inserted into the dovetail, and the furnace is drawn into place over the crystal. The electrical contacts are made to the heating coil through the contact post screwed into (1), and through the grounder furnace support. The temperature is controlled by varying the voltage across the heating coil by means of a Variac. The total energy consumed by the heating coil is measured by a wattmeter whose reading is used to determine the furnace temperature from a calibration curve. This curve must be established by thermocouple and known melting-point measurements.

### Biography

The author was born in West Bend, Wisconsin on August 16, 1938 and attended primary and secondary schools in West Bend and Watertown, Wisconsin. He attended the University of Wisconsin at Madison from 1956 to 1961 receiving the degree of Bachelor of Science with Senior Honors, in June 1960 and the degree of Master of Science (Geology) in August 1961.

From September 1961 to June 1966 he has been enrolled in a Ph. D. program at the Massachusetts Institute of Technology.

The author is a member of the American Crystallographic Association, the Mineralogical Society of America, and the American Association for the Advancement of Science. The author's previous publications are listed on the following page.
