ON THE DYNAMICS OF SHALLOW WATER CURRENTS IN  
MASSACHUSETTS BAY AND ON THE NEW ENGLAND CONTINENTAL SHELF

BRADFORD BUTMAN

Submitted to the Massachusetts Institute of  
Technology — Woods Hole Oceanographic Institution  
Joint Program in Oceanography on April 7, 1975, in  
partial fulfillment of the requirements for the degree  
of Doctor of Philosophy.

ABSTRACT

Massachusetts Bay is a coastal Bay 100 km long and 40 km wide located in the western Gulf of Maine. The Bay is closed by land to the north, west and south, but is open to the Gulf to the east; the opening is partially blocked by a shallow bank. The bottom sediment distribution in the Bay is complex; fine grained material is found in the deep basin, sand and gravel on the shallow bank, and mixtures of sand, gravel and fine material nearshore. Richardson current meters were moored 1 m from the bottom over a one year period at several locations in the Bay to study the bottom currents and the equilibrium between current and sediments. The current measurements suggest that the bottom sediments can be expected to move only occasionally in certain areas. The maximum bottom speeds are principally determined by the strong tidal currents in the basin.

In winter, the near bottom currents are dominated by wind stress associated with strong storms. Bottom currents in the shallow areas are generally in the direction of the wind while currents in the deep portion of the basin are often opposite to the direction of the wind. Sea surface setup in the direction of the wind is observed, as well as absolute changes in sea level as the Bay adjusts to changes in the level of the adjacent Gulf of Maine. Adjustment of the bottom currents to wind events requires approximately 12 hours.

Moored current meter measurements and synoptic hydrographic observations made in Massachusetts Bay show that freshening from the spring runoff dominates the low frequency currents and the hydrography of the Bay in the spring months. The major freshening is attributed to the Merrimack River which empties into the Gulf of Maine 30 km to the north of the Bay; discharge of the Merrimack increases by at least a factor of two in spring. Flow directly into the basin from several smaller rivers is not important. Two major features are found: a fresh surface plume confined to the upper 10 m of the water column which becomes more distinct as the seasonal thermocline develops, and a large deep fresh lens. Flow is clockwise around the deep lens and is consistent with the thermal wind relation. Sustained currents of 10 - 20 cm sec<sup>-1</sup> with time scales of 5 - 10 days were observed as the deep lens (or lenses) slowly advected through the basin. Current observations made in the previous spring show similar low frequency behavior.

Two simple linear models of the semidiurnal tide on the continental shelf are used to estimate the vertical turbulent eddy viscosity, a linear bottom drag coefficient, and the change in the bottom drag coefficient during storms. The analytic solution for the response of a homogeneous water column with constant eddy viscosity to a sinusoidal body force with a slip bottom boundary condition is presented. With measurements of the tidal current at two depths, four parameters are shown to be independent of the body force: the ratio of the clockwise current at two depths, the ratio of counterclockwise current at two depths, the change in the tidal ellipse orientation, and the change in phase of the tidal ellipse. Observations of the semidiurnal tidal current on the New England continental shelf are consistent with a vertical eddy viscosity of  $20 - 50 \text{ cm}^2 \text{ sec}^{-1}$  and a bottom drag coefficient of  $.02 - .05 \text{ cm sec}^{-1}$ . The Ekman depth is thus 10 m and the integrated adjustment time is approximately 28 hours.

An integrated linear model with linear damping of the semidiurnal tide on the continental shelf, forced uniformly at the shelf edge, shows an increasing phase lag of the tide at the coast with increased damping; amplitude remains relatively constant over a wide range of damping coefficient. Observations of the tide at the coast during storms shows a phase lag of as much as 10 degrees for the semidiurnal tide. For approximate dimensions of the New England shelf, this implies an increase by a factor of 3 - 5 of the bottom drag coefficient and an integrated motion adjustment time of 6 - 9 hours. Waves may be an important contribution to the increased bottom stress.

Thesis Supervisor: Dr. Robert C. Beardsley  
Associate Professor of Oceanography  
Massachusetts Institute of Technology

## ACKNOWLEDGMENTS

I wish to thank my thesis advisor, Robert C. Beardsley, and the members of my thesis committee, W.F. Simmons, G.T. Csanady, J.S. Schlee and H.M. Stommel, for support and encouragement, and an appropriate mix of guidance, assistance and neglect during the course of this thesis work. For sharing their knowledge and insight, I thank my committee and the teachers at M.I.T. and W.H.O.I.

Financial aid was provided during various phases of my graduate education by a Massachusetts Institute of Technology teaching appointment, a National Science Foundation Graduate Fellowship, the Massachusetts Institute of Technology Sea Grant Program (NG 43-72) and the National Science Foundation (Grant NSF GA 30729X) for which I am grateful.

Funds for field studies and computer time were provided by the U.S. Geological Survey, the Massachusetts Department of Public Works, the Massachusetts Institute of Technology Sea Grant Program, the National Science Foundation (Grant NSF GA 41075), the Office of Naval Research (N00014-74-C-262 NR 083-004), and the Woods Hole Oceanographic Institution Education Program.

J.S. Schlee kindly allowed me to work with the bottom current data presented in Chapter I, and to incorporate the sediment-bottom current study as part of my thesis research. His enthusiasm and patience is appreciated. V. Manohar-Maharaj provided the hydrographic data for the sections of March 29-30, April 15-16, May 5-6, and June 2-3 shown in Chapter II. R.C. Beardsley and C.F. Flagg provided data from the 1974 M.I.T. Winter Shelf Dynamics Experiment (NSF Grant GA 41075) to test the vertical Ekman model of the bottom boundary layer (Chapter III).

Many people assisted in the collection of data at sea; J.S. Schlee, C.H. O'Hara, R.C. Beardsley, V. Manohar-Maharaj, J. Vermersch, C. Flagg, R. Beebe-Center, S. Riser and P. May. The crew of the Tug Whitefoot (Capt. R. Campbell and Mate C. Conroy) and the R.V. Verrill (P. Graham, F. Duing, C. Gaudy) provided assistance with the current meter moorings; the R.V. Shrock provided a platform for density work in Massachusetts Bay.

The help of J. Maltais, use of the Woods Hole Oceanographic Institution Buoy Group computer programs, and assistance of the Woods Hole Oceanographic Institution Information Processing Center is acknowledged.

The assistance of the following agencies is acknowledged; U.S. Geological Survey, National Ocean Survey, U.S. Coast Guard, National Climatic Center.

Mrs. May Reese cheerfully and professionally typed the manuscript for which I am grateful.

Finally, the support of my parents and friends during this thesis work is appreciated.

## INTRODUCTION

This thesis investigates several physical processes which are important in the dynamics of currents in shallow water. Among oceanographers, coastal or continental shelf oceanography has generally been of less interest than study of the deep oceans. However, the need to understand the biological and physical environment of the nearshore coastal areas has increased in the last several years as use and development of coastal resources have grown. To assess the environmental consequences of these activities requires knowledge of the processes which mix and transport substances in the water and on the bottom.

Perhaps the slow development of coastal physical oceanography is a result of the complexity of the coastal physical environment. In shallow water meteorological forcing (heating, cooling, and wind stress), the physical boundaries of the coast and bottom topography, the flux of fresh water from rivers, and the fluxes of mass and momentum at the shelf boundary will be important factors affecting the currents. On the northeast coast of the United States, much of our knowledge of the circulation has come from studies of drift bottle and seabed drifter returns (Bumpus, 1973) which do not adequately resolve short time and space scale phenomena. However, short time scale (periods of days) and space scale (horizontal scales of several tens of kilometers) currents associated with meteorological forcing or with the seasonal density distribution may in fact dominate the nearshore flow. The objective of this thesis is to identify, describe and understand several of these short time and space scale physical processes.

Chapter One, prepared in collaboration with Dr. John Schlee of the U.S. Geological Survey, reports the results of a study of the equilibrium between the near bottom currents and the bottom sediments and the factors which drive the bottom currents in Massachusetts Bay, a semi-enclosed basin located in the western Gulf of Maine. Bottom currents were monitored over a one year period using Richardson current meters in areas of widely different bottom sediment types. The study suggests that the bottom sediments can be expected to move only occasionally in certain areas, and that the strong tidal currents in the Bay basically determine the bottom current speed. Strong storms dominate the net near bottom flow pattern in winter.

Chapter Two is a study of the current and density distribution in Massachusetts Bay during the period of the spring runoff. The Bay is located 30 km from a major river which discharges into the western Gulf of Maine. Synoptic hydrographic observations and moored current measurements show that the low frequency current in the spring months is primarily driven by the strong density gradients associated with the increased spring river discharge and that winds are not important.

Chapter Three is a study of the effects of friction on the currents on the New England continental shelf, and on the parametrization of the frictional effects. Two simple dynamical models appropriate for winter conditions are developed and used to estimate a bottom drag coefficient and a vertical eddy viscosity, and the change in the bottom drag coefficient during storms. The bottom drag coefficient determines the bottom stress for a given current and thus specifies the adjustment or decay time for integrated motions on the shelf, while the value of the vertical eddy viscosity determines the vertical distribution of the stress.

A brief chronology of this thesis work explains the author's interest in these aspects of the physical oceanography of Massachusetts Bay and the continental shelf. When I began thesis work in 1972 I was particularly interested in the field of coastal oceanography and especially in field observations of important time dependent processes; unfortunately there was little ongoing research within the community. At that time, Dr. John Schlee of the U.S. Geological Survey was conducting a survey of bottom currents in Massachusetts Bay as an extension of his work on the bottom sediment distribution. I had worked with Dr. Schlee on the currents in Massachusetts Bay in preparation for this monitoring program, and he kindly allowed me to work with the bottom current records. Chapter I presents the results of the bottom monitoring experiment.

The spring current records from the monitoring experiment and historical data suggested that the freshening associated with the spring runoff strongly influenced the hydrography and currents in Massachusetts Bay in spring, and was an important physical process. To study the importance of the spring runoff in the low frequency currents, a field experiment was conducted in the spring of 1973 using moored current meters and hydrographic observations (Chapter II).

At the same time, the author conducted a pilot experiment with Prof. R.C. Beardsley on the continental shelf to study the response to strong winter storms, and to test the feasibility of making current measurements on the continental shelf using similar mooring techniques as used in Massachusetts Bay (Beardsley and Butman, 1974). It was clear from that experiment and from my work on the wind driven currents in Massachusetts Bay that an estimate of frictional effects was important in under-

standing shallow water currents. Similar work had been begun using Massachusetts Bay data, but the shelf presented a less complicated geometry with which to work. Dr. Beardsley kindly allowed me to use data from a second more extensive shelf experiment conducted in late winter of 1974 to estimate the vertical eddy viscosity and the bottom drag coefficient using an Ekman model of the bottom boundary layer.

## CHAPTER I

## NEAR BOTTOM CURRENTS AND THE SEDIMENT DISTRIBUTION

## IN MASSACHUSETTS BAY

A. Introduction

Massachusetts Bay and its southeast extension, referred to as Cape Cod Bay, are bounded on three sides by the Massachusetts coast and open to the Gulf of Maine on the northeast between Cape Cod and Cape Ann (Figure 1.1). The opening is partially blocked by Stellwagen Bank which rises to within 20 m of the surface. Stellwagen Basin, located in the center of Massachusetts Bay, has a maximum depth slightly in excess of 100 m, though most is about 80 m deep. Depth changes in Cape Cod Bay, Stellwagen Basin, and on Stellwagen Bank occur gently (grades of .1 - .5%), except on the western side of Stellwagen Bank (grades of 6%). In contrast, the bottom along the western side of the Bay from Cape Ann to Plymouth (42°20'N 70°40'W) is hummocky and rough with depth changes of 5 m in .1 km (see C&GS chart No. 0808N-50 Cape Cod to Cape Ann).

Although complex, the bottom sediment distribution can be grouped in four categories by location and sediment type (Schlee and others, 1973; Oldale and others, 1973; Tucholke and others, 1972). Nearshore adjacent to the rocky coast from Cape Ann to Plymouth the rough bottom is a patchwork of gravel, sand, mud, and bedrock, while adjacent to constructional features (outwash and moraines) from Plymouth around Cape Cod, the generally smooth bottom is well sorted sand mixed with gravel. Offshore, the shallow bank is well sorted sand, or sand and gravel. Finest grained sediment of clay, silt and sand is found in the deep basin and in the

Figure 1.1 Map of Cape Cod and Massachusetts Bays. Smoothed 40 and 80 m contours show major bathymetric features (Plymouth located  $42^{\circ}20'N$   $70^{\circ}40'W$ ).

Figure 1.2

channels entering the Bay (figure 1.2).

In general, the bottom sediment distribution will reflect the present and long term environmental conditions which have deposited, reworked and redistributed existing material (for example, studies by Kranck, 1972), and the diverse agents (ice, rivers, etc.) which have deposited the sediment under entirely different geologic conditions from those of today. The glaciation of the New England coast and the subsequent rise of sea level formed the major bathymetric features and sediment deposits in Massachusetts Bay (Oldale and others, 1973; Tucholke and Hollister, 1973). The accumulation of fine sediments in the deep basin is attributed to winnowing of material from the topographic highs and nearshore and redeposition in the basins, most of the deposition occurring just after glacial retreat. The sedimentation rate has steadily decreased as these sources have become less important and is estimated currently to be 1 - 2 cm per thousand years (Tucholke and Hollister, 1973).

With such a complex sediment distribution and bottom topography, two questions arise: (1) Does movement of the bottom sediment occur in Massachusetts Bay under present conditions and if movement does occur, where and how frequently? (2) What is the pattern of bottom water movement in the Bay which might redistribute sediment if eroded and what are the major factors which drive the bottom currents? This chapter reports the results of a monitoring survey of the bottom currents in Massachusetts Bay using moored current meters. A brief review of the bottom boundary layer is presented, followed by a description of the field experiment.

The equilibrium between bottom sediments and bottom currents at the monitoring locations in the Bay is discussed next. Finally, winds were found to be a major factor in generating net bottom flow in winter, and the bottom flow pattern and associated sea level adjustment in Massachusetts Bay during strong winter storms is presented.

B. The Bottom Boundary Layer and Incipient Sediment Motion

A vast literature exists on the benthic boundary layer and processes of sediment motion and transport. (A review article by Wimbush and Munk (1971), work of Weatherly (1972), and a collection of articles edited by Swift, Duane and Pilkey (1972) were found useful references.) For this study of the adjustment of bottom sediments to currents, an estimate of the stress required to erode the existing material and a method to determine the bottom stress occurring in the marine environment is needed.

Field and laboratory studies have shown that the velocity profile in the bottom boundary layer is logarithmic, extending 1 - 4 m from the bottom (Sternberg, 1971, 1972; Miller and others, 1972; Weatherly, 1972).

Thus

$$u(z) = \frac{u^*}{\kappa} \ln (z/z_0) , \quad (1)$$

where

$\kappa$  = VonKarman's constant = .4 ,

$u^*$  = friction velocity =  $(\tau/\rho)^{1/2}$  ,

$\tau$  = bottom stress,

$z_0$  = roughness length,

$z$  = height from bottom.

The value of  $z_0$  is found empirically to vary with flow characteristics.

Specifically, the value of  $z_0$  depends on the relative size of the laminar

sublayer and the roughness elements ( $d$ ) of the boundary. The depth of the laminar sublayer is

$$\delta_l \approx \frac{12\nu}{u^*}, \quad \nu = \text{kinematic viscosity } \text{cm}^2\text{sec}^{-1} .$$

For hydrodynamically smooth flow, the roughness elements are enclosed completely within the laminar sublayer, while for rough flow the layer is disrupted by the roughness elements. The conditions for smooth or rough flow are summarized in Table 1.1. For a smooth bottom, velocity measurements at a single height will give an estimate of  $u^*$  but for a rough bottom an estimate of  $z_0$  is also required. Alternatively, for measurements at a fixed height above the bottom (1) can be written as

$$u^{*2} = \rho C_D u^2 ,$$

where  $C_D$  is a property of the bottom roughness and is empirically determined. The drag coefficient is larger for rough bottoms than for smooth bottoms.

Measurements of the logarithmic bottom layer, particularly those of Sternberg (1971) and Weatherly (1972), have shown considerable variability in estimates of  $z_0$ . Variability decreased if the velocity profile was averaged over longer times (Weatherly, 1972). It may be that the roughness height is not a physical property of bed, but more a property of the fluid flow. Despite these rather serious reservations, estimates of the bottom stress will be made using bottom photographs to determine roughness, and (1).

Empirical curves of the bottom velocity (Sundborg, 1956; Allen, 1965), or of the bottom stress (Inman, 1963; Bagnold, 1962) required to erode well sorted sediment of a given grain diameter and density have been found to agree roughly with field measurements in a tidal channel (Sternberg,

TABLE 1.1

CONDITIONS FOR FLOW OVER SMOOTH AND ROUGH BOTTOM

<u>Smooth Bottom</u>	<u>Rough Bottom</u>
$d < \frac{4\nu}{u^*}$	$d > \frac{40\nu}{u^*}$
$z_0 \sim \frac{1\nu}{u^*}$	$z_0 \sim d/30$
$u(z) = \frac{u^*}{\kappa} \ln \left( \frac{zu^*}{.1\nu} \right)$	$u(z) = \frac{u^*}{\kappa} \ln (z/z_0)$

$d$  = characteristic roughness element height

$\nu$  = kinematic viscosity

$z$  = height from bottom

$z_0$  = effective roughness

$u^*$  = friction velocity

$\kappa$  = VonKarman's constant

1971; Miller and others, 1972). The bottom stress required for movement is a minimum in the sand range (.1 - 1 mm diameter) and is about 4 dynes ( $u^* = 2 \text{ cm sec}^{-1}$ ); larger stress is required to move coarser material ( $u^* = 8 \text{ cm sec}^{-1}$  for diameter 1 cm). For material in the silt and clay range, the stress required for incipient movement depends on the degree of consolidation or 'age' of the sediment after deposition (Postma, 1967; Southard, Young, Hollister, 1971). The curves of Inman suggest a  $u^*$  of at least  $4 \text{ cm sec}^{-1}$  is required to erode consolidated silts and clays, but there is little experimental data; one exception is the laboratory study of Southard, Young, Hollister (1971), where a  $u^*$  of  $1.37 \text{ cm sec}^{-1}$  was required to move a deep sea mud.

If the bottom boundary layer is sufficiently turbulent deposition of fine grained material will not occur, or will be resuspended immediately. The Sundborg curve indicates no deposition of material less than .05 mm in diameter (silt) for velocities of  $1 \text{ cm sec}^{-1}$ . McCave (1972), summarizing laboratory studies, reports deposition of fine material will not occur for  $u^*$  in the range of  $.6 - .9 \text{ cm sec}^{-1}$ .

It must be emphasized that the effects of cohesion, biological reworking and resuspension, aging after deposition, bed form and sorting on conditions for incipient sediment motion are not well understood. Rhoads and Young (1971) show intense biological reworking and resuspension of fine grained bottom sediment in Cape Cod Bay, and biological activity may be a significant factor in Massachusetts Bay. Also, bedform contributes to measured shear stress, not just grain diameter. Despite these problems the approximate bottom stress and velocities required for incipient motion of material in the sand, silt and clay, and gravel range

TABLE 1.2

ESTIMATES OF BOTTOM STRESS REQUIRED FOR INCIPIENT  
SEDIMENT MOTION AND DEPOSITION.

	Required Friction Velocity (U*) cm/sec	Speed 100 cm from bottom <sup>2</sup> cm/sec	
		Smooth	Rough
<u>Inciipient Motion</u> <sup>1</sup>			(a) (b)

Consolidated silt and clay	4	129	80 64
Gravel (1 cm diameter)	8	272	160 128
<u>Deposition</u> <sup>3</sup>			
Silt and clay	.6 - .9	17-26	12-18 10-14

<sup>1</sup>Estimated from Inman (1949), reproduced in Miller and others (1972); Southard, Young and Hollister (1971), Postma (1967).

<sup>2</sup>Velocities estimated from equation 1.1 . For a rough bottom two roughness heights are used: a)  $d = 1$  cm, b)  $d = 5$  cm ( $z_o = d/30$ ). All estimates to nearest cm/sec.

<sup>3</sup>Estimates from McCave (1972).

are estimated (Table 1.2) using the logarithmic law (1). The estimates in the sand and gravel range are probably fairly accurate while the estimates for finer material are somewhat uncertain, primarily because of uncertainty in the degree of consolidation and cohesion of the sediments and lack of laboratory and direct field erosion data. Although stress and velocity estimates in Table 1.2 should be viewed as approximate, they should provide useful ranges of erosion velocities for this study.

### C. Field Program

#### 1. Bottom Current Monitoring

Measurements of the near bottom currents were made in Massachusetts Bay from May, 1971 through July, 1972 at several locations (figure 1.3) which were selected to define the bottom current pattern in Massachusetts and Cape Cod Bays, if possible, and to measure the currents over various types of bottom sediments. Stations A and F were placed to monitor flow in the two channels leading into Stellwagen Basin; stations B and E were selected to monitor circulation on the coastal shelf. Station C was placed in Stellwagen Basin, and station D was placed to monitor on Stellwagen Bank, Stations A, C and F are in areas of fine sediments, while B, D and E are in areas with coarser bottom material. A current meter was deployed throughout the study at the Boston Lightship to provide continuous measurements at one location. It was hoped to obtain a one month bottom current record each season at stations A-F, however temporary loss of one current meter and malfunctions prevented this objective. The latitude and longitude of the stations and the dates of the successful measurements are listed in Appendix A. The time sequence of current meter deployments is shown in figure 1.4.

Figure 1.3 Location of bottom current monitoring stations and bottom photographs.

Figure 1.3

Figure 1.4 Schedule of current meter deployment in Massachusetts and Cape Cod Bays. Records are numbered sequentially at each station and dashed lines indicate records with inaccurate sampling rate and time base. See figure 1.3 for station locations.

Figure 1.4

The current meters at stations A-F were moored 1 m from the bottom, with all floatation within approximately 5 m of the bottom (figure 1.5). The mooring was designed with groundlines on either side of the main anchor to facilitate recovery of the instrument if the surface marker was lost, and a small acoustic beacon was attached to the meters to aid in locating the instrument. The Boston Lightship meter was suspended from the lightship approximately 8 m from the bottom. One Geodyne model 850 and the two model 102 Richardson type current meters were used in the survey; the 850 current meter was deployed continuously from the Boston Lightship, while the 102 meters were rotated among the offshore stations. No current meters were permanently lost during the program, and approximately 60% of the instruments returned useable data. Instrument malfunction occurred in the 102 current meters which record on film, and was due to film advance problems, malfunction of the circuitry, or to an inaccurate time base. The 850 current meter was found extremely reliable.

## 2. Bottom Sediment Composition and Texture Near Current Meter Stations

Grain size analysis of the bottom sediment near the current meter stations (Table 1.3) was obtained from an earlier sediment survey (Schlee and others, 1973; Hathaway, 1971). Most of the samples are sandy silt or sand, except at station E where there is a large amount of gravel. At the deeper stations (A,C,F) the bottom composition is similar: 44-47% sand, 32-39% silt, 16-19% clay. At station B and D, the bottom is sand or sand and gravel.

Bottom photographs (see figure 1.2 for locations) obtained from previous studies clearly show the different bottom sediments, sorting and texture. Near Station B a thin layer of fine material overlies gravel

and coarse sand (figures 1.6 a,b) suggesting little active current erosion. The two photographs at station B illustrate the typical patchiness of the bottom sediment distribution and the difficulty in estimating a meaningful roughness height in areas with poor sorting. In the deep basin (figure 1.6 c,d) the bottom is soft silt, sand and clay, much smoother than at station B (roughness elements less than 1 cm), and again there is little evidence for active erosion. In contrast, on Stellwagen Bank (station D, figure 1.6 e) there is no apparent fine material and ripple marks suggest active or recent erosion. Here an approximate roughness height is estimated to be 5 cm. At station E (figure 1.6 f) the bottom is coarse sand with no evidence of active erosion.

In summary, for the purposes of this study the bottom photographs suggest that the bottom in the deep basin (station C) should be considered smooth, while at stations B, D, and E the bottom is rough. No bottom photographs were available at stations A or F, but the bottom sediment is similar to station C suggesting that the bottom might be considered smooth.

#### D. Speed Statistics and Estimates of Bottom Sediment Movement

The stations may be grouped in three classes by the observed maximum speed and average speed (Table 1.4); the largest maximum and average speeds occur at stations D and F at the southern mouth of the Bay. Nearshore (stations B and E) the maximum and average speeds are weaker, while at the deep stations (A and C) the average speeds are similar to the nearshore stations, but the maximum speeds are somewhat less. The speed distribution in the basin is primarily controlled by the strength of the tidal current and the depth. At the mouth of the Bay the tidal currents are strong and the water is shallow so that wind generated currents and possibly waves contribute to the maximum speed. In the deep basin and on the shallow border of the Bay the tidal currents are substantially weaker, but maximum

speeds are larger in the shallow regions probably because of wind and wave action.

At station B, D, and F, the observed maximum speeds are above the estimated minimum critical erosion speeds (Table 1.2), assuming a rough bottom. None of the observed speeds are large enough to move sand if the bottom is smooth. At stations A and C, the maximum speeds are substantially below critical erosion speeds for consolidated or unconsolidated silt and clay. At all stations during most of the measurement period, the current speed was substantially less than the critical erosion speed, and thus bottom movement of sediments, if it occurs at all, is infrequent. There is some suggestion that the maximum bottom speeds occurred in the fall and winter months (Table 1.5); however the data is too sparse to make any generalizations with statistical reliability. The average current at stations D and F is sufficiently high to prevent deposition of fine material, while at the stations A, B, C deposition is possible 95% of the time.

A graph of median grain size versus the maximum one minute average current speed observed during each of the bottom current meter records (figure 1.6) shows that most of the points fall within the limits of the competency curves of Sundborg. It should be noted that these empirical curves do not take into account bottom roughness except through grain diameter. Only at station E do the values fall far below the competency curve, and this is because most of the sample used to characterize the bottom sediments at station E is gravel which is relict glacial material.

In summary in the well sorted sand regions (station B and D), we can expect occasional movement if the bottom is assumed to be rough with roughness elements of at least 1 cm. Estimates of critical erosion stress for the silt-sand bottoms are uncertain, but the data suggest that the

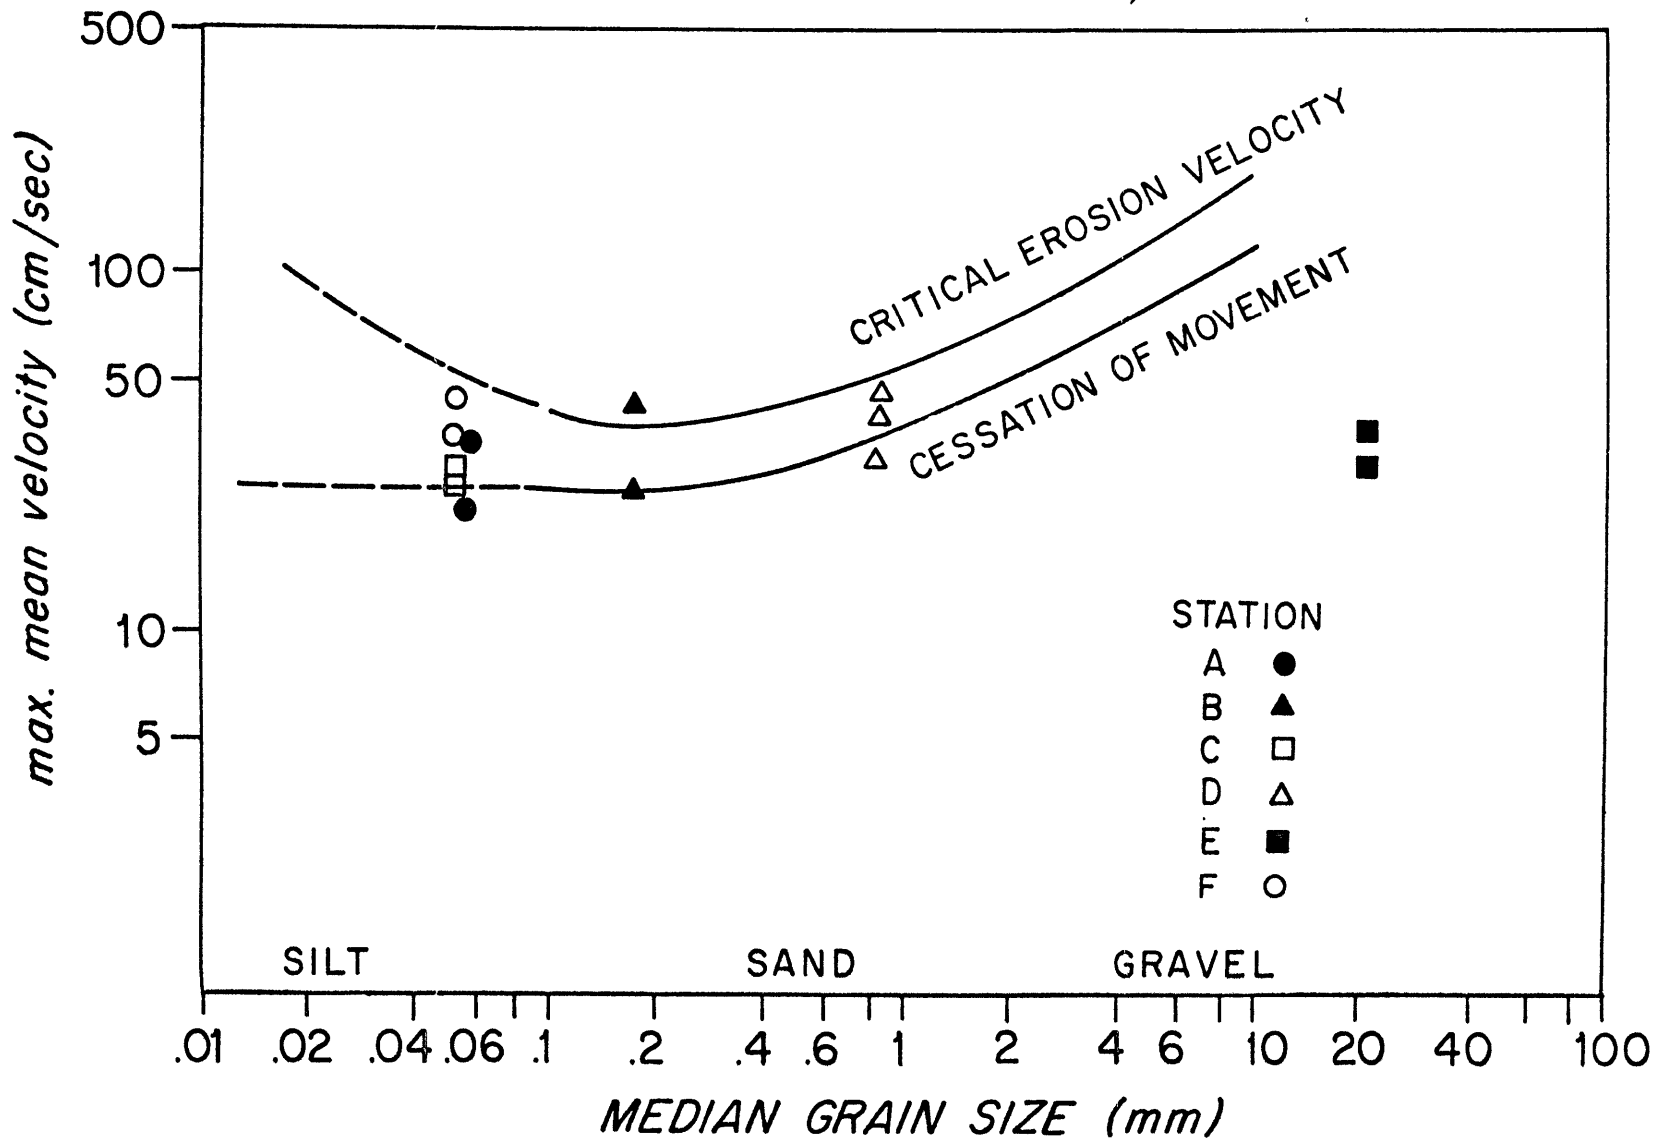

Figure 1.7

observed maximum speeds are not strong enough to move bottom material at stations A and C. At station F where the bottom is also sandy silt it is not possible to determine whether occasional incipient motion occurs if the bottom is unconsolidated without additional information on critical erosion stress of the material and bottom roughness. For a consolidated bottom — hard packed clay material retrieved with the current meter anchor suggests the bottom is consolidated — movement will not occur. The distinction between smooth and rough bottom is important since at no station was the maximum speed strong enough to move sand assuming a smooth bottom. Stresses are low enough to allow deposition of fine material for a large fraction of the time at stations A, B, C, and E but only for shorter periods at stations D and F, primarily because of the large tidal currents at the mouth of the bay.

#### E. Wind Driven Near Bottom Currents In Winter

One of the most striking features of the winter bottom currents is that rapid changes in the direction and magnitude of flow occur on time scales of 1 - 5 days (figure 1.8), with many of the changes associated with strong wind events. Similar dominance of the low frequency currents by wind stress on the continental shelf and Great Lakes has been noted by Beardsley and Butman (1974), Csanady (1973a,b) and Blanton (1974) among others. Theoretical and numerical studies of flow in closed basins such as the Great Lakes (Rao and Murty, 1970; Bennett, 1974; Csanady, 1973a) suggest that topographic variations in a long lake produce a 'two gyre' flow pattern in response to wind along the major axis; flow is in the direction of the wind in shallow areas and opposite to the wind in the deep regions, the return flow being driven by a surface pressure gradient or setup. The large depth changes and the semi-enclosed geometry of

Figure 1.8a

Figure 1.8b

Massachusetts Bay suggests that a similar flow pattern may occur during strong wind events which could be important in redistributing the fine bottom sediments from the nearshore areas and bank to the deep basin. In this section we investigate the response of the bottom currents and sea level in Massachusetts Bay to strong winter storms, using coastal sea level observations and the bottom current measurements made during December - February, 1972 (figure 1.4). Due to the limited nature of the bottom current data set, the discussion is necessarily qualitative.

#### 1. Sea Level Response to Wind

Because Massachusetts Bay is a semi-enclosed basin opening on the east to the Gulf of Maine, sea level will reflect changes in the level of the Gulf at the mouth of the Bay, as well as local changes due to wind stress. The low frequency response of sea level to winds parallel to the major axis of the basin ( $150^\circ - 330^\circ$  T, figure 1.9) indicates a setup in the direction of the wind (figure 1.10 a,b). A northwest-southeast wind stress of 1 dyne (using a drag coefficient of  $1.1 \times 10^{-3}$ ) results in a change in elevation between Boston and Sandwich of approximately 5 cm, with the setup occurring almost immediately.

The basin response to a wind blowing across the minor axis of the Bay ( $60 - 240$  T, figure 1.10) is more complicated than a simple setup in the direction of the wind. A wind blowing to the northeast results in a large drop in sea level at Boston and Sandwich (order 50 cm for a 1 dyne wind), while a wind blowing to the southwest results in a large rise. Although no sea level observations were made in the outer part of the Bay it is unreasonable to expect that such a large setup (an order of magnitude larger than the setup for winds along the long axis) occurs

Figure 1.9 Map of Massachusetts and Cape Cod Bays showing location of tide and meteorological stations, and major and minor axes.

Figure 1.9

Figure 1.10 a,b      Low frequency response of sea level in Massachusetts Bay to wind, Jan.-Feb., 1972.

Top:      Difference in sea level between Sandwich and Boston and component of wind stress parallel to major axis of the Bay (330°-150°T, figure 1.9).

Bottom:      Deviation of sea level at Boston from mean and component of wind stress parallel to minor axis of the Bay, and across the open side (60°-240°T). Deviation from mean level is corrected for the inverse barometer effect using atmospheric pressure measured at Logan Airport.

- Notes:
1. All series have been filtered with a Gaussian filter ( $\frac{1}{2}$  power at 56 hr., see Appendix B).
  2. Note difference in sea level scale between top and bottom figures; upper scale expanded five times.
  3. Wind stress is computed from Logan wind data using a constant drag coefficient of  $1.1 \times 10^{-3}$ . The wind stress would be approximately a factor of two higher for wind observations from the Boston Lightship. The drag coefficient may vary by as much as a factor of two - three over the period (Csanady, 1972b; Parker, 1974) as the stability of the air-water interface changes.
  4. Sea level difference between Sandwich and Boston has not been corrected for atmospheric pressure differences. Parker (1974) indicates that the difference is less than 3 mb, and usually less than .5 mb, at least in summer.
  5. Wind at Logan and Boston Lightship shown for the period Feb. 18-22 where the two observations differed significantly (Logan, solid line; Lightship, dotted line).

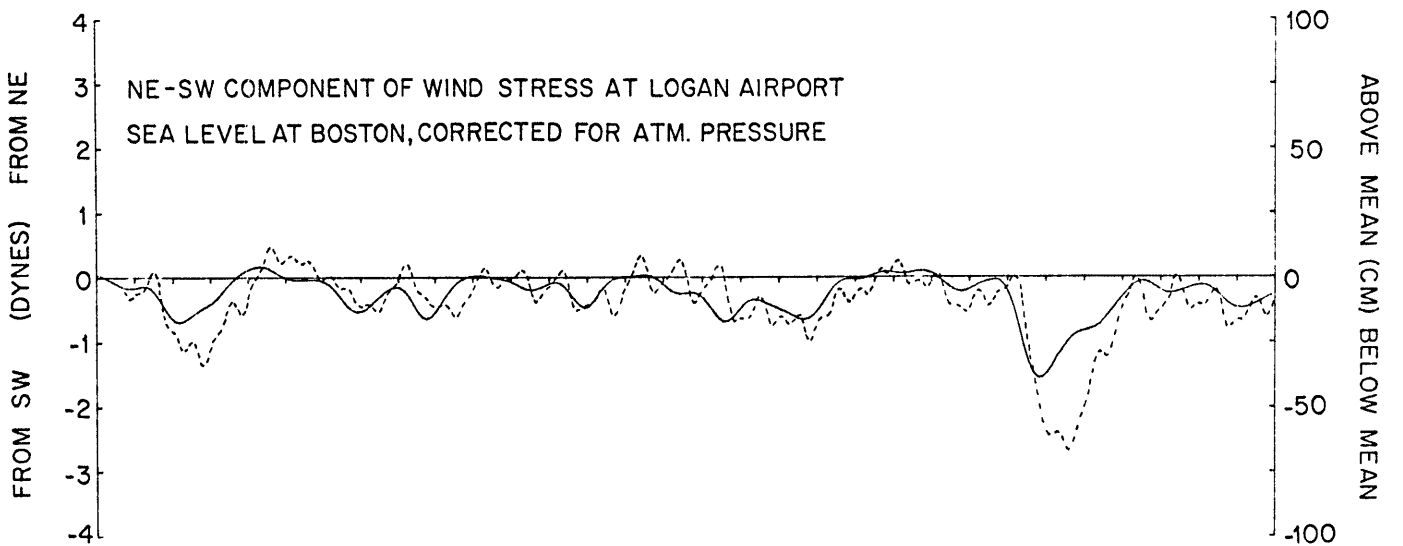

Figure 1.10a

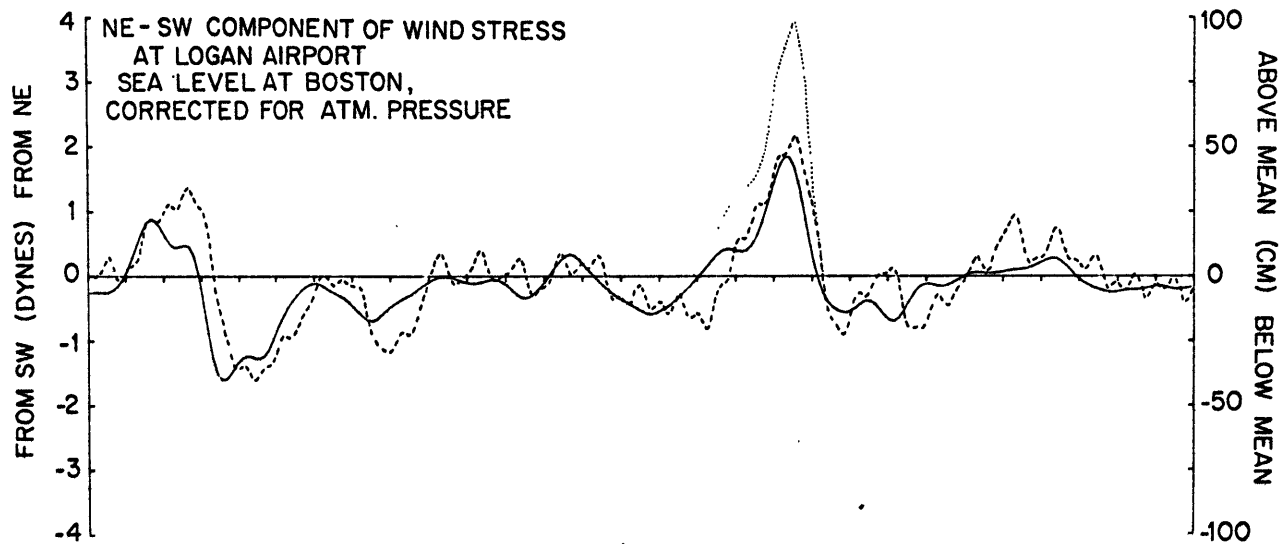

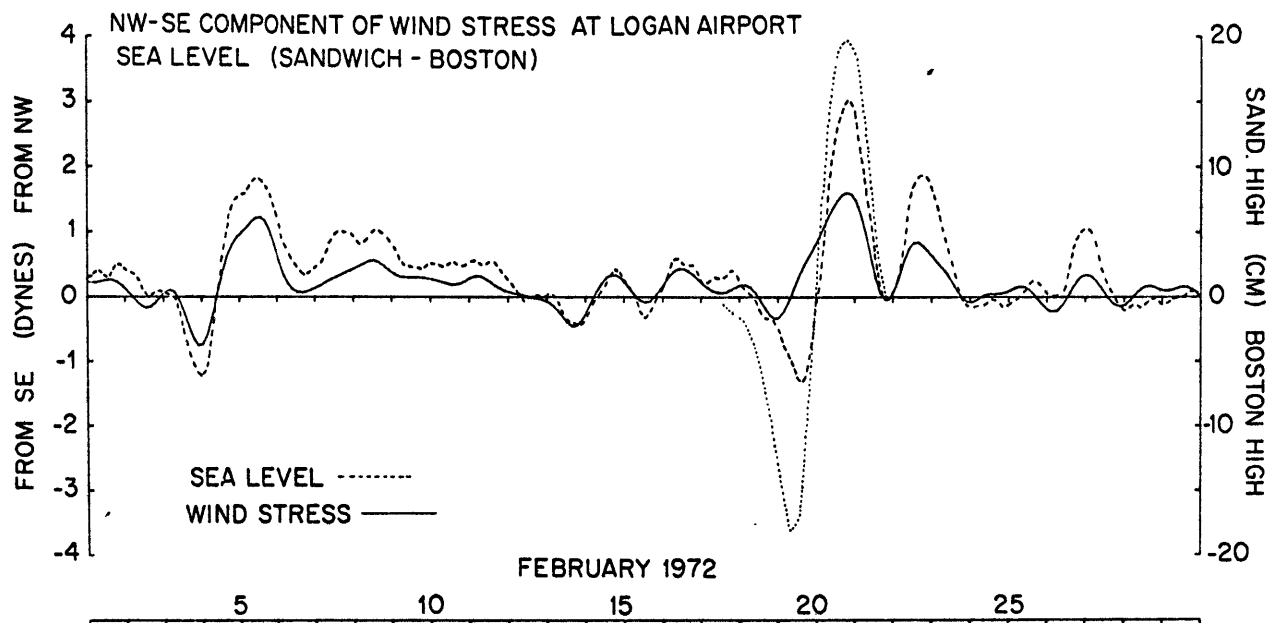

Figure 1.10b

across the short axis of the Bay. The large change in sea level in response to northeast-southwest winds probably reflects a change in the level of the Gulf of Maine to which the Bay must adjust. Superimposed on this change may be a small setup in the direction of the wind with magnitude similar to the setup observed along the long axis. The response time for sea level at Boston and Sandwich to northeast-southwest winds is approximately 6-12 hours (figure 1.10 a,b), significantly longer than the setup time observed for northwest-southeast winds, which also suggests that the response of the Gulf of Maine, a larger system than Massachusetts Bay, controls the elevation. The large change in level is in agreement with Csanady's (1974) model of the barotropic response of the Gulf of Maine to wind.

## 2. Bottom Current and Sea Level Response to Strong Wind Events

### a. January 25 - 27, 1972 (Figure 1.10 a,b; 1.11)

During the morning of January 25 winds at Boston were from the south, became more westerly during the day, and were strongly from the northwest on January 26 and 27, with a magnitude of 3-5 dynes. On January 25 the bottom current at station D closely followed the rotation of the wind stress from north to east to southwest. On January 26 and 27, the flow was consistently to the southeast, approximately parallel to the coastline in the western Gulf of Maine. At the Boston Lightship flow was generally northwest-southeast parallel to the coast in the direction of the wind. During the 26th and 27th, with constant northwest wind, the current at Boston Lightship rotated slightly to the west and gradually decreased. The flow pattern in response to the northwest wind (January 26) was established within 6 - 12 hours and did not change significantly throughout the 26th.

Figure 1.11 Wind and near bottom current in Massachusetts Bay January 25-27, 1972. Current records have been filtered with a Gaussian filter ( $\frac{1}{2}$  power at 33 hours, see Appendix B) to remove tidal oscillations. Values of current and wind stress shown every six hours. Current meter located 1 m from the bottom at station D and F, 10 m from the bottom at the Boston Lightship.

JAN 25, 1972

Figure 1.11

JAN 26, 1972

Figure 1.11

JAN 27, 1972

Figure 1.11

Sea level difference between Sandwich and Boston (figure 1.10a) shows a slight setup on the 24th and early on the 25th in response to the southerly wind. The strong northwest wind on the 26th and 27th produced a large setup, with Sandwich higher than Boston by approximately 10 cm. As the wind rotated through north to south, the absolute level at Boston dropped 65 cm; the outflow is clearly seen at station D at 1800 hr on January 25. The inflow on the 27th is somewhat more gradual and is not obvious from the current record at station D.

b. February 2 - 5, 1972 (Figure 1.10, 1.12)

Winds over Massachusetts Bay were light on the morning of the 2nd, gradually became easterly in the afternoon and continued from the east on the 3rd, then changed to westerly on the 4th. On the 5th, winds were from the northwest throughout the day. The bottom current at station D on the 2nd was to the west into the Bay as sea level at Boston and Sandwich rose. The flow, at least early on the 2nd does not appear to be locally wind driven. It is suggested that the flow at stations D and F was driven by a rise in sea level at the western end of the Gulf of Maine; wind over most of the Gulf on the morning of the 2nd was to the southwest, but was only to the southwest at Boston in the afternoon. The flow at station D became more parallel to the western coast of the Gulf on the 3rd as the rise in sea level at Boston diminished. Flow at station F late on the 3rd and early on the 4th was in the direction of the pressure gradient caused by the slight setup of the bay to the north. On February 4th the wind changed from southeast to south to southwest to northwest. The bottom flow at station D closely followed the rotating wind; sea level in the Bay fell below mean level as the bottom flow at station D passed through east. The current at station F rotated from south to north as the wind

Figure 1.12 Wind and near bottom current in Massachusetts Bay February 2-5, 1972. Current records filtered with a Gaussian filter ( $\frac{1}{2}$  power 33 hours, see Appendix B) and plotted every six hours. Current meters located 1 m from the bottom.

Figure 1.12

shifted. The strong northwest wind continued on the 5th with little change in the bottom flow pattern.

c. February 18 - 21, 1972 (Figure 1.10, 1.13)

On February 18, winds over Massachusetts Bay and the Gulf of Maine were from the east and southeast. Flow at station B and at the Boston Lightship was southerly parallel to shore while flow at station C in the deep central basin was to the east, opposite to the direction of the wind. The wind stress increased from the southeast during the morning of the 19th; in response the velocities at all stations increased, but the flow pattern remained basically unchanged. Late on the 19th and early on the 20th the wind rotated from southeast to northwest. Flow at station C remained to the south for the first twelve hours of the northwest wind, but then gradually rotated to the northwest after sea level at Boston reached equilibrium. Flow at station B was to the northwest at midday on the 20th and became northeasterly on the 21st. The flow pattern at 0600 on the 21st strongly suggests a double gyre flow pattern, with the northwest flow at station C feeding both shore parallel flows at station B and at the Boston Lightship.

3. Bottom Wind Driven Circulation Pattern

Although the spatial coverage of the currents during any one storm is sparse, a composite picture of the bottom flow pattern in the basin in winter for several wind directions can be developed from measurements made at different times but under similar wind conditions (figure 1.14). The composite response suggests near bottom flow in the shallow parts of the Bay parallel to the wind and flow opposite to the wind in the deep central basin. Nearshore, flow is parallel to the coast. Flow on Stellwagen Bank is almost always in the direction of the wind, while

Figure 1.13 Wind and near bottom current in Massachusetts Bay February 18-21, 1972. Current records filtered with a Gaussian filter ( $\frac{1}{2}$  power at 33 hours, Appendix B) and plotted every six hours. Flow at station B is shown only occasionally because of a failure in the timing circuitry of the current meter. Measurements at stations B and C 1 m from the bottom, measurements at Lightship 10 m from the bottom. Wind stress at both Boston Lightship and Logan Airport shown on Feb. 19, when direction of the two observations differ significantly. Scale for Logan stress is 0-2.5 dynes.

FEB. 18, 1972

Figure 1.13

FEB. 20, 1972

FEB. 21, 1972

Figure 1.14 Generalized response of bottom currents to wind constructed from measurements made at different times but under similar wind conditions. Magnitude of the current is not indicated, although some relative magnitudes are suggested for wind stress on the order of 1 - 3 dynes. If no flow is indicated at a station, no measurement was made for that wind direction.

## BASIN RESPONSE (BOTTOM)

flow in Stellwagen Basin for a northwest or southeast wind is nearly opposite to the wind direction. The observed northwesterly flow at Boston Lightship with a northwest wind appears to accept the flow from the deep basin and feed the northeast flow at station B, or the southerly flow at station E. Similarly, the southerly flow at Boston Lightship associated with a southeast wind may feed the easterly flow in the central portion of the basin, and not continue down the coast.

In summary, the response of sea level and of the bottom currents in Massachusetts Bay in winter to strong wind stress is as follows:

(1) A sea surface setup in the direction of the wind. Superimposed on the setup are changes in the absolute level of the Bay controlled primarily by the response of the Gulf of Maine. Local setup is established in less than 1 hr; absolute changes require 6 - 12 hours.

(2) The bottom current is coherent over basin scales during strong wind events, with flow in the direction of the wind in the shallow parts of the basin and opposite to the wind in the deep basin. Flow is more complicated near the ends and corners of the Bay where the current must adjust to the coast. On Stellwagen Bank, flow is in or out of the basin as sea level adjusts to the level of the Gulf of Maine.

(3) The local bottom wind driven current is established approximately 12 hours after the wind stress is applied and remains basically unchanged even if the wind stress lasts as long as 24 hr. In some cases, however, the time to establish the flow pattern is as long as 18 - 24 hours, particularly in the corners of the basin, and there is a slight modification of the flow pattern with time. (The rapid adjustment of winter wind driven currents is also observed on the New England continental shelf, and is investigated in Chapter 3.)

#### F. Summary and Conclusions

The bottom currents in Massachusetts Bay have been monitored over a one year period in areas of different sediment types, bottom roughness and depth. With the reservations about stress estimates, critical erosion stress and the effects of bioturbation, it appears that the bottom sediments are in equilibrium with the bottom currents: the observed currents are not sufficient to move existing material regularly, except possibly on Stellwagen Bank and in the shallow nearshore regions. The speed distribution is primarily determined by the strong tidal currents.

In the winter, the net near bottom current is dominated by strong wind events. Despite the limited nature of the data and the only partially closed geometry of the Bay, there is indication of a two gyre flow pattern, with flow in the direction of the wind in the shallow areas and opposite to the wind in the central basin. Sea level is controlled both by local wind in the Bay and by the response of the Gulf of Maine; inflow and outflow over the shallow bank at the mouth of the Bay is observed as sea level in Massachusetts Bay adjusts to the Gulf. The net bottom flow pattern could be important in redistributing fine material from the shallow bank and nearshore areas, where occasional incipient sediment motion occurs, into the deep basin.

## CHAPTER II

## THE SPRING RUNOFF IN MASSACHUSETTS BAY

A. Introduction

This chapter investigates the currents during the period of the spring runoff in Massachusetts Bay, and the relation of the current pattern to the observed density field. Recent investigations have shown the importance of wind, topography, and thermal structure in determining the circulation on the continental shelf, shallow seas, and the Great Lakes (for example, Bennett, 1974; Csanady, 1973a,b, 1974, and others). A somewhat neglected aspect (with the notable exception of Stommel and Leetmaa (1972) ), or assumed to be less important, has been the circulation driven by the discharge of fresh water at the coast by rivers. This study is concerned with river influenced currents in regions somewhat distant, on the order of 10-20 km from a river mouth, but not distant enough to consider the in-flow as in Stommel and Leetmaa's model. The major discharge of fresh water from rivers in temperate regions is from the spring runoff; typically fifty percent of the yearly streamflow occurs in March, April and May. Because of this major increase in river flow and the generally weak wind stress, density gradients associated with river discharge may have an important influence on the currents in nearshore areas in spring, even those distant from major rivers.

Studies of rivers as they discharge into the sea fall into two broad categories: studies of the surface plume of fresh water near the river mouth (the near field), [for example, studies by Wright and Coleman (1971) of the Mississippi River, and by Garvine (1974a) and Garvine and Monk (1974) of the Connecticut River], and studies of the large scale salinity

distribution associated with the river discharge far from the initial mixing zone (the far field), [for example, studies by Barnes et al (1972) of the Columbia River and by Gibbs (1970) and Ryther et al (1967) of the Amazon River]. The studies show a major influence of river discharge on the surrounding ocean. For example, freshening associated with the Amazon and Columbia Rivers extends several hundred kilometers seaward in a large plume. The shape and position of the plume may depend on the local currents, winds, and the river discharge; the position of a river plume with respect to the river mouth may vary on short time scales, for example due to tidal currents (Garvine, Connecticut River), or on a seasonal time scale due to seasonal large scale ocean currents (Barnes, Columbia River). The studies generally interpret the surface plume as passively advected on the prevailing currents. Garvine (1974a) did measure currents in the frontal zone of the plume, but none of these studies included direct current measurements of the large scale currents directly associated with the source of buoyancy.

Models of river discharge into the ocean have primarily been of the near field, or of the small scale structure of the river plume (Garvine, 1974b; Takano, 1954; Wright and Coleman, 1971) and have generally ignored the effects of rotation and the far field circulation, with two exceptions. One model of the medium to far field circulation driven by river discharge in a rotating system is of steady river flow distributed evenly along a coastal boundary. The discharge will result in fresher water nearshore, with the strength of the associated horizontal density gradients dependent on the magnitude of the fresh water discharge and on the extent of the vertical and horizontal mixing. Because of the thermal wind relation, offshore horizontal gradients will tend to produce flow parallel to shore,

to the right (looking out from shore) in the northern hemisphere. Such a model is presented by Stommel and Leetmaa (1972) for the U.S. east coast continental shelf.

A second relevant model (Csanady, 1971) is of the inertial adjustment of a column of light warm water nearshore and a column of heavier water offshore. The two layer adjusted state is either a 'wedge-shaped' or a 'lens-shaped' thermocline with length scales of the internal Rossby radius. For the wedge-shaped thermocline currents are to the right in the surface layers and to the left in the bottom layer (looking offshore). In the lens-shaped thermocline flow in upper and lower layers is in the same sense, to the left on the inshore edge of the lens, looking offshore, and to the right on the outer edge. The model was developed to explain the thermally driven spring lake circulation, but the dynamics are similar if applied to coastal freshening by river flow.

The effects of river discharge on the currents in Massachusetts Bay will differ from these models in several ways: (1) the current pattern is three dimensional and varies over length scales of 10-20 km in the along-shore direction, (2) the major source of fresh water is not at the coast but to the north of the basin, (3) the major fresh water flow occurs as spring runoff and is thus not steady throughout the year, and (4) a summer thermocline gradually develops during the runoff period.

#### B. Background

Studies in the Gulf of Maine show a general freshening of the near-shore waters in the spring as a result of increased river runoff, and an increased local freshening adjacent to the large river systems (Meade, 1971; Graham, 1970; Colton, 1968; Bigelow, 1927). Associated with the nearshore freshening is a southerly flow of about  $10 \text{ cm sec}^{-1}$  along the western coast

(Bumpus, 1973; Graham, 1970; Bumpus and Lauzier, 1965), the western side of the Gulf of Maine gyre. The strength of the gyre is strongest in spring suggesting the importance of runoff, but interpretation of the gyre as a wind driven flow can also be made (Csanady, 1974).

Massachusetts Bay is a semi-enclosed basin, located on the southwestern end of the Gulf of Maine, 'downstream' from all the major rivers which discharge into the Gulf (figure 2.1). There are two river systems which affect the salinity distribution. A small system of several rivers, of which the largest is the Charles River, discharges directly into the Bay through Boston Harbor. This group of rivers will be referred to as the Charles River system. The spring runoff typically begins in late February and continues through March (figure 2.2a), with a maximum spring flow of approximately  $30 \text{ m}^3 \text{ sec}^{-1}$ . The second nearby source of fresh water is the Merrimack, a major river which discharges 30 km to the north of Massachusetts Bay. The peak spring runoff of approximately  $500 \text{ m}^3 \text{ sec}^{-1}$  generally occurs in April, somewhat after the peak runoff from the Charles River system (figure 2.2b). The two fresh water sources are thus separated in time and space. On the average, the first inflow of fresh water to Massachusetts Bay is at the coast from the Charles River and is relatively small; the second source is much larger, dominated by the Merrimack, and is located to the north and east of the open side of Massachusetts Bay. In the spring of 1973, discharge was much larger than average and considerably more time dependent than the monthly average figures might suggest; the discharge over a five-day period may change by a factor of two during the peak runoff season.

During the period of the spring runoff a seasonal thermocline gradually develops in Massachusetts Bay. The water column in March and April is

isothermal, but by late May and early June the difference between surface and bottom temperature is 5-10°C (Bumpus, 1974). The early river discharge is into an unstratified water column, while the later discharge is into a more stable water column, both due to the surface heating and surface freshening. In addition, wind stress during the spring months is not large. Because of the increased stratification, downward mixing of the fresh water discharge may be significantly reduced as the spring progresses.

### C. The Field Program

Hydrographic observations and moored current meter measurements were made during the spring runoff period of March-May, 1973. The objectives of the field program were to:

- (1) describe the spatial and temporal variation of the salinity and density fields during the runoff period in the northern part of Massachusetts Bay (north of 42°10'),
- (2) describe the major (subsurface) current patterns associated with the density field, particularly the competing influence of the local discharge of the Charles, and the expected freshening from the north and east.

#### 1. The Current Measurements

Three Savonius rotor Richardson current meters were deployed in Massachusetts Bay from March 4 - June 3, 1973 (figure 2.1). Two instruments were located near the Boston Lightship at 20 and 30 m in water 35 m deep (station 1). A third current meter was located 15 km due west at a depth of 35 m in water 65 m deep (station 2).

Several considerations heavily influenced placement of the three available current meters. Current measurements at the Boston Lightship (figure 2.1) made in the spring of 1972 indicated strong currents

Figure 2.3 Progressive vector diagram of current at Boston Lightship 10 m from the bottom, spring 1972 (see figure 2.1 for location). The surface salinity dropped approximately 1‰ on April 25 and May 5, coincident with the major change in current flow. The bottom salinity did not change significantly, although the data is sparse (salinity from U.S. Coast Guard).

(10-20 cm sec<sup>-1</sup>) aligned northwest-southeast parallel to the coast with periods of 5-10 days; abrupt changes of flow direction, occurring in less than one day, were often associated with a major change in the surface salinity (figure 2.3). The long time scale of the flow, the associated surface salinity changes, and lack of obvious wind dependence strongly suggested that the flow was density driven. Currents measured during this period were the largest sustained flows observed throughout the year at the lightship station. It was of interest to investigate this aspect of the spring flow further. Four questions were of particular interest, and the three available instruments were deployed with these in mind:

- (1) Is the pattern associated with the local fresh water flow, or due primarily to the influence of the Merrimack?
- (2) What is the spatial scale of the current?
- (3) What causes the reversing nature of the flow?
- (4) Is the flow barotropic or sheared (as in Csanady, 1971)?

To minimize wave influence, instruments were deployed on subsurface moorings with the flotation 20 m from the surface.

## 2. The Hydrographic Observations

Detailed surveys of the density field were made on a two-week basis while the current meters were deployed. Four surveys were conducted by Mr. Veshpati Manohar-Maharaj (March 29-30, April 14-15, 21-22, May 5-6, and June 2-3) and an additional survey was made on May 15-16. Approximately 30 stations 7-9 km apart were occupied on each cruise in a period of 24 hours. The cruise of April 14-15, 21-22 was broken into two parts due to bad weather. Unfortunately, due to equipment problems, the first hydrographic cruise was not made until late March.

An M.I.T. built C.T.D. was used to obtain vertical profiles of conductivity and temperature. Salinity was computed from conductivity and temperature. The C.T.D. was not well calibrated; a temperature dependent correction was made on the basis of surface C.T.D. readings and bottle samples (See Maharaj and Beardsley (1974) for details). Estimated relative errors in temperature, salinity, and sigma-t are  $T \pm .1^{\circ}\text{C}$ ,  $S \pm .1\text{‰}$ ,  $\sigma\text{-t} \pm .1$ . The relatively poor accuracy of the instrument will not affect the conclusions of this study.

#### D. Results

In this work, the main concern will be the spatial distribution of density, the changes of the distribution during the spring, and the relationship of the currents to the observed density field. Throughout the spring period the density is primarily controlled by the salt distribution, although temperature becomes an important factor later in the spring.

The salinity observations, with the exception of the cruise of May 15-16, are presented in Maharaj and Beardsley (1974) but they do not discuss the density or temperature distribution. A volumetric analysis of the amount of fresh water in the basin as a function of time compared favorably with the amount discharged by the Charles River system and Merrimack River, with suitable corrections for time lag and mixing. Maharaj and Beardsley conclude that the major freshening of the bay is due to fresh water which enters from the north (inferred from a distinct surface plume), and that within experimental error, all of the fresh water runoff of the Merrimack and Charles River systems can be accounted for in the freshening of Massachusetts Bay north of  $42^{\circ}25'\text{N}$  and west of  $70^{\circ}20'\text{W}$ . The volumetric aspects of the salt distribution will not be discussed further.

The current observations must be discussed in the context of the entire spring runoff period. Thus, although Maharaj and Beardsley (1974) have previously described the salt distribution, a brief review which emphasizes the changes in the spatial distribution of salinity and density is appropriate. The previously unreported observations of May 15-16, 1973 as well as a discussion of the changes in temperature and sigma-t is included. With the exception of the surface salinity distribution, the observations have been recontoured. With this hydrographic background, the current measurements will be presented and the two hydrographic cruises made while the current meters were deployed will be discussed in detail.

#### 1. The Hydrographic Observations

##### a. The surface salinity distribution

The surface salinity distribution clearly shows the effect of the spring runoff (figure 2.4,a-e). The major features are summarized below:

##### March 29-30, 1973

The central portion of the basin is occupied by water with salinity greater than 31‰. The surface water nearshore, offshore (east of approximately 70°30'), and north of 42°30'N is slightly fresher, between 30-31‰. A salty core occupies the central basin with fresher water to the west, north, and east. The nearshore freshening is attributed to local runoff and the offshore freshening to the general freshening of the Gulf of Maine.

##### April 15-16, 21-22, 1973

The surface salinity over the surveyed area is between 30.2‰ and 30.8‰. The major accumulation of fresh water in the Bay occurred between March 29-30, and April 21-22.

Figure 2.4 Surface salinity distribution in northern part of Massachusetts Bay and east-west salinity distribution along  $42^{\circ}20'N$ , spring, 1973. Surface distribution in a,b,c,e drawn from continuous sampling along indicated track (redrafted from Maharaj and Beardsley, 1974); distribution in d drawn from surface samples at indicated stations. East-west section contoured from CTD stations at indicated locations, usually starting between 1 - 3 m. Slight discrepancies between east-west and surface contours result from the different data sources (CTD casts starting at approximately 2 m vs. continuous surface sampling) used to draw the contours.

Figure 2.4a

Figure 2.4b

Figure 2.4c

Figure 2.4d

Figure 2.4e

May 5-6, 1973

A clearly discernible plume with salinity less than 29‰ occupies the center of the basin with saltier water to the west and east. The plume only occurs in the upper layers and does not contribute a major volume of fresh water to the basin.

May 15-16, 1973

The surface plume, indicated by the 29‰ isohaline, has moved approximately 10 km to the east and is compressed from the previous section. The 30‰ isohaline remains near the Boston Lightship. (It should be noted that the survey is of smaller north-south extent than the others, but with closer station spacing).

June 2-3, 1973

The surface plume has moved back to the west toward the center of the basin and is somewhat narrower. There is no 30‰ water left on the surface; an intrusion or pool of fresher water appears in the northwest.

b. The horizontal salinity distribution

Two features dominate the east-west salinity distribution (figure 4a-e) during the spring period which are not adequately resolved by the surface distribution. The major freshening of the basin occurs as a relatively deep lens of water located on the western side of the basin with salinity less than 31‰. The lens does not occur on the first section of 29 March; at that time fresher water to the east and west surrounds a central salty core, as discussed in the surface distribution. The fresh lens is well established on April 15 however (figure 4b), and is most clearly marked by the 31‰ isohaline. During the spring the lens gradually becomes more salty and less distinct, and moves 5-10 km in an east-west direction. Cruises were not frequent enough to determine

if the lens was a continuous feature which remained in the Bay throughout the spring or was a series of low salinity patches which advected through the basin.

The second major feature of the east west salinity distribution is the well defined lens of fresh water which appears near the surface during the later stages of the spring. The freshest water occurs in this lens (marked by the 29‰ isohaline in figure 4); the lens occurs in mid basin, but there is horizontal movement. In particular, both the surface and deep lens are displaced significantly to the east on the 15th of May.

c. The vertical structure at mid basin

As the spring progresses there are four major changes in the vertical structure of the water column: a decrease in the salinity of the water column in early spring primarily in a deep well mixed surface layer, a gradual increase of salinity at depth and further freshening at the surface, a warming of the water column, and the establishment of a pycnocline between 10 m and 30 m. These changes are illustrated for a typical mid basin station in figure 2.5a-c (near station 2, figure 2.1).

The sequence of vertical profiles are a result of vertical mixing, horizontal advection, and changes in the river flow. The surface layer changes can be explained in the following way. The major runoff occurs before the development of a seasonal thermocline, and the large volume of fresh water mixes deeply (a fresh mixed layer extends to 35 m on April 15-16). During the later part of the spring season, although there is smaller volume of runoff, the fresh water does not mix as deeply and thus the surface layers continue to freshen. The decreased vertical mixing is attributed to the establishment of a spring thermocline and to the generally weak wind stress in May (figure 2.7). The depth to which the

Figure 2.5 Progression of (a) temperature, (b) salinity and (c) sigma-t at mid-basin (42°20'N, 70°35'W, near station 2, figure 2.1).

Figure 2.5a

Figure 2.5b

Figure 2.5c

runoff mixes may also be a function of local conditions at the river mouth during various stages of river flow. Changes in the position and strength of the near surface plume also affect the distributions in the surface layer.

The change with time of salt and heat in the deep layers is somewhat more difficult to interpret. The gradual warming of the deep water must occur by the downward mixing of heat. The surface waters are low salinity however, and thus downward mixing cannot be accompanied by an increase in the salinity, as is observed. The changes in the deep water thus must be advective, which implies that the basin flushing rate during the spring is less than two weeks. This rate is consistent with the net drift of Bumpus (1973, 1965) for the western Gulf of Maine in spring.

d. Summary: Stages of the spring runoff

In summary, there are four stages of the spring runoff which can be identified by the hydrographic measurements:

<u>Stage</u>	<u>River Flow</u>	<u>Hydrography</u>
Early Spring	moderate	Freshening of the eastern and western edges of the basin, central salty core, well mixed water column
Mid Spring	maximum	Major decrease in salt throughout the basin, small horizontal variations, deep well mixed surface layer
Mid Spring	moderate	Well defined surface plume in basin with lateral movement, gradual heating
Late Spring	moderate, decreasing	Decrease in size and integrity of plume, gradual salting of deep layers and continued warming

## 2. The Current and Simultaneous Density Observations

The low passed current records from the upper instruments at stations 1 and 2 are characterized by relatively strong currents (5-20  $\text{cm sec}^{-1}$ ) which persist for 5-10 days (figure 2.6). The record obtained at station 1 is very similar to the one obtained in the spring of 1972 (figure 2.3). The magnitude of the current at least suggests that displacements on the order of basin scales occur in a few days during the spring period. Both northerly and southerly current is observed at station 1, but only southerly flow at station 2. The major flow axis is north-south. The current 5 m from the bottom at station 1 is similar to the current 15 m from the bottom, but much reduced in magnitude; the low passed current at the lower instrument does not exceed 5  $\text{cm sec}^{-1}$  during the experiment.

The wind stress is relatively weak throughout the measurement period, except for one event on the 26th and 27th of April where the stress reaches one dyne (using a drag coefficient of  $1.1 \times 10^{-3}$ ). In response, the current at station 1 accelerates parallel to shore and the flow at station 2 is offshore, opposite to the wind, as discussed in Chapter I. Otherwise the low passed wind stress (as measured at Logan Airport) is less than  $.5 \text{ dynes cm}^{-2}$ . Sea level at Boston, shown in Chapter I to be a good indicator of wind driven currents, also shows little change during the experiment except for 26-27 April and May 17-18.

The slow change of the currents with time and the lack of strong winds suggests that the observed flows are density driven. Any model of the currents during the spring runoff period must satisfactorily explain the following characteristics:

Figure 2.6 Low passed current, wind and sea level, April 26 - June 2, 1973. Arrows indicate period of hydrographic observations.

- a) Current at station 2, 35 m.
- b) Current at station 1, 20 m.
- c) Current at station 1, 30 m.
- d) Wind stress at Logan Airport  
(computed using  $\tau = \rho C_D u^2$ ,  $C_D = 1.1 \times 10^{-3}$ ).
- e) Sea level at Boston.

All series have been filtered with a Gaussian filter ( $\frac{1}{2}$  power at 56 hours) to suppress tidal and inertial oscillations. The current meter records have been subsampled every three hours and plotted as vectors (north at top of page). A time base malfunction on the lower current meter at station 1 has been graphically corrected (see Beardsley and Butman, 1974b).

Figure 2.6

- (1) large current velocities ( $5-20 \text{ cm sec}^{-1}$ ) which persist for 5-10 days,
- (2) rapid reversals in direction of flow,
- (3) large horizontal shear,
- (4) large vertical shear with low velocities near the bottom.

To begin, the observed current and density distribution on May 5-6, 1973 and May 15-16, 1973 are presented in detail.

a. Observations of May 5-6, 1973

On May 5-6 the surface density distribution is dominated by a shallow plume of fresh water (figure 2.4c and figure 2.7a) which enters the basin from the north. Denser water is found to the east and west. At 20 m (figure 2.7b) the plume is displaced to the west. At 30 m (figure 2.7c) an isolated lens of lighter water ( $\sigma_t$  less than 24.6) is found on the western edge of the basin, offset from the center of the surface plume. Denser water occurs to the north, east, and south, and the lens appears to intersect the bottom on the western side of the bay. An east-west density section clearly shows the surface plume and the deep lens (figure 2.7e).

The hydrographic cruise was conducted during a major current event (figure 2.6); the low passed current was to the northwest at station 1 and to the southwest at station 2 for approximately eight days from May 4-12. The direction of the low passed current is parallel to the  $\sigma_t$  contours (figure 2.7b,d) to within the accuracy with which the contours can be drawn. It should be noted that at the 30 m surface the 24.80  $\sigma_t$  contour in the southwest corner of the basin has been closed. It would be consistent with the data however to have both the inshore and offshore 24.8 contour continue to the south, without closing. At 35 m (figure 2.7d)

Figure 2.7a

Figure 2.7c

Figure 2.7a

Figure 2.7e

the sigma-t contours appear to run normal to the coast; the station spacing is not close enough to accurately map the adjustment of the fresh lens to the boundary.

The geostrophic shear computed from the thermal wind relation accounts for all of the observed east-west shear and 60% of the north-south shear at station 1 (figure 2.7e and Table 2.1). At station two, the computed shear relative to 50 m (the deepest observed depth) accounts for about 40% of the observed current and is in the correct sense. The estimates of shear are judged to be accurate to  $\pm 10\%$  on the basis of station position errors alone. It should also be noted that only one station defines the fresh water lens (station 12, figure 2.7e), and thus the observed density differences could reasonably be distributed over a smaller distance. Finally, the low passed currents are compared to an instantaneous measurement of the density field.

Despite these reservations, several conclusions can be made from the section of 5-6 May and the observed currents.

- (1) The major current event of May 4-12 is associated with a subsurface fresh water lens, not directly with the well defined surface plume.
- (2) The observed shear at station 1 is approximately geostrophic and the shear at station 2 is in the correct sense if we assume zero flow near the bottom.

b. Observations of May 15-16, 1973

In contrast to the strong currents and large horizontal shear observed on May 5-6, the low passed current on May 15-16 was almost zero at both stations. The sigma-t distribution shows clearly that the surface plume has moved to the east at the surface (figure 2.8a), and that

the deep lens has also moved to the east (figure 2.8b,c). The current meter at the nearshore station is removed from the region of large horizontal gradients, while the offshore instrument is located in the center of the lens.

The geostrophic shear (Table 2.2, figure 2.8a,c) is much reduced at station 2. Unfortunately, at station 1 the hydrographic observations did not extend deep enough to compute the north-south shear between the two levels.

#### E. Discussion and Conclusions

The simultaneous current and hydrographic observations show that the density distribution associated with the spring river runoff dominates the low frequency currents observed during the spring period in Massachusetts Bay. The major observed flow for a period of eight days was due to clockwise flow around a lens of light water; in this case much of the flow can be accounted for using the thermal wind relation and assuming zero flow near the bottom. The northerly flow at station 1 is a result of freshening offshore, not to local discharge and a vertically sheared current, as in Csanady (1971). The similarity between the spring records at station 1 in 1972 and 1973 suggests that the decreasing surface density offshore and the associated nearshore northerly flow is a yearly occurrence.

Although the observed flow during the period 4-12 May and 15-16 May can qualitatively be explained, it remains to explain other similar low frequency events in the current record. As an academic exercise, one can speculate about the density distribution required to produce the flow patterns but such speculation does not really serve a useful purpose; two comments are appropriate however. If the currents are a result of similar light lenses as observed on 5-6 May, the axis of these features must be

to the west (inshore) of station 2 since only weak or southerly flow is observed at that station, while both north and south flow is observed at station 1. The internal radius of deformation is on the order of 10 km in the spring period (radius =  $\sqrt{g'H/f}$  where  $g' = g \Delta\rho/\rho$ ,  $\Delta\rho$  = density difference between top and bottom layers,  $H$  = layer depth,  $g$  = gravity,  $f$  = Coriolis parameter). Density features will be on this scale as is observed in the deep lens and surface plume, and current may not be highly correlated over larger distances.

A central question unanswered by the observations is whether the observed lens of light water is established during the period of maximum runoff and remains throughout the spring season, gradually modified, or whether the changes in the deep hydrography are advective, as in the surface layers. It is difficult to explain the deep changes in salt and temperature without advection, and the hydrographic section of 15-16 May suggests that the lens of 5-6 May is slowly moving to the south. In addition, the river discharge is hardly constant but consists of short bursts of flow which would tend to create an uneven, patchy salt distribution. On the other hand, the horizontal structure across the basin is similar throughout the season (figure 4). These inferences and questions can only be tested by further observations with denser hydrographic sampling both in time and space. An appropriate sampling interval for the hydrographic sections would be 5 days.

In conclusion, the low frequency currents in Massachusetts Bay in spring are primarily controlled by the density distribution established by the spring runoff; wind stress is not important. The major influence is due to freshening from the outer side of the basin, not from local discharge and is attributed to the Merrimack River.

## CHAPTER III

CURRENTS ON THE NEW ENGLAND CONTINENTAL SHELF IN WINTER: AN ESTIMATE  
OF THE VERTICAL EDDY VISCOSITY AND THE BOTTOM DRAG COEFFICIENTA. Introduction

This chapter is concerned with the currents on the broad continental shelf of the east coast of North America under winter conditions. Of primary interest is the role of the vertical turbulent eddy viscosity or mixing (broadly defined) on the currents, and the parametrization of the mixing.

Wind stress and the discharge of fresh water at the coast due to river runoff will be two fundamental driving forces of the currents. Csanady (1974) has discussed the idealized transient wind circulation, while Stommel and Leetmaa (1972) have addressed the steady wind and density driven flow problem, both with simplified topography. Using basically linear dynamics, Csanady studied the forced integrated flow pattern associated with short intense wind events and showed that the flow in the shallow parts of the shelf will reach a frictionally controlled state in a period of order  $10^4$  seconds. The work suggests that barotropic transient frictionally limited currents associated with major wind events may dominate the currents on a shallow shelf. Recent observations on the New England continental shelf (Beardsley and Butman, 1974) show that short intense wind events do drive strong alongshore currents.

Stommel and Leetmaa (1972) investigate the steady flow pattern associated with wind stress and river discharge. The basic mechanism for transport of salt across the shelf is offshore surface wind driven

transport of fresh water, with return flow of saline water at the bottom. The cross shelf transport is short circuited by vertical mixing which gives an effective horizontal eddy viscosity of  $A_x = (T_x/\rho f)^2/3A_v$  where  $A_v$  is the vertical eddy viscosity,  $\rho$  is density, and  $T_x$  is the along shelf wind stress. The observed salt distribution gives  $A_x = 2.3 \times 10^6 \text{ cm}^2 \text{ sec}^{-1}$  and a vertical eddy coefficient of  $30 \text{ cm}^2 \text{ sec}^{-1}$ . Stommel and Leetmaa note the strong dependence of the effective horizontal eddy viscosity on the wind stress.

The extent of the vertical mixing, in essence the value of the vertical eddy viscosity, is a critical parameter in both of these models. Stommel and Leetmaa calculate a relatively small vertical turbulent eddy viscosity consistent with their model of the salt balance and the mean wind field, while a well mixed water column requires a larger vertical turbulent eddy viscosity at least during the wind events.

Several other aspects of the winter shelf circulation also depend on the value of the vertical eddy viscosity and the change in viscosity during wind events. Beardsley and Butman (1974a) observed no large amplitude inertial oscillations on the shelf in winter (less than  $5 \text{ cm sec}^{-1}$  at mid depth) in contrast with observations of the mixed layer at open ocean sites (Pollard and Millard, 1970). The oscillations may be frictionally damped, confined to a small surface layer, or the wind energy may occur in free modes not possible in the open ocean, for instance surface setup. Finally, the mixing of momentum downward in the water column in response to strong winds is of interest. Several mechanisms for the downward transport of momentum on a shallow shelf are conceivable; direct mixing is one possible mechanism but requires a large eddy viscosity on the order of  $500 \text{ cm}^2 \text{ sec}^{-1}$  (Ekman depth of 30 m).

Acceleration of alongshore current at depth by a cross shelf surface pressure gradient or by cross shelf transport are other possibilities.

It is of interest then to estimate from field observations the magnitude of the turbulent vertical eddy viscosity and the bottom drag coefficient and the changes of these parameters during winter storms. The basic nature of the density driven circulation and of the wind driven currents, in addition to the mixing of momentum, depend on the magnitude of the vertical eddy viscosity and bottom drag: the bottom drag coefficient is a measure of the damping associated with a particular current speed and thus of the adjustment or decay time for integrated motions, while the vertical eddy viscosity determines the distribution of the stress in the vertical. Although use of an eddy viscosity in dynamic models is a crude parametrization of nonlinear effects and leaves much to be desired, estimates should qualitatively assist in our understanding of the continental shelf circulation. In this chapter, observations of the vertical structure of the tidal current in the bottom Ekman layer are used to estimate the vertical eddy viscosity and the bottom drag coefficient during non-storm conditions, while coastal tide gauge observations are used to estimate changes in an average shelf wide bottom drag coefficient during storms. The spirit throughout is to use relatively simple dynamical models.

## B. The Vertical Structure of a Tidal Current

### 1. The Model

To investigate the vertical structure of a tidal current in a rotating system with viscosity, consider the following linear equations in a horizontally infinite constant depth ocean:

$$\begin{aligned} \frac{\partial u}{\partial t} - fv &= A \frac{\partial u}{\partial z^2} + B_1 \cos \omega t + B_2 \sin \omega t, \\ \frac{\partial v}{\partial t} + fu &= A \frac{\partial v}{\partial z^2} + B_3 \cos \omega t + B_4 \sin \omega t, \end{aligned} \quad (1)$$

where

- $u, v$  = horizontal velocity components,
- $z$  = vertical coordinate,  $z = 0$  at the bottom,
- $f$  = Coriolis parameter,
- $B_1$ - $B_4$  = arbitrary constants,
- $\omega$  = frequency of tidal forcing,
- $A$  = constant vertical eddy viscosity,
- $H$  = total depth.

The boundary conditions are:

- a) surface ( $z = H$ ),

$$\frac{\partial u}{\partial z} = \frac{\partial v}{\partial z} = 0 \quad (\text{no stress}), \quad (2)$$

- b) bottom ( $z = 0$ ),

$$u = v = 0 \quad (\text{no slip}), \quad \text{or} \quad (3a)$$

$$\left. \begin{aligned} A \frac{\partial u}{\partial z} &= ku \\ A \frac{\partial v}{\partial z} &= kv \end{aligned} \right\} \quad (\text{slip}). \quad (3b)$$

For the bottom condition 3b, the bottom drag coefficient  $k$  is

$C_D \overline{|U|}$  (overbar designates time average) which approximates the non-linear bottom boundary condition (as best as possible in a linear system)

$$\tau_{\text{bottom}} = \rho C_D |\underline{u}| \underline{u} , \quad (4)$$

where

$$\begin{aligned} \tau &= \text{vector bottom stress} , & \underline{u} &= \text{vector velocity} , \\ C_D &= \text{drag coefficient} , & \rho &= \text{water density} . \end{aligned}$$

This constant viscosity model with various bottom boundary conditions is the simplest system which incorporates the effects of viscosity on a tidal current with the surface tide modeled as a prescribed body force at a point ( $B_1 - B_4$  are arbitrary constants). The objective is not to model the complete tidal current pattern over the continental shelf, but to use a very local model of the bottom Ekman layer in a tidal current to estimate the vertical eddy viscosity.

A scale analysis of the full equations of motion for shelf dimensions shows that the nonlinear and frictional terms are small (about 1%) compared to the time dependent, forcing and Coriolis term (for example, see Welander, 1951). The ratio of the inertial to the vertical viscous term is

$$\epsilon = \frac{u H^2}{A_v L} \cong \frac{50}{A_v} , \quad (5)$$

where

$$\begin{aligned} A_v &= \text{vertical eddy viscosity (cm}^2\text{sec}^{-1}\text{)} , \\ L &= \text{shelf width (} 5 \times 10^6 \text{ cm)} , \\ H &= \text{depth (} 5 \times 10^3 \text{ cm)} , \\ u &= \text{typical tidal velocity (} 10 \text{ cm sec}^{-1}\text{)} . \end{aligned}$$

For  $A_v = 50$  , the vertical viscous term and nonlinear term are equal.

For  $\varepsilon < .1$  the depth of the frictional layer is  $2.2 \times 10^2 (A_v)^{\frac{1}{2}}$  or about 15 m ( $A_v = 50 \text{ cm}^2 \text{ sec}^{-1}$ ) and frictional effects will be observable only in a relatively thin bottom layer. The horizontal viscous terms may be safely neglected with respect to the vertical viscous terms as long as  $A_H/A_v < 10^5$ .

The solution of (1-3) is:

$$u = \frac{1}{L} (M \cos \omega t + N \sin \omega t),$$

$$v = \frac{1}{L} (P \cos \omega t + Q \sin \omega t),$$

(6)

where

$$L = (\omega^2 - f^2),$$

$$M = -\lambda_1 B_1 + \lambda_3 B_2 + \lambda_2 B_3 + \lambda_4 B_4,$$

$$N = -\lambda_3 B_1 - \lambda_1 B_2 - \lambda_4 B_3 + \lambda_2 B_4,$$

$$P = -\lambda_2 B_1 - \lambda_4 B_2 - \lambda_1 B_3 + \lambda_3 B_4,$$

$$Q = \lambda_4 B_1 - \lambda_2 B_2 - \lambda_3 B_3 - \lambda_1 B_4,$$

and

$$\lambda_1 = \omega(b_1 + b_2) + f(b_2 - b_1),$$

$$\lambda_2 = \omega(a_2 - a_1) + f(a_1 + a_2 - 1),$$

$$\lambda_3 = \omega(a_1 + a_2 - 1) + f(a_2 - a_1),$$

$$\lambda_4 = \omega(b_2 - b_1) + f(b_1 + b_2).$$

For the no slip bottom condition (3a)

$$a_i = \frac{\cosh \beta_i z \cos \beta_i (z-2H) + \cosh \beta_i (z-2H) \cos \beta_i z}{2(\cosh 2\beta_i H + \cos 2\beta_i H)},$$

$$b_i = \frac{\sinh \beta_i z \sin \beta_i (z-2H) + \sinh \beta_i (z-2H) \sin \beta_i z}{2(\cosh 2\beta_i H + \cos 2\beta_i H)}.$$

For the slip bottom boundary condition (3b)

$$a_i = \frac{R_i}{D_i}, \quad b_i = \frac{I_i}{D_i},$$

$$R_i = \beta_i k [\sinh \beta_i z \cos \beta_i (z-2H) + \cosh \beta_i z \sin \beta_i (z-2H) \\ - \sinh \beta_i (z-2H) \cos \beta_i z - \cosh \beta_i (z-2H) \sin \beta_i z] \\ + k^2 [\cosh \beta_i z \cos \beta_i (z-2H) + \cosh \beta_i (z-2H) \cos \beta_i z],$$

$$I_i = \beta_i k [\cosh \beta_i z \sin \beta_i (z-2H) - \sinh \beta_i z \cos \beta_i (z-2H) \\ + \sinh \beta_i (z-2H) \cos \beta_i z - \cosh \beta_i (z-2H) \sin \beta_i z] \\ + k^2 [\sinh \beta_i z \sin \beta_i (z-2H) + \sinh \beta_i (z-2H) \sin \beta_i z],$$

$$D_i = 4\beta_i^2 (\cosh 2\beta_i H - \cos 2\beta_i H) \\ + 4\beta_i k (\sinh 2\beta_i H - \sin 2\beta_i H) \\ + 2k^2 (\cosh 2\beta_i H + \cos 2\beta_i H),$$

$$\beta_1 = \left( \frac{\omega+f}{2A} \right)^{\frac{1}{2}} \quad \beta_2 = \left( \frac{\omega-f}{2A} \right)^{\frac{1}{2}}.$$

For  $\omega < f$ ,  $\beta_2 = \left( \frac{|\omega-f|}{2A} \right)^{\frac{1}{2}}$   
and  $b_2 = -b_2$ .

For moderate values of the viscosity (length scales of viscous effects  $\beta_1^{-1}, \beta_2^{-1}$  small) the solution approaches the inviscid solution far from the bottom (figure 3.1). For  $\omega < f$  the major axis is aligned with the body force and lags by 90 degrees; the ellipse rotates clockwise. For  $\omega > f$ , the current is more geostrophic with the tidal ellipse in phase with the body force and oriented 90 degrees to the right. Near the bottom frictional effects become important. For  $\omega < f$ ,

Figure 3.1 Tidal ellipse for  $B_1 = 1, B_2 = B_3 = B_4 = 0,$

Bottom)  $\omega = .73 \times 10^{-4}$  ( $<f$ ).

See Appendix C for ellipse representation.

Figure 3.1

the near bottom current is more in phase with the body force and thus leads the interior flow and the ellipse is rotated slightly to the right of the body force. For  $\omega > f$ , the ellipse orientation is more closely aligned with the body force than the interior flow. With the slip bottom condition, the viscous effects are reduced and the solution approaches the interior flow closer to the bottom, as if the bottom layer is cut away. For smaller values of the viscosity or frequencies further from the inertial, the viscous effects are confined in a smaller boundary layer. Similar solutions are obtained by Sverdrup (1927) and Fjelstad (1929).

In general the phase and amplitude of the flow at any depth is a relatively complicated function of the viscosity, the bottom drag coefficient, and the body forces  $B_1$ - $B_4$ , which are not known. However, there are four properties of the tidal current at two depths which are only a function of the vertical eddy viscosity and the bottom drag coefficient. Using current observations at two points in the water column, the vertical viscosity and the bottom drag coefficient can be estimated without explicit knowledge of the body forces. If the current at two depths is represented as a tidal ellipse, with a clockwise and counterclockwise rotating component (see Appendix C for ellipse notation), the following quantities depend only on the vertical eddy viscosity, the bottom drag coefficient, and the depth.

$$\begin{aligned}
 \text{a. } \frac{\text{Counterclockwise component at depth 1}}{\text{Counterclockwise component at depth 2}} &= \frac{U_+(z_1)}{U_+(z_2)} = \left[ \frac{\delta(z_1)}{\delta(z_2)} \right]^{\frac{1}{2}}, \\
 \delta(z) &= \lambda_1^2 + \lambda_2^2 + \lambda_3^2 + \lambda_4^2 \\
 &\quad - 2(\lambda_1\lambda_4 + \lambda_2\lambda_3). \tag{7}
 \end{aligned}$$

$$b. \frac{\text{Clockwise component at depth 1}}{\text{Clockwise component at depth 2}} = \frac{u_-(z_1)}{u_-(z_2)} = \left[ \frac{\gamma(z_1)}{\gamma(z_2)} \right]^{\frac{1}{2}},$$

$$\begin{aligned} \gamma(z) &= \lambda_1^2 + \lambda_2^2 + \lambda_3^2 + \lambda_4^2 \\ &\quad + 2(\lambda_1\lambda_4 + \lambda_2\lambda_3). \end{aligned}$$

c. Rotation of major axis with depth

$$\tan 2[\theta(z_1) - \theta(z_2)] = \frac{2[\xi(z_1)\epsilon(z_2) - \xi(z_2)\epsilon(z_1)]}{\epsilon(z_1)\epsilon(z_2) + 4\xi(z_1)\xi(z_2)},$$

$$\epsilon = \lambda_1^2 + \lambda_3^2 - \lambda_2^2 - \lambda_4^2,$$

$$\xi = \lambda_1\lambda_2 - \lambda_3\lambda_4.$$

d. Phase difference in flow along major axis

$$\tan 2[\tau(z_1) - \tau(z_2)] = \frac{2[\alpha(z_1)\beta(z_2) - \alpha(z_2)\beta(z_1)]}{\beta(z_1)\beta(z_2) + 4\alpha(z_1)\alpha(z_2)},$$

$$\alpha = \lambda_1\lambda_3 - \lambda_2\lambda_4,$$

$$\beta = \lambda_1^2 + \lambda_2^2 - \lambda_3^2 - \lambda_4^2.$$

The derivation is straightforward using the ellipse parameters (Appendix C) and the solutions for the velocity. Observations of the tidal current at two depths thus give four independent estimates of pairs of the vertical eddy viscosity and the bottom drag coefficient at a particular frequency.

## 2. Observations and Data Analysis

Current observations at two depths within approximately 15 m of the bottom in a well mixed water column during steady state tidal conditions are required to match to the model of the bottom Ekman layer.

Three current moorings were deployed on the New England continental shelf from Feb. 27 - Apr. 3, 1974 as part of the MIT Shelf Dynamics Program (Fig. 3.1). At mooring one ( $40^{\circ}55.8'N$   $71^{\circ}6.9'W$ ), Richardson current meters (Table 3.2) were located 1.2, 15 and 30 m from the bottom in 58.5 m of water. Because of the expected size of the bottom boundary layer, analysis is concentrated on the bottom instruments; a time base error occurred five days after deployment in these instruments, however, and thus only the first part of the records are used. Data obtained at moorings 2 and 3 is not used because the bottom instrument at mooring 2 has a serious time base malfunction, while the shelf slope-water interface may complicate the vertical structure at station 3.

The model of the bottom Ekman layer is valid for body forces at any frequency and can be applied to the semidiurnal and the diurnal tide to estimate the vertical eddy viscosity and the bottom drag coefficient. However, estimates of the tidal ellipse at the diurnal frequency were noisy and only the semidiurnal estimates are presented. The semidiurnal tidal ellipse at each depth was computed from the current records in the following way; the record was broken into overlapping segments two tidal cycles long (24.84 hours) and a sine and cosine at the tidal period of interest (12.42 hours) was fit by least squares to the data. The semidiurnal tidal ellipse and the four independent parameters (7a-d) were computed for each data segment, giving eight estimates over the first four days of record (Table 3.2). The standard error was computed to estimate the range of confidence for the parameters.

The accuracy of the ellipse estimates is of considerable importance, with error due to instrument calibration and to noise in the record. Absolute direction is assumed to be good to  $\pm 5$  degrees. This is typical of VACM instruments (Harry Bryden, personal communication), but may be optimistic for the film instruments. Errors in speed are difficult to estimate. Ratios of speed are used in the model so that percentage errors (due to rotor pumping, or from calibration) will not be as important, but offsets will be.

The semidiurnal tide dominates the current spectrum and is almost completely clockwise. The energy continuum beneath the tidal peak is  $.05 - .10 \text{ cm}^2 \text{ sec}^{-1}$ , which corresponds to errors in a sine or cosine coefficient of approximately  $\pm .5 \text{ cm sec}^{-1}$ . Because the tidal ellipse is nearly circular (counterclockwise component = 0), small errors in the coefficients give large errors in the ellipse orientation and phase. The random phase and orientation errors become smaller if the ellipse is flatter or if a number of estimates are averaged, and thus longer records would be desirable to reduce noise and to obtain better frequency resolution.

The accuracy of the time base of the current meters is important. The time base on the film current meters (12 and 13) is established by marking the record at known times before and after deployment of the instrument, with elapsed time computed from the number of samples recorded from the start. The relative accuracy of the time base established by this method is at worst one sampling interval, assuming no instrument malfunction occurs. A crystal clock is used in the VACM and the time of each sample is recorded as part of the data record;

time base errors with the VACM are negligible. The relative time base error for instrument 13 (5 minutes  $\cong 2.5^\circ$  for the semidiurnal tide) is small compared to the expected signal. The error for instrument 12 is significant (30 minutes  $\cong 15^\circ$  for the semidiurnal tide) and a serious ambiguity arises. With several assumptions however, the time marks specify the time base to within 15 minutes ( $7.5^\circ$  for the semidiurnal tide) and thus the maximum time base difference between 12 and 13 is  $\pm 20$  minutes ( $10^\circ$ ).

As a test of the steadiness of the body force assumed in the model the amplitude and phase of the semidiurnal tide at the coast as a function of time was estimated from sea level records at Woods Hole, Mass., Sandy Hook, N.J., and Atlantic City, N.J. by a similar least squares procedure. The period Feb. 28 - Mar. 5 is during the neap tide, and the amplitude of the semidiurnal tide was quite constant. However, the tidal signal in the current meter records is weaker than during the spring tide.

### 3. An Estimate of the Vertical Eddy Viscosity and Bottom Drag Coefficient

The expected value of the four parameters (7a-d) as a function of the bottom drag coefficient and vertical eddy viscosity are shown in Figure 3.3 for a water depth of 58 m and observations 1.2 and 15 m from the bottom. It is clear from the ratio of clockwise components that the slip bottom condition is superior to the no slip condition. As expected, the near bottom flow does lead the interior flow, with the amount uncertain due to the time base errors. Further support for the near bottom flow leading the interior flow is found by comparing instruments 11 and 13 which have accurate time bases. Although phase changes

Figure 3.3 Ellipse parameters as a function of viscosity and bottom drag coefficient for observations 1.2 m (instrument 13) and 15 m (instrument 12) from the bottom, and observed values with error bars  $1.9 \times$  standard error (see equation 7 and Table 3.2) plus estimated instrument error.

Figure 3.3

cannot be entirely attributed to frictional effects, the ellipse 30 m from the bottom does lag the ellipse 1 m from the bottom by 30 degrees. The ratio of clockwise components is in large part noise, and should be disregarded. The orientation estimates fall within the instrument error and would agree more favorably if an absolute  $10^\circ$  correction were applied to direction of 12.

It is difficult to choose an eddy viscosity and bottom drag pair because of the noise in the estimates and the relative sensitivity of the curves; the ratio of the clockwise components has the smallest error. From physical considerations, the bottom drag coefficient should be in the range  $.01 - .05 \text{ cm sec}^{-1}$  ( $k \cong C_D \overline{|U|}, \overline{|U|} \cong 5 - 10 \text{ cm sec}^{-1}$ ). The observed ratio of clockwise components suggests that  $k > .02 \text{ cm sec}^{-1}$ . For  $k = .04 \text{ cm sec}^{-1}$  the ratio of clockwise components gives  $A_v = 20 - 50 \text{ cm}^2 \text{sec}^{-1}$ . More accurate estimates should be possible with longer records and instruments placed more closely in the bottom layer.

This estimate of the vertical eddy viscosity is in agreement with scaling arguments and with measurements in the near surface layer of the Great Lakes (Csanady, 1972a), which suggest that the vertical eddy viscosity should be a function of the friction velocity ( $u^* = (\tau/\rho)^{1/2} \text{ cm sec}^{-1}$ ), depth (H), and the Coriolis parameter (f). Specifically,

$$\begin{aligned} A_v &\cong f(u^*, f, H), \\ &\cong \frac{u^* H}{20} \quad \text{for } H < \text{Ekman depth}, \\ &\cong \frac{1}{200} \frac{u^{*2}}{f} \quad \text{for } H > \text{Ekman depth}. \end{aligned} \tag{8}$$

From this scaling,

$u_{\text{bottom}} \sim 5-10 \text{ cm sec}^{-1}$ ;  $u^{*2} = k u_b = .2-.4 \text{ cm}^2 \text{sec}^{-2}$ ;  $A_v \sim 10-20 \text{ cm}^2 \text{sec}^{-1}$ . The estimate is similar to the value found by Stommel and Leetmaa (1972)

of  $30 \text{ cm}^2 \text{ sec}^{-1}$ , but is somewhat higher than estimates of Carter and Okubu (1965) of  $2 - 20 \text{ cm}^2 \text{ sec}^{-1}$ . The Carter and Okubu estimates were under summer conditions however. Estimates of the vertical eddy viscosity under storm conditions using the scaling arguments give

$$A_v = 100 - 200 \text{ cm}^2 \text{ sec}^{-1} (u^*{}^2 \cong 2 - 4 \text{ cm}^2 \text{ sec}^{-2}).$$

### C. Response of the Tide to a Change in Bottom Drag

The adjustment of currents during storms is of particular interest because storm generated currents appear to dominate the flow on the shallow shelf in winter. It is expected that the vertical eddy viscosity will increase with increased surface or bottom stress, and that the bottom drag coefficient ( $k \approx C_D \overline{|U|}$ ) may increase due to a larger mean current or to waves. In this section the change in bottom drag coefficient during storm conditions is estimated from coastal tide observations. The typical storm duration is one or two days and the adjustment time of the bottom boundary layer to a changing eddy viscosity or bottom drag coefficient is  $f^{-1}$ ; the steady state assumption of the previous model is thus not satisfied and the method is not appropriate. However, the bottom drag coefficient apparently increases significantly during storms so that an integrated tidal model can be considered in steady state.

#### 1. The Model

As in the previous section the simplest model which incorporates the desired effects of friction on the shelf tides is developed. Consider the following model of the tide on the continental shelf forced by the deep ocean tide:

The integrated linear equations of motion are:

$$\frac{\partial u}{\partial t} - fv = -g \frac{\partial \xi}{\partial x} - Ru,$$

$$\frac{\partial v}{\partial t} + fu = -g \frac{\partial \xi}{\partial y} - Rv, \quad (9)$$

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = -\frac{1}{H} \frac{\partial \xi}{\partial t},$$

where

$u, v$  = depth averaged velocities,

$f$  = Coriolis parameter,

$\xi$  = surface elevation above equilibrium,

$R$  = bottom drag coefficient,

$g$  = gravity,

$H$  = depth.

Here the bottom stress is modeled as a bottom drag proportional to the velocity ( $R \cong C_D \overline{|U|}/H \cong k/H$ ;  $R$  has units  $\text{sec}^{-1}$  and is assumed constant across the shelf). The surface stress is assumed to be zero. The boundary conditions are

$$\begin{aligned} \text{at the coast } (x = 0), \quad u &= 0, \\ \text{at the shelf edge } (x = a), \quad \xi &= \xi_0 \cos \omega t. \end{aligned} \tag{10}$$

Assuming that there is no along shelf variation ( $\frac{\partial}{\partial y} = 0$ ), the complex solution for the velocity and surface elevation is:

$$\begin{aligned} u &= \frac{-i\omega\xi_0}{H\alpha} \frac{\sinh \alpha x}{\sinh \alpha a} e^{i\omega t}, \\ v &= \frac{\omega\xi_0}{H\alpha} \frac{f}{(\omega^2+R^2)} (\omega+iR) \frac{\sinh \alpha x}{\sinh \alpha a} e^{i\omega t}, \\ \xi &= \xi_0 \frac{\cosh \alpha x}{\cosh \alpha a} e^{i\omega t}, \end{aligned} \tag{11}$$

where

$$\begin{aligned} gH\alpha^2 &= \omega^2 \left( \frac{f^2}{\omega^2+R^2} - 1 \right) + i\omega R \left( \frac{f}{\omega^2+R^2} + 1 \right), \\ \frac{v}{u} &= \frac{f}{(\omega^2+R^2)^{1/2}} e^{i(\phi-\pi/2)}, \end{aligned}$$

$$\tan \phi = R/\omega .$$

For  $R = 0$  the solution is a trivial one of a wave travelling in the  $\pm x$  direction with phase speed

$$\frac{\omega}{k} = \sqrt{gH} \frac{1}{[1-(f/\omega)^2]^{1/2}} . \tag{12}$$

The ratio of the along shelf to cross shelf velocity is

$$\frac{v}{u} = -\frac{f}{\omega} e^{-i\pi/2}.$$

The velocity vector rotates clockwise and the amplitude ratio of the velocity components is independent of the cross shelf position. For  $R \ll f$  the solution is not frictionally affected while for  $R > \omega$  there is a phase lag in the current and surface elevation with respect to the forcing at the shelf edge (figure 3.4). For  $R$  between  $10^{-4}$ - $10^{-2} \text{sec}^{-1}$  the amplitude of the cross shelf velocity and the elevation remain approximately constant but the along shelf velocity is significantly damped.

Although the model is oversimplified to fit in detail to current or sea level observations to estimate the damping coefficient  $R$ , especially because of the idealized topography, changes in phase of the tide at the coast might indicate approximate changes in the damping coefficient during storm conditions. Assuming that the forcing at the edge of the shelf remains constant during storms, an increase in the damping coefficient  $R$  will be reflected in a phase lag of the surface tide at the coast with respect to normal conditions. From the previous calculations, the damping coefficient  $R$  is estimated to be approximately  $10^{-5} \text{sec}^{-1}$  ( $R \sim C_D \overline{|U|} / H \cong k/H = .05/5 \times 10^3 \text{sec}^{-1}$ ) under non-storm conditions. The phase and amplitude of the tide at the coast relative to the forcing at the shelf edge is shown in figure 3.5 at three east coast tide stations and for the range of expected  $R$ . A 10 degree phase lag from normal conditions at these tide stations would suggest an increase in  $R$  by a factor of 4 to 5. The slope of the phase

See figure 3.2 for locations.

Figure 3.5

change is greater as  $R$  increases and thus for a given phase change the associated change in  $R$  will be greater the smaller the non-storm value. Note that if the non-storm value of  $R$  is unknown an observed shift of phase can be used to estimate at least a lower bound on the value of  $R$  under storm conditions by assuming  $R = 0$  initially. Also note that for these shelf dimensions the amplitude of the tide is insensitive to damping in the range  $10^{-5}$  to  $10^{-4} \text{ sec}^{-1}$ . Finally, the predicted ratio of the amplitude of the semi-diurnal tide at Atlantic City to Sandy Hook is .92, in agreement with the observed value of .89 (Redfield, 1958; Hicks and others, 1965).

## 2. Observations of Tidal Phase During Storms

Beardsley and Butman (1974a) described the response of sea level and currents on the New England continental shelf to three winter storms in March of 1973. The first storm occurred on March 18 and 19 with strong winds from the west which produced little alongshore flow and a sea surface setup in the direction of the wind. The second and third storms (March 22-23, March 27-28) were northeasters and winds produced alongshore flow and a rise of sea level at the coast, but little setup. The asymmetric response of the currents and sea level was attributed to differences in the large scale wind pattern arising from different storm tracks. We will investigate the change in the semidiurnal tide at the coast during these three storms.

Estimates of the phase and amplitude of the semidiurnal tide at Sandy Hook, Atlantic City, and Cape May as a function of time were obtained by fitting by least squares a cosine and sine with a period of 12.42 hours to sea level data over 24.84 hour overlapping segments. The sea level records were first high pass filtered by subtracting a low passed version (Gaussian filter, one half power at 43.6 hours) from the original series. This left the semidiurnal signal essentially unchanged, reduced the diurnal

tidal signal by 30% and removed the lower frequency sea level fluctuation due to the storms. A reference tidal signal was generated from harmonic constants supplied by the National Ocean Survey using constituents with amplitudes greater than 3 cm and periods shorter than 30 hours. The following tidal lines were used:

Sandy Hook  $M_2, S_2, N_2, K_2, \nu_2, K_1, O_1$

Atlantic City  $M_2, S_2, N_2, K_2, K_1, O_1, P_1$

Cape May  $M_2, S_2, N_2, K_2, K_1, O_1, P_1$

The generated records were high pass filtered and the amplitude and phase of the semidiurnal tide as a function of time computed in an identical manner to that used for observed sea level. The unfiltered sea level record, filtered record, and generated record at Sandy Hook are shown in figure 3.6.

The difference in phase lag of the semidiurnal tide between the observed signal and the generated signal (figure 3.7) clearly shows a delay in the tide at the coast during each storm by about 5 - 10 degrees (10-20 minutes), with the increased phase lag most pronounced during the second and most intense storm. The ratio of observed amplitude to generated amplitude at the semidiurnal frequency (figure 3.7b) shows no consistent change in amplitude during the storms. The tide at Montauk shows similar results while the signal at Nantucket is less consistent, perhaps due to local conditions and the adjacent Gulf of Maine. Using the curves in figure 3.5 and a non-storm  $R$  at  $10^{-5} \text{sec}^{-1}$ , a change in tidal phase of 5-10° gives an estimate for  $R$  of  $3 - 5 \times 10^{-5} \text{sec}^{-1}$  during storms and an adjustment time ( $R^{-1}$ ) of 6 hours, justifying application of the integrated steady state model under storm conditions.

OBSERVED - GENERATED PHASE LAG

OBSERVED / GENERATED AMP.

Figure 3.7

The increase in the damping coefficient ( $R \sim C_D \overline{|U|}/H$ ) must be attributed to an increased near bottom mean current or to waves, if the bottom drag coefficient  $C_D$  is assumed to be a fixed property of the bed. An increase in the mean flow was observed 20 m from the bottom during storms two and three, but it is unclear how much of the increase might be due to pumping of the current meter rotor by waves. There was not a significant mean current associated with the first storm, yet a change in tidal phase is observed.

Bottom velocities expected from waves were calculated using wave height and period reported by ships and observed at the Nantucket Lightship during the three storms (Table 3.3). The bottom velocities are significant especially during the second storm, and are large enough to account for at least a doubling of the bottom drag assuming non-storm bottom velocities of  $5-10 \text{ cm sec}^{-1}$ . It should be noted that waves generated by offshore winds will decrease toward shore, and should be less effective in increasing bottom drag than waves generated by onshore winds. Also, the increase in the damping coefficient (and thus a larger phase lag) will be larger for a shallow shelf where the wave induced bottom velocities are stronger and the bottom stress is distributed over a smaller depth. Neglect of topography, cross shelf and along shelf variations in damping and in the tide, and local effects may account for some of the variability in the phase and amplitude estimates.

#### D. Discussion and Summary

Two simple dynamical models of the semidiurnal tide on the continental shelf have been used to estimate the vertical eddy viscosity and the bottom drag coefficient at one location, and the change in an average shelf wide damping

<sup>2</sup>Drag coefficient and viscosity are consistent with tidal observations at one station.

<sup>3</sup>The damping coefficient should be considered as averaged over the shelf.

coefficient during storms (Table 3.4). The available observations of tidal currents in the bottom Ekman layer are consistent with a bottom drag coefficient of  $.04 \text{ cm sec}^{-1}$  and a vertical eddy viscosity of  $20 - 50 \text{ cm}^2 \text{ sec}^{-1}$ . In theory, two independent estimates of the bottom drag and viscosity are possible with current observations at two levels in the bottom boundary layer, but in practice the instrumental and estimation errors are large and only one parameter can be estimated with the other specified.

The value of the vertical viscosity is similar to the estimates of Stommel and Leetmaa (1972) and is consistent with scaling estimates (Csanady, 1972a). The Ekman depth is on the order of 10 m, which suggests that most wind generated flow under non-storm conditions will be confined to within 30 m of the surface although extrapolation of the viscosity to the surface layer is perhaps questionable.

During strong storms the surface semidiurnal tide arrives at the coast later (by about 10 degrees, 20 minutes) than under non-storm conditions. This phase lag is attributed to an increased bottom drag coefficient caused by increased bottom speeds due to waves and/or from a mean current generated by winds. The increase in bottom drag implies an adjustment time for integrated motions during storms of 6 - 9 hours, which is consistent with the observed rapid adjustment of sea level and currents during storms (Beardsley and Butman, 1974a). The large damping also implies that inertial energy during storms should not be observed at least in the depth averaged currents. Finally, the increased bottom drag coefficient suggests a significant average bottom stress over the shelf during major wind events.

## APPENDIX B

## GAUSSIAN FILTER

In this thesis a Gaussian filter is used to filter time series of currents and sea level. The filter is a standard one employed by the Woods Hole Buoy Group (see write-up of program TAPDIS). For data spaced at uniform intervals, the filter is performed as follows in the time domain:

$$\begin{aligned}
 U_1(t_i) &= \text{original time series,} \\
 U_2(t_i) &= \text{filtered time series,} \\
 U_2(t_j) &= A \sum_{k_1}^{k_2} U_1(t_k) \exp(-\alpha(t_k - t_j)^2), \\
 A^{-1} &= \sum_{k_1}^{k_2} \exp(-\alpha(t_k - t_j)^2), \\
 k_1 &= j - (N), \\
 k_2 &= j + (N), \\
 N &= \text{number of data points in time } T_{\frac{1}{2}}, \\
 \alpha &= \pi^2/4.5 T_{\frac{1}{2}}^2.
 \end{aligned}$$

In the frequency domain, by the convolution theorem (Bracewell, 1965), the result of the filtering is to multiply the Fourier transform of the original series by the Fourier transform of the filtering function. In this case the transform of the Gaussian filter in time is also Gaussian in frequency. The transfer function for the Gaussian filter as a function of  $T_{\frac{1}{2}}$ , the parameter which determines the frequency response at the filter is shown in figure B.1. The half-power point of the filter occurs approximately where  $T_{\frac{1}{2}}/T = .275$ .

## ELLIPSE REPRESENTATION OF CURRENT

A current in two spatial dimensions at one frequency may be represented as two components, as the sum of a clockwise and counterclockwise rotating vector, or as an ellipse. In each case, four quantities are necessary to specify the current. The component representation is most generally used, where

$$\underline{U} = u + iv = \text{vector velocity} , \quad (1)$$

$$u = A_1 \cos \omega t + B_1 \sin \omega t = \text{east-west component} ,$$

$$v = A_2 \cos \omega t + B_2 \sin \omega t = \text{north-south component} .$$

Representing the total complex velocity  $\underline{U}$  as the sum of a clockwise and counterclockwise rotating current gives:

$$\begin{aligned} \underline{U} &= u + iv \\ &= U_+ e^{i\omega t} + U_- e^{-i\omega t} , \end{aligned} \quad (2)$$

$$e^{i\omega t} = \text{unit vector which rotates counterclockwise} ,$$

$$e^{-i\omega t} = \text{unit vector which rotates clockwise} ,$$

$$U_+ \text{ and } U_- \text{ are complex quantities.}$$

Equating (1) and (2) yields

$$\begin{aligned} \underline{U} &= (A_1 + iA_2) \cos \omega t + (B_1 + iB_2) \sin \omega t , \\ &= (U_+ + U_-) \cos \omega t + i(U_+ - U_-) \sin \omega t , \end{aligned} \quad (3)$$

or

$$\begin{aligned} U_+ &= \frac{1}{2} [(A_1 + B_2) + i(A_2 - B_1)] , \\ U_- &= \frac{1}{2} [(A_1 - B_2) + i(A_2 + B_1)] . \end{aligned} \quad (4)$$

In complex form

$$\begin{aligned} U_+ &= |U_+| e^{i\phi_+} , \\ U_- &= |U_-| e^{i\phi_-} , \end{aligned} \quad (5a)$$

$$\begin{aligned} |U_+| &= \frac{1}{2} [(A_1 + B_2)^2 + (A_2 - B_1)^2]^{\frac{1}{2}} , \\ |U_-| &= \frac{1}{2} [(A_1 - B_2)^2 + (A_2 + B_1)^2]^{\frac{1}{2}} , \end{aligned} \quad (b)$$

$$\begin{aligned} \tan \phi_+ &= \frac{A_2 - B_1}{A_1 + B_2} , \\ \tan \phi_- &= \frac{A_2 + B_1}{A_1 - B_2} . \end{aligned} \quad (c)$$

The four quantities which specify a current ellipse are (figure C.1):

$V$  = magnitude of major axis ,

$rV$  = magnitude of minor axis ,

$\theta$  = ellipse orientation ,

$\tau$  = phase of ellipse (where current reaches maximum speed) .

To determine the phase of the current ellipse, we wish the time (relative to  $t = 0$ ) where the velocity vector reaches a maximum. The current magnitude is

$$\begin{aligned} |U|^2 &= \underline{U} \underline{U}^* , \\ &= (U_+ e^{i\omega t} + U_- e^{-i\omega t}) (U_+^* e^{-i\omega t} + U_-^* e^{i\omega t}) , \\ &= |U_+|^2 + |U_-|^2 + 2|U_+||U_-| \cos(2\omega t + \Delta\phi) , \end{aligned} \quad (6)$$

where

$$\Delta\phi = \phi_+ - \phi_- .$$

Figure C.1 Current ellipse showing major and minor axis, orientation, and phase.

## CURRENT ELLIPSE

MAJOR AXIS =  $V$

MINOR AXIS =  $rV$

PHASE =  $\tau$

ORIENTATION =  $\theta$

Figure C.1

The maximum speed is reached where

$$\begin{aligned}
 2\omega t + \Delta\phi &= 0, \\
 \omega t &= -\frac{\Delta\phi}{2}, \\
 &= \frac{\phi_- - \phi_+}{2} = \tau.
 \end{aligned} \tag{7}$$

From (6) the minimum speed occurs where  $\omega t$  is  $\tau + \pi/2$ , and is a maximum again at  $\omega t = \tau + \pi$ . Using (5c) and (7) gives

$$\tan 2\tau = \frac{2(A_1 B_1 + A_2 B_2)}{A_1^2 - B_2^2 + A_2^2 - B_1^2}. \tag{8}$$

The amplitude of the major and minor axes is given by (6);

$$\text{at } \omega t = \tau, \quad |\underline{U}| = |U_+| + |U_-| = \text{major axis}, \tag{9}$$

$$\text{at } \omega t = \tau + \pi/2, \quad |\underline{U}| = |U_+| - |U_-| = \text{minor axis}.$$

Finally, to determine the orientation of the ellipse (the angle the major axis makes with respect to the x-axis when  $|\underline{U}|$  is maximum), simply compute  $\underline{U}$  at  $\omega t = \tau$ :

$$\begin{aligned}
 \underline{U}_{\text{max}} &= |U_+| e^{i(\omega t + \phi_+)} + |U_-| e^{-i(\omega t - \phi_-)} \Bigg|_{\omega t = \frac{\phi_- - \phi_+}{2}}, \\
 &= (|U_+| + |U_-|) \cos \bar{\phi} + i(|U_+| + |U_-|) \sin \bar{\phi},
 \end{aligned} \tag{10}$$

$$\text{where } \bar{\phi} = \frac{\phi_- + \phi_+}{2}.$$

The velocity (10) forms an angle  $\theta$  with the x-axis

$$\tan \theta = \frac{\sin \bar{\phi}}{\cos \bar{\phi}} = \tan \bar{\phi}.$$

Using (6c) and (10)

$$\tan 2\theta = \frac{2(A_1A_2 + B_1B_2)}{A_1^2 + B_1^2 - (A_2^2 + B_2^2)} \quad (11)$$

Alternatively,  $\bar{\phi}$  can be derived by evaluating the phase of the quantity

$$U_+U_- = |U_+||U_-|e^{i(\phi_+ + \phi_-)} .$$

## BIOGRAPHICAL NOTE

Bradford Butman was born October 4, 1947 in Medford, Massachusetts. He attended public school in Concord, Massachusetts and received his B.A. from Cornell University in 1969. After seriously considering graduate school in city and regional planning, he entered the Massachusetts Institute of Technology—Woods Hole Oceanographic Institution Joint Program in Oceanography in 1969. Guided by interests in science, the environment, the ocean, and by summers spent on Nantucket Island, he pursued a thesis in coastal oceanography. The author has accepted a position with the U.S. Geological Survey in Woods Hole.
