EQUATIONS OF STATE OF OXIDES AND  
SILICATES AND NEW DATA ON THE ELASTIC PROPERTIES OF  
SPINEL, MAGNETITE, AND CADMIUM OXIDE

by Anthony Wayne England

Submitted to the Department of Geology and Geophysics in May, 1970,  
in partial fulfillment of the requirement for the degree of Doctor of  
Philosophy.

ABSTRACT

The elastic constants and their pressure and temperature derivatives are presented for single-crystal  $\text{MgO} \cdot 3.0\text{Al}_2\text{O}_3$  spinel and for polycrystalline cadmium oxide. The elastic constants and their pressure derivatives are reported for a natural magnetite and for a polycrystalline  $\text{MgO} \cdot 1.1\text{Al}_2\text{O}_3$  spinel. The measured volume thermal expansion of cadmium oxide is  $(32 \pm 1) \times 10^{-6}$ . Some of the more important results are:

A comparison of four spinels shows their elastic properties to be independent of the magnesia-alumina ratio. This is consistent with the universal equations of state.

A new technique for measuring ultrasonic velocity in coarse grained samples was used to study the effect of spherical pores on dynamic elastic properties. Various forms of Mackenzie's equations adequately predict the change in elastic parameters with porosities to approximately 10%. No adequate theory exists for the effect of porosity on the pressure derivatives of the elastic parameters.

A critical review in the light of most of the applicable data indicates that the universal equations of state are of marginal value. A modified quasi-harmonic equation of state tailored to a specific composition is required for reliable extrapolations to mantle temperatures and pressures.

Key parameters in the quasi-harmonic theory are the mode Gruneisen's ratios. Theoretically, it is shown that the mode Gruneisen's ratios of covalently bonded crystals are independent of wave vector. This new argument implies that the ultrasonic mode Gruneisen's ratios apply to all wave vectors in that mode. The result is a modified quasi-harmonic equation of state that is more rigorous than the Mie-Gruneisen equation.

A new theoretical expression is derived for the volume derivative of Gruneisen's ratio, and the results are listed for 10 compounds. The volume dependence of neither the Slater nor the Dugdale-MacDonald formulation of  $\gamma$  is correct. The implication to the reduction of shock data is discussed.

## ACKNOWLEDGMENTS

The assistance of unnumerable talented people has made this work possible. I am indebted particularly to Dr. D. H. Chung for his time, counsel, experimental equipment, and expertise, especially in the art of hot-pressing. Dr. W. F. Brace provided valuable counsel in pressure techniques. Dr. D. Readey and D. Camilli of Raytheon generously assisted with hot-pressing. Professor C. Frondel of Harvard University generously provided the magnetite sample. I sincerely thank Dr. Dave McKay of the Manned Spacecraft Center for his microprobe analysis of the samples.

Appreciation is extended to Professor Gene Simmons for guidance throughout this work. Greatest debt is to my wife, Kathi, for monumental patience.

Financial support was provided by a National Science Foundation Graduate Fellowship, by the National Science Foundation grant GA 579, and by the National Aeronautics and Space Administration contract NGR 22-009-176. The support by the Manned Spacecraft Center of the National Aeronautics and Space Administration of manuscript preparation, electron microprobe analysis, and digital computation is acknowledged.

## I. INTRODUCTION

Theoretically based equations of state relate properties of materials to pressure, temperature, and composition. With such equations of state, it is possible to extend laboratory measurements made at low pressures and moderate temperatures to the pressures and temperatures that exist in planetary interiors. Certain forms of these equations are used to reduce shock-wave data. Some of these equations of state are reviewed by Knopoff (1963) and Brush (1967). Examples of geophysical applications of these and of empirical equations of state are found in Birch (1961a, 1963), Clark and Ringwood (1964), and D. Anderson (1967a,b).

Of the empirical relations, a Birch-type equation (Simmons, 1964a) most satisfactorily relates an elastic property to density and composition. (The effect of crystal structure can be ignored to the level of approximation in these empirical equations.) A weakness of the empirical equations is that they cannot be extrapolated to high pressures and/or temperatures without corroborating measurements (such as the Hugoniot). Complete theoretical equations of state exist for pressures in the millions of bars and/or temperatures greater than  $50,000^{\circ}$  K. For pressures and temperatures corresponding to the interior of the earth, a basis for an equation of state is found in the quasi-harmonic theory of lattice vibrations, but the parameters in the resulting equation have to be determined experimentally. A difficulty is that these parameters vary with density. This dependence on density is a prime concern of this study.

For the purely empirical laws, it is assumed that data for a few key rocks and minerals can be cast into a law applicable to all geophysically interesting materials. For example, if the equations of state for important

end-member oxides were known, the equations of state of more complex minerals might be inferred through some mixing law. Detailed studies of several end members as a function of pressure or temperature are underway in several laboratories. Results are available for quartz (Thurston, et al., 1965), periclase (Chung, et al., 1964; Bogardus, 1965), alumina (Schreiber and O. Anderson, 1966), forsterite (Schreiber and O. Anderson, 1967), polycrystalline calcia (Soga, 1968), and rutile (Chung and Simmons, 1969).

In this report, several new materials are added to the list of those studied. The elastic properties, along with their pressure and temperature derivatives, were measured on single crystals of  $\text{MgO} \cdot 3.0\text{Al}_2\text{O}_3$  spinel and magnetite and on polycrystals of  $\text{MgO} \cdot 1.1\text{Al}_2\text{O}_3$  spinel and cadmium oxide ( $\text{CdO}$ ). The temperature derivatives were omitted in the case of magnetite because several kilobars of confining pressure were required to obtain consistent data.

Often, only very small crystals of a substance are available. Cadmium oxide and high-pressure polymorphs such as stishovite are examples. In such cases, hot-pressing provides samples large enough to measure the elastic constants. Hot-pressed products are seldom free from pores. After repeated attempts to hot-press cadmium oxide, the best specimen still had a 3.8% porosity. This report includes an experimental study of the effect of porosity on the elastic constants and their pressure derivatives.

## II. EFFECT OF SPHERICAL PORES ON THE ELASTIC CONSTANTS AND THEIR PRESSURE DERIVATIVES

For precise measurements of the elastic constants of a crystal, the specimen must have dimensions of several millimeters. Such relatively large crystals are not available for all materials. In addition, for less symmetrical crystal structures, elastic constants are more complex, and hence, more difficult to obtain. For these reasons, often it is simpler to study an isotropic hot-pressed product rather than a single crystal.

A hot-pressed specimen free from pores is difficult to manufacture. The porosity of most products is several percent. As in sintering (Mackenzie and Shuttleworth, 1949), the dynamics of hot-pressing favor formation of spherically shaped pores. An exception is the porosity caused by differential thermal contraction (Coble and Kingery, 1956). In this chapter, only spherically shaped pores are discussed. The goal is to relate the effective elastic properties to intrinsic elastic properties and porosity.

The seven largest porous glass samples were selected from a set of thirteen samples fabricated for an earlier study. The details of the manufacture of the samples can be found in Walsh, Brace, and England (1965) and England (1965). Each sample was cut into a right circular cylinder approximately 1.5 centimeters in diameter by 2 centimeters long. The ends were cut parallel to 6 minutes of arc and polished on a lu wheel. The pores within the samples are generally smaller than 0.1 millimeter, are almost spherical, and are not contiguous.

A variation on the Papadakis (1967) pulse-echo overlap method was used to measure compressional and shear-wave velocities in the specimen. The geometry of the sample and the pressure system is shown in figure II-1. A

plug made of 4340 steel hardened to  $R_c$  55 was used as a sound transmission line and as the upper end of the pressure vessel. Peselnick, et al. (1967) originally showed the advantages of such an arrangement: elimination of electrical leads into the vessel and of the need to bond a transducer to each sample. The transducers can be bonded permanently to the plug. An X-cut quartz transducer was epoxied to one steel plug, and an ac-cut quartz transducer was epoxied to another. Both transducers were 1/2 inch in diameter and cut to a 5-MHz fundamental.

The sample-to-plug bonding was Eastman 910 quick-setting cement. This cement is ideal because it is not a filler and requires close juxtaposition of the surfaces before it will harden. To remove the sample, the bond was softened by baking the plug-sample assembly at 150° C for half an hour. This baking did not damage the epoxy seals.

The pressure system was a standard piston and cylinder apparatus capable of 10 kilobars. Because the porous glass samples were relatively fragile, pressures were kept at less than 3 kilobars. The pressure medium was petroleum ether, and the pressure was measured on a recently calibrated Heise gauge. Accuracies of the pressure measurement are discussed in chapter III.

The ultrasonic round-trip travel time in the sample can be obtained by pulsing the transducer once, by watching the multiple reflections inside the specimen, and by triggering the oscilloscope sweep so that these reflections appear superimposed on the cathode ray tubes (CRT). The reciprocal of the triggering frequency becomes the travel time. A schematic of the signal seen at the transducer is shown in figure II-2. If the oscilloscope is triggered at the times indicated by vertical hash marks and the times are chosen properly, the reflections become superimposed. The sweep

rate must be such that a complete sweep is shorter than the time between hash marks. Phase stability of event A with respect to sweep triggering was obtained by use of the same source frequency divided by 64. The result is an event A for every 64 sweeps across the scope. The reflected signals decay completely between events A.

Oscilloscope clutter is reduced by trace-intensity modulation which highlights a chosen time period. Event A, with a variable delay line, triggers a variable length pulse that then is applied to the Z-axis of the oscilloscope. For best signal-to-noise ratio, a time that included only reflections B and C was selected.

By use of the alternate trace feature of a dual-trace scope, with inputs connected in parallel, reflections B and C are obtained on separate traces. This allows selective amplifications of the reflections and choice of their vertical separation; both features aid identification of the exact overlap. Typical reflections of a shear-wave signal are shown in figure II-3. The bottom traces match exactly, whereas the triggering frequency for the top two traces is mismatched by one part in  $10^3$ . This sensitivity in the identification of the overlap in this new method is improvement of an order of magnitude in precision over the pulse-mercury delay-line technique frequently used to measure velocities of rocks. More than one order of magnitude improvement in accuracy exists because the signal in the delay-line method passes through media with different filter characteristics before the comparison. Points between dissimilar waveforms then must be matched. Systematic errors are likely. A schematic of the electronic components is shown in figure II-4.

Velocity data, lengths, porosities, and densities of the samples are given in table II-1. Raw data are listed in Appendix G. Because pores

were not interconnected, porosity could be measured by a comparison of the dry weight and the weight submerged in carbon tetrachloride, i.e., by measurement of the density. The uncertainty in porosity reported in table II-1 is  $\pm 0.01$ . Velocities are valid to 0.1%. The uncertainty in P-wave pressure derivatives is  $\pm 1.8 \times 10^{-3}$  km/sec kb and that of S-wave pressure derivatives is  $\pm 1.0 \times 10^{-3}$  km/sec kb. These uncertainties in the derivatives are caused by scatter in measured velocities rather than by uncertainties in pressure.

The results (table II-1) are plotted in figures II-5, II-6, and II-7. Mackenzie (1950) suggested a thick spherical shell embedded in a matrix as a model of material containing spherically shaped pores that were distributed homogeneously. The properties of the thick shell are taken equal to the intrinsic elastic constants; the elastic properties of the matrix are equal to the elastic properties of the overall porous medium. The theory can be recast as

$$\begin{aligned}
 \text{II-1)} \quad K' &= K \left( \frac{1 - \eta}{1 + \frac{3}{4} \frac{K}{G} \eta} \right) \\
 G' &= G \left[ 1 - 5\eta \left( \frac{3K + 4G}{9K + 8G} \right) \right] \\
 v_p' &= v_p \left[ \frac{K' + \frac{4}{3} G'}{\left( K + \frac{4}{3} G \right) (1 - \eta)} \right]^{1/2} \\
 v_s' &= v_s \left[ \frac{G'}{G(1 - \eta)} \right]^{1/2}
 \end{aligned}$$

where  $K'$ ,  $G'$ ,  $v_p'$  and  $v_s'$  refer to the bulk modulus, the shear modulus, the compressional velocity, and the shear velocity of the porous medium, respectively;  $\eta$  is porosity. The trace of equations II-1 are included in figures II-5, II-6, and II-7. The agreement is good at porosities less

than 10% of values commonly found in hot-pressed samples. A similar agreement was observed for the static bulk modulus (Walsh, Brace, and England, 1965).

For sufficiently low porosities, approximations for  $K'$  and  $G'$  are

$$\text{II-2)} \quad K' = K \left\{ 1 - \eta \left[ 1 + \frac{3}{4} \left( \frac{K}{G} \right) \right] \right\}$$

$$G' = G \left[ 1 - \frac{5}{3} \eta \left( 1 + \frac{1}{\frac{9}{4} \frac{K}{G} + 2} \right) \right].$$

The pressure derivatives of equations II-2 are

$$\text{II-3)} \quad \frac{\partial K'}{\partial P} = \frac{\partial K}{\partial P} \left\{ 1 - \eta \left[ 1 + \frac{3}{2} \left( \frac{K}{G} \right) \right] \right\}$$

$$+ \frac{\partial G}{\partial P} \left[ \eta \left( \frac{3}{4} \right) \left( \frac{K}{G} \right)^2 \right] - \left( \frac{\partial \eta}{\partial P} \right) K \left[ 1 + \frac{3}{4} \left( \frac{K}{G} \right) \right]$$

$$\frac{\partial G'}{\partial P} = \frac{\partial G}{\partial P} \left\{ 1 - \frac{5}{3} \eta \left[ 1 + \frac{2}{\left( \frac{9}{4} \frac{K}{G} + 2 \right)^2} \right] \right\}$$

$$- \frac{5}{3} G \frac{\partial \eta}{\partial P} \left( 1 + \frac{1}{\frac{9}{4} \frac{K}{G} + 2} \right) - \frac{\partial K}{\partial P} \frac{\frac{15}{4} \eta}{\left( \frac{9}{4} \frac{K}{G} + 2 \right)^2}$$

From the equation for  $K'$  in equations II-1, it is easily shown that

$$\left( \frac{\partial \eta}{\partial P} \right) = - \left( \frac{3}{4} \right) \left( \frac{\eta}{G} \right). \quad \text{Assume linear } K \text{ and } G, \text{ i.e.,}$$

$$\text{II-4)} \quad K = K_0 + \left( \frac{\partial K}{\partial \bar{P}} \right)_0 \bar{P}$$

$$G = G_0 + \left( \frac{\partial G}{\partial \bar{P}} \right)_0 \bar{P}$$

where  $\bar{P}$  is the average pressure in the solid. Note that  $\bar{P} = \frac{P}{(1-\eta)^{2/3}}$ , and that  $\left(\frac{\partial K, G}{\partial P}\right)_0 = \left(\frac{\partial K, G}{\partial \bar{P}}\right) (1-\eta)^{-2/3}$ .

Equations II-3 become

$$\begin{aligned}
 \text{II-5)} \quad \left(\frac{\partial K'}{\partial P}\right)_0 &= \left(\frac{\partial K}{\partial \bar{P}}\right) \left\{ 1 - \eta \left[ \frac{1}{3} + \frac{3}{2} \frac{K}{G} \right] \right\} \\
 &+ \left(\frac{\partial G}{\partial \bar{P}}\right) \left[ \eta \left( \frac{3}{4} \right) \left( \frac{K}{G} \right)^2 \right] + \frac{3}{4} \left( \frac{K}{G} \right) \eta \left[ 1 + \frac{3}{4} \left( \frac{K}{G} \right) \right] \\
 \left(\frac{\partial G'}{\partial P}\right)_0 &= \frac{\partial G}{\partial \bar{P}} \left\{ 1 - \eta \left[ 1 + \frac{\frac{10}{3}}{\left( \frac{9}{4} \frac{K}{G} + 2 \right)^2} \right] \right\} \\
 &+ \frac{5}{4} \eta \left( 1 + \frac{1}{\frac{9}{4} \frac{K}{G} + 2} \right) - \frac{\partial K}{\partial \bar{P}} \frac{\frac{15}{4} \eta}{\left( \frac{9}{4} \frac{K}{G} + 2 \right)^2}.
 \end{aligned}$$

For  $\eta = 0$ ,  $\left(\frac{\partial K}{\partial \bar{P}}\right)_0 = \left(\frac{\partial K}{\partial P}\right)_0$ . Therefore, for small  $\eta$ ,

$$\begin{aligned}
 \text{II-6)} \quad \left(\frac{\partial K}{\partial P}\right)_0 &= \frac{\partial K'}{\partial P} \left\{ 1 + \eta \left[ \frac{1}{3} + \frac{3}{2} \left( \frac{K}{G} \right) \right] \right\} \\
 &- \eta \left( \frac{3}{4} \right) \left( \frac{K}{G} \right) \left[ 1 + \left( \frac{K}{G} \right) \left( \frac{3}{4} + \frac{\partial G'}{\partial P} \right) \right] \\
 \left(\frac{\partial G}{\partial P}\right)_0 &= \frac{\partial G'}{\partial P} \left\{ 1 + \eta \left[ 1 + \frac{\frac{10}{3}}{\left( \frac{9}{4} \frac{K}{G} + 2 \right)^2} \right] \right\} - \frac{5}{4} \eta \left( 1 + \frac{1}{\frac{9}{4} \frac{K}{G} + 2} \right) + \frac{\partial K'}{\partial P} \frac{\frac{15}{4} \eta}{\left( \frac{9}{4} \frac{K}{G} + 2 \right)^2}.
 \end{aligned}$$

Except for the inclusion of the average pressure  $\bar{P}$  the derivation is equivalent to that of O. Anderson, et al. (1968). Equations II-6 provide poor fits to the pressure derivatives obtained for the porous glass. The assumption of a linear dependence of  $K$  and  $G$  on pressure (eq. II-4) is particularly poor for glass, and this may have caused the discrepancy. As

presented in chapter III, the elastic properties and their pressure derivatives were obtained for both a single-crystal spinel and for a porous polycrystalline spinel. Although the (MgO/Al<sub>2</sub>O<sub>3</sub>) ratios differed, the comparison should be valid. As will be shown in chapter III, the elastic properties are weak functions of stoichiometry. Schreiber and O. Anderson (1967) obtained the pressure derivatives of a 6% porous forsterite. Kumazawa and O. Anderson (1969) did the same for single-crystal forsterite. These data and values corrected according to equations II-6 are listed in table II-2. The corrections were generally inadequate.

Although equations II-1 provide adequate corrections to  $v_p$ ,  $v_s$ ,  $K$ , and  $G$ , the values of  $\frac{\partial K}{\partial P}$  and  $\frac{\partial G}{\partial P}$  given by equations II-6 are unreliable, perhaps because of the combined effect of the assumptions of spherical pores, noninteraction of stress fields, and linearity of the elastic parameters with pressure.

TABLE II-1.- ELASTIC PROPERTIES OF POROUS GLASS. (THE UNITS OF DENSITY AND LENGTH ARE cgs, OF PRESSURE AND ELASTIC MODULI ARE kb, AND OF VELOCITY km/sec.)

| Sample identification                                      |        |        |        |        |        |        |        |

### III. THE ELASTIC PROPERTIES OF SPINEL, MAGNETITE, AND CADMIUM OXIDE

#### The Samples

Ultrasonic velocities and their pressure and temperature derivatives were measured on a single-crystal spinel. Velocities and their pressure derivatives were measured on a polycrystalline, hot-pressed spinel. At ambient pressure, cracks in the polycrystalline spinel badly attenuated the signals so that the temperature derivatives, which were obtained at ambient pressure, could not be measured. A few kilobars of confining pressure closed these cracks.

A microprobe analysis of the gem-quality single-crystal spinel yielded  $\text{MgO} \cdot 3.0\text{Al}_2\text{O}_3$ . (Compositions of the samples are listed in table III-1.) The matrix of the polycrystalline spinel had a composition of  $\text{MgO} \cdot 1.1\text{Al}_2\text{O}_3$ . The polycrystalline specimen was degraded by inclusion of nearly pure alumina ( $\text{Al}_2\text{O}_3$ ). These inclusions occupied less than 5% volume and were not distributed homogeneously. Because velocity measurements taken at several points across the specimen were not noticeably different, the effect of the inclusions is considered small.

Velocities in a natural magnetite crystal were measured as a function of pressure. Although the specimen was superior to most natural magnetite, it contained many flaws. Like the polycrystalline spinel, a confining pressure was required for acceptable signal-to-noise ratios. Internally consistent data were taken between 5 and 10 kilobars. These results were extrapolated to obtain the zero pressure parameters.

The microprobe analysis showed the magnetite to be essentially pure iron oxide (table III-1). Such analyses are insensitive to the oxidation

state. A chemical analysis of Newhouse and Glass (1936) of magnetite collected from the same area (Mineville, New York) showed an  $\text{FeO}$  to  $\text{Fe}_2\text{O}_3$  ratio of 0.45. All their listed concentrations (table III-1) were close to the microprobe results.

Several cadmium oxide polycrystalline samples were hot-pressed. The best of these had a density that was 96.2% of X-ray density. Velocities and their pressure and temperature derivatives were measured on this specimen. The successful manufacture of the specimen involved sieving reagent-grade cadmium oxide to obtain a  $\mu$  powder. The powder was packed into a 1-inch-diameter graphite die with an ultrasonic tamper. The die, mounted in a press, was heated in an oxidizing atmosphere to  $950^\circ\text{C}$  and was maintained at that temperature for several hours to calcine off absorbed carbon dioxide. A pressure of 3000 psi was applied for 3 hours while the assembly cooled. Although the microprobe analysis was relatively insensitive to carbon, an upper limit of 2% could be assigned to the cadmium carbonate concentration. The other contaminants are listed in table III-1.

The weight of each sample when dry and the weight of the sample after being immersed in carbon tetrachloride were used to obtain the density. The balance was a Sartorius precision instrument.

The single-crystal specimens were oriented by use of the Laue X-ray technique (Binnie and Geib, 1959) to  $\pm 1/2$  degree, and the faces were cut parallel to the (100) and (110) crystallographic planes. The cutting and polishing techniques are described in appendix D. The polished faces were flat to a few wavelengths of sodium light and were parallel to 3 minutes of arc. The dimensions, measured with a Starrett T221L high-precision micrometer, and the densities are listed in table III-2.

## The Velocity Measurements

Ultrasonic velocities in magnetite were measured at 5 MHz. The phase-comparison technique was used on the magnetite rather than the more convenient pulse-echo overlap (PEO) method described in chapter II. The techniques, equipment, and analysis developed for phase comparison and an error study applicable to all measurements are presented in appendix E. The phase-comparison method is less restrictive because the transducer is isolated from the sample by a buffer rod. This arrangement allows velocity to be measured over extended temperature ranges. The phase-comparison technique could be used at temperatures greater than 500° C, at which most transducers are ineffective. The phase-comparison technique should be more accurate because the simple bond geometry facilitates a calculation of the phase lag at interfaces. In practice, the result of the calculation is inaccurate, and reducing the phase-lag effect to near zero by the use of very thin bonds, as in the PEO technique, is undoubtedly the better approach. The phase-comparison technique is slightly more sensitive than the PEO method. In the phase-comparison technique, the signals are added electrically, and the maximum is determined unambiguously; for PEO, two traces are compared visually. The principal advantages of the PEO method are a much better signal-to-noise ratio, steady-state operation of all components, and less opportunity for operator error.

The PEO equipment assembly used to obtain velocities in all samples but the magnetite is shown in figure III-1. The function of the assembly (Chung, et al., 1969) is similar to that described for the apparatus used to measure velocity in porous glass (chapter II). In this case, rather than a simple pulse, a pulse envelope of 20 MHz continuous wave (cw) is

transmitted. Exact overlap could be determined to less than one part in  $10^4$ . The transducers were quartz, either X- or AC-cut, were polished for third overtone operation at a fundamental of 20 MHzs; they were coated coaxially. The transducer was bonded to the sample with a 50/50 phthalic anhydride and glycerine mixture that was chosen for its resistance to dissolution in petroleum ether.

Pressures of 7 kilobars (10 kilobars in the case of magnetite) were achieved in a piston-in-cylinder pressure vessel. The useful volume inside the vessel was 1-1/4 inches in diameter by 8 inches long. The pressure medium, petroleum ether, was chosen for its low viscosity. For instance, kerosene becomes so viscous at 10 kilobars that the manganin pressure sensor is damaged.

A recently calibrated Heise bourdon tube gauge was used to measure pressure in the 7-kilobar runs. Above 7 kilobars, a manganin coil was used. In all cases, accuracies of the pressure measurements were better than 0.5%. Because these 0.5% errors were systematic, they are not additive, and pressure differences are good to approximately 0.5%. The temperature in the pressure vessel was held at 25.0° C by a water jacket and a temperature-controlled bath.

All measurements as a function of temperature were made at 1 bar in a refrigerated, circulating, ethanol bath. Temperatures between 25° C and minus 35° C were obtained. Temperature could be held to  $\pm 0.1^\circ$  C.

## Results

As in chapter II, the oscilloscope sweep frequency  $F$  is the reciprocal of travel time in the sample.  $F/F_0$  as a function of pressure or temperature ( $F_0$  refers to ambient pressure or temperature) can be related

to changes in the elastic constants (table III-3). Figures III-2 to III-8 are the plots of  $F/F_0$  for the several samples. Tables III-4, III-5, and III-6 are lists of elastic properties derived from the previously mentioned figures, from the equations in table III-3, and from equations in the review of the elasticity of crystalline solids presented in appendix C.

Accuracy was limited by the uncertain effect of the bonds between the transducer and the sample. Great care was taken to reduce the thickness of the bonds, but it is still probable that the thickness contributed a few degrees of phase lag. Measuring the thickness of the sample and transducer separately and then when bonded yielded an upper limit to the bond thickness of  $1\mu$ . For an estimated velocity of 1 km/sec in the bond, the uncertainty in the round-trip travel time would be  $2 \times 10^{-9}$  seconds. Because travel times were generally greater than  $6 \times 10^{-6}$  seconds, the error in velocity would be less than three parts in  $10^4$ . A precise treatment of bond effect may be found in appendix B.

Accuracies of pressure and temperature derivatives are determined by the scatter in the data, by the uncertainty in the pressure of 0.5%, and by the uncertainty in the temperature of  $\pm 0.1^\circ$  C. These errors are discussed in appendix E.

Only three independent elastic constants exist for crystals that have cubic symmetry. One of the four velocities obtained on each of the single crystals is redundant and serves as a check. It is easily shown that (appendix C)

$$\text{III-1) } v_s^2(110)[110] = v_s^2(110)[100] - \left[ v_p^2(110) - v_p^2(100) \right]$$

where  $v_s(ijk)[lmn]$  is the shear-wave velocity normal to the  $(ijk)$  crystallographic plane,  $[lmn]$  is its displacement vector, and  $v_p(ijk)$  is the compressional wave velocity normal to the  $(ijk)$  plane. In addition, it is easily shown that

$$\text{III-2) } \frac{\partial}{\partial \chi} \left( \frac{F}{F_0} \right) (100)[110] = \frac{1}{v_s^2(110)[110]} \left\{ v_s^2(110)[100] \frac{\partial}{\partial \chi} \left( \frac{F}{F_0} \right) (110)[100] \right. \\ \left. - \left[ v_p^2(110) \frac{\partial}{\partial \chi} \left( \frac{F}{F_0} \right) (110) - v_p^2(100) \frac{\partial}{\partial \chi} \left( \frac{F}{F_0} \right) (100) \right] \right\}$$

where  $\chi$  is pressure or temperature. The parameters computed from equations III-1 and III-2 are included in table III-4. These derived parameters in the case of spinel are in excellent agreement with the measured parameters. The difference between the derived and the measured velocities for the magnetite was less than 0.5%. The check involves small differences of large numbers. For magnetite, the inaccuracy of the check of velocity was 1%, and the inaccuracy of the check of pressure derivative was approximately 6%. Although agreement in velocity was excellent, agreement of pressure derivatives for magnetite was relatively poor. It is likely that pressure derivatives were influenced to an unknown extent by the flaws in the natural magnetite crystal. Intrinsic derivatives in the magnetite should not differ by more than 10% or 20% from the measured derivative, because most cracks were closed in the 5- to 10-kilobar range in which the measurements were made.

Dorasiwami (1947) measured the elastic constants of magnetite and obtained  $C_{11} = 2.70$ ,  $C_{12} = 1.08$ ,  $C_{44} = 0.987$ , and  $K = 1.62$  megabars. The new zero pressure constants,  $C_{11} = 2.676$ ,  $C_{12} = 1.056$ ,  $C_{44} = 0.953$ ,

and  $K = 1.596$  megabars are in fair agreement. Dorasiwami did not report the composition of his magnetite.

O. Anderson (1968a) discussed the significance of the negative pressure derivatives of  $v_s$  found in some oxides. His examples, zinc oxide and  $\alpha$ -quartz, were not nearly as extreme as is magnetite ( $\frac{\partial v_s}{\partial P}$  (zinc oxide) =  $-0.0032$ ,  $\frac{\partial v_s}{\partial P}$  ( $\alpha$ -quartz) =  $-0.0034$ , and  $\partial v_s / \partial P$  (magnetite) =  $-0.025$ ). Anderson's theory applies to oxides with relatively low shear moduli and low atomic coordination. Although neither is true of magnetite, an alternative explanation is not apparent.

The polycrystalline spinel was 2% porous. If the corrections for porosity discussed in chapter II are applied, the corrected values for the polycrystalline sample are close to those of the single crystal (table III-4). Verma (1960) and Schreiber (1967, 1968) list data for spinel. Their compositions were  $MgO \cdot 3.5Al_2O_3$  (Verma) and  $MgO \cdot 2.61Al_2O_3$  (Schreiber). A comparison with the new data for  $MgO \cdot 1.1Al_2O_3$  and for  $MgO \cdot 3.0Al_2O_3$  is shown in table III-7. No strong systematic variation of the elastic properties exists with stoichiometry. The factor of 2 difference in Schreiber's value of  $(\frac{\partial K}{\partial T})_P$  compared with the new data (table III-7) has its origin in the difference between Schreiber's value of  $(\frac{\partial v_p}{\partial T})_P$ ,  $-0.00031$  (unpublished data), and the new  $(\frac{\partial v_p}{\partial T})_P$ ,  $-0.000441$ . Pointon and Taylor (1968) measured  $v_p(100)$  and  $v_p(110)$  in a spinel at  $4.2^\circ$  K. From these velocities and the Cauchy relation, the three elastic constants listed in table III-8 were inferred. The use of the Cauchy relation for this purpose appears to be satisfactory because the new data reported here for spinel obey the Cauchy relation. An extrapolation of the new temperature data falls reasonably close. The small difference between the  $C_{11}$  may be caused by the smaller thermal contribution to the dynamic

elastic constants at temperatures near absolute zero. Because the new temperature derivatives are consistent with the data of Pointon and Taylor and are internally consistent, the derivatives are probably correct.

The thermal expansion of cadmium oxide was needed to find  $(\partial q/\partial T)_P$  where  $q$  is any elastic constant. The thermal expansion of cadmium oxide had not been measured. A platinum-rhodium ribbon furnace (Smith, 1963) in a Norelco X-ray diffractometer was used to obtain lattice spacing as a function of temperature to 847° C. Magnesium oxide mixed with cadmium oxide powder provided a standard. Data on magnesium oxide (Skinner, 1957) were used to calibrate the  $2\theta$  angles. The calibrated data are shown in figure III-9. The National Bureau of Standards value for the 27° C (111) lattice dimension of cadmium oxide is 2.712 Å. This compares favorably with the measured dimension of 2.709 Å. The measured volume thermal expansion of cadmium oxide is  $(32 \pm 1) \times 10^{-6}$ .

#### IV. UNIVERSAL EQUATIONS OF STATE FOR OXIDES AND SILICATES

Equations of state relate such material parameters as elastic constants and density to pressure and temperature. Although equations of state are used to interpolate laboratory measurements, the main use is the extrapolation of such measurements to conditions outside the range of measurements. The success of various forms of equations of state (reviewed by Knopoff, 1963, for example) is well known. In general, the constants of the equations differ for each material. Recently, several relations that are believed to be independent of the details of composition and crystallographic structure have been proposed in the geophysical literature (Birch, 1961b; O. Anderson-Nafe, 1965; and D. Anderson, 1967). These relations, which may be called universal equations of state, express uniquely the elastic parameters as explicit functions of density only and are believed to apply to all, or at least most, of the oxides and silicates. In these equations, composition and pressure do not appear explicitly, but enter implicitly through such variables as density and mean atomic weight or volume per ion pair. These relations have been used to interpret the velocities of elastic waves and densities of the interior of the earth (Birch, 1964; D. Anderson, 1965; and Press, 1968). However, all three relations are empirical, and many data show significant departures from each. The purpose here is to examine these universal equations of state on the basis of available data.

The elastic properties of materials of significance to the interpretation of observations on the interior of the earth have been measured by several techniques. For the purpose of examining the proposed relations among the elastic properties and such parameters as pressure and

composition, data obtained with field techniques are excluded because of uncertainties in the composition and state of the rocks through which the seismic waves propagate. Attention is focused on data obtained in the controlled conditions of the laboratory where, in principle at least, all the parameters can be measured precisely. (In practice, data of very high precision are often so incomplete as to be almost useless.) Various classes of techniques for measuring elastic properties are summarized in table IV-1, together with sufficient references to allow examination of the techniques in detail. Because the universal equations of state are designed to apply to the bulk properties of elastically isotropic aggregates, only those techniques which lead to this information are listed in table IV-1. Both precision and accuracy of the bulk properties computed from single-crystal data are reduced to approximately  $10^{-4}$  because of uncertainties in the schemes, such as those of Voigt and Reuss (Hearmon, 1961) and Hashin and Strikman (1962), that must be used to estimate the properties of elastically isotropic, monomineralic aggregates from the single-crystal measurements.

The ultrasonic data obtained on both single crystals and rocks are shown in table IV-2 with mean atomic weight, density, and other parameters. Similar data obtained with either high-pressure X-ray techniques or simple compression measurements on the compressibility of oxides with sodium chloride structure are given in table IV-3.

The difficulties in obtaining from the literature all the requisite data for a given material for such studies may be illustrated by the work on hornblende. Alexandrov and Ryzhova (1961), as part of their extensive work on the elastic properties of rock-forming minerals, determined a complete set of single-crystal second-order elastic constants for two samples

of hornblende. The only information they presented that can be used to estimate the composition consisted of optical properties (2V, dispersion, and qualitative statement of pleochroism) and density; they concluded from these data that both samples were "ordinary hornblendes." However, the composition of common hornblende ranges between the various end members shown in table IV-4 (Winchell and Winchell, 1951). In an attempt to salvage something from Alexandrov and Ryzhova's data but without placing too much reliance upon it, take the composition of both samples to be 40%  $H_2Ca_2Fe_5Si_8O_{24}$  and 60%  $H_2Ca_2Mg_5Si_8O_{24}$ , a composition that is consistent with the scanty data. For this (possible) composition,  $\bar{m} = 22.4$ . Hornblende is no exception to the fact that most rock-forming minerals show such large variation in composition that the designation (even if correct) of spinel, magnetite, pyroxene, garnet, etc., is insufficient to express the composition of a particular specimen.

Birch (1961b) noted that the velocity of compressional waves is a function of the density and mean atomic weight. For those oxides and silicates with  $\bar{m} \approx 21$  and  $v_p = a + bp$ , several values of the two constants were obtained by Birch from the linear regression analysis of various subsets of his data. Additional data that have been obtained later continue to show the general relationship, but with a number of exceptions. Simmons (1964a) called attention to the failure of materials with high contents of calcium oxide to conform to the Birch relationship. Materials for which the experimental data differ from the predicted compressional velocities by 0.5 km/sec are listed in table IV-5. Several of these materials contain high contents of calcium oxide. Particularly disturbing are the discrepancies of sillimanite, aegirite, apatite, and  $\alpha$ -quartz.

In a study of ultrabasic rocks in which there was little variation in content of either iron or calcium, Christensen (1966) showed that the velocities of both compressional and shear waves, at 10 kilobars, are related linearly to density with correlation coefficients greater than 0.999. The rocks that he studied were chiefly mixtures of olivine (approximately  $fo_{92}$ ), enstatite, and chrysotile. The range of mean atomic weights of these minerals is approximately 19.8 to 20.8. The chief variation of chemical composition in the rocks, although not explicitly examined by Christensen, is probably in water content. The implication of Christensen's data is that Birch's relation describes adequately the properties of materials of restricted composition.

O. Anderson and Nafe (1965) observed that the bulk modulus of many "oxide compounds" followed the relationship

$$\text{IV-1)} \quad \ln K = -x \ln \left( \frac{2\bar{m}}{\rho} \right) + C$$

where  $(2\bar{m}/\rho)$  is twice the average volume per atom and  $C$  is a constant. In the context of their work, the phrase "oxide compounds" is used not only for such oxides as magnesium oxide and titanium oxide, but also for silicates, nitrates, and pyrex. This usage is neither common in mineralogy nor to be recommended in geophysics. More data are now available than were used in the initial compilation. Figure IV-1 is a plot of bulk modulus  $K$  compared to  $(2\bar{m}/\rho)$  and includes most available data. Linear scales are used to show the large scatter; log-log plots tend to emphasize the gross relationships at the expense of showing clearly any large variation that may exist. O. Anderson and Nafe showed that many silicates and oxides for

which data are available fall within a region bounded by

$$\text{IV-2)} \quad \ln K = 4 \ln \left( \frac{2\bar{m}}{\rho} \right) + 17.3$$

$$\ln K = -3 \ln \left( \frac{2\bar{m}}{\rho} \right) + 15.1$$

where the same values of  $K$  and  $2\bar{m}/\rho$  used by Anderson and Nafe for stishovite have been used to evaluate the constant  $C$ . Even neglecting the fact that hematite, rutile, chromite, sillimanite, beryl, topaz, barium titanate, aegirite, montecellite, calcium oxide, cadmium oxide, and zircon do not satisfy the relationship, the limits are so large that the relationship is of little value in predicting the bulk modulus of a material from its density and mean atomic weight. Only in the most qualitative sense is it true that bulk modulus is related (by the Anderson-Nafe law) to composition through the parameter  $(2\bar{m}/\rho)$ .

D. Anderson (1967a) extended and modified Birch's relation to the form  $\rho = A\bar{m}\phi^n$ , where  $\phi \equiv K/\rho$ . A least square fit to the data for 31 selected minerals and rocks gave  $\rho = 0.048\bar{m}\phi^{0.323} \pm 0.12$ . (This standard deviation, given by Anderson in his equation 37 is that of  $\rho$ , rather than  $\rho/\bar{m}$  [D. Anderson, personal communication].) An equivalent statement of the  $\phi$ -law is that the bulk modulus is a linear function of pressure. This relation is shown in figure IV-2 with the data used by Anderson to evaluate the constants and many other data from table IV-2. There seems to be little reason to select some of these data and discard all the others. From inspection of figure IV-2, it can be seen that the data for many materials — and including the precise single-crystal values of  $\alpha$ -quartz, magnetite,

garnet, periclase, alumina, rutile, and calcia — depart more than one standard deviation (as determined by Anderson for his smaller set of selected data).

Implicit in the use of the D. Anderson  $\Phi$ -law to interpret the properties of the earth is the assumption that the only important parameters for the determination of  $\Phi$  for earth materials are  $\rho$  and  $\bar{m}$  and that details of crystallographic structure and composition are (relatively) unimportant. Specifically, it is hoped that the properties of high-pressure phases can be predicted from  $\rho$  and  $\bar{m}$ . Data for such phases obtained with static pressures are not yet available. Inasmuch as the plausible suggestion has been made that the material in the deep interior may be present as oxides, it seems desirable that any relation used to predict the properties of these hypothetical oxides should at least fit the available data on oxides that have the sodium chloride structure at atmospheric conditions. These data are shown in figure IV-3. Although neither cadmium oxide, europium oxide, strontium oxide, nor several of the other oxides is likely present in sufficient quantities in the interior of the earth to affect the physical properties of the earth, it would seem fair to use these data to test relationships expected to be useful in predicting the properties of simple oxides with close-packed structures. No data are closer than two standard deviations (taking  $\bar{m} \geq 20$ ) determined for the original set of data. It is concluded that the relation lacks general validity and suggested that application of the relation to the prediction of the elastic properties of high-pressure phases is at least doubtful.

It is instructive to test also the O. Anderson-Nafe law with the data for oxides with the sodium chloride structure. These test results are

shown in figure IV-4. Very large discrepancies exist between the values predicted from the O. Anderson-Nafe law and the values determined experimentally. Clearly, the Anderson-Nafe relationship does not fit the observed data well enough to justify its use as a tool for predicting  $K$ .

An alternate test of the several relations is afforded by the correlation coefficients (C.C.) and the standard errors (S.E.) that can be obtained by analysis of the data of tables IV-2 and IV-3 which constitute a larger set of data than was used initially by the various authors. For this purpose, take D. Anderson's relation in the form  $\ln(\rho/\bar{m}) = a + b\ln\phi$  for ease of computation and Birch's relation in the form  $v_p = a + b\rho + c\bar{m}$ . The results are shown in table IV-6. From a geophysical viewpoint, the correlation coefficients are uncomfortably small, and the standard errors are large. (Although the S.E. for the D. Anderson relation (~15%) may appear small, it is a larger fraction of the total range of the variable.) The standard error (or similar statistical parameter) is a measure of the dispersion of a given sample set (e.g.,  $S_1$ ) of data. Its use as a statistical estimator of the S.E. for the population (e.g.,  $S$ ) consisting of the appropriate data on all oxides and silicates at pressures from 4 to 2000 kilobars depends on the sample set  $S_1$  having been obtained in such a way that the following two requirements are satisfied: (1) each element of  $S_1$  is independent of the other elements, and (2) the distribution function for set  $S_1$  is the same as it is for the population  $S$ . Because neither of these requirements is satisfied by the present set of data, it is incorrect (statistically) to use the standard errors of table IV-6 to estimate the S.E. of such parameters as  $\bar{m}$  for the earth derived from seismic and other data by means of the various relations. It is the hope of those who use the relations to interpret the data on the earth that the

S.E. given for the relations do apply to the data for the earth. At best, these standard errors should be considered minimum values. The S.E. for any relation can be made as small as desired by selecting the subset of data used to evaluate it. For example, by restricting the set of data to those materials for which  $20 \leq \bar{m} \leq 25$ , quite high correlation coefficients for the Birch relation ( $>0.95$ ) may be obtained.

V. A MODIFIED QUASI-HARMONIC EQUATION OF STATE  
AND GRUNEISEN'S RATIO

As concluded in chapter IV, the elastic properties of the various oxides and silicates are not correlated adequately by any of the universal equations of state. A stipulation of each of the universal equations is that the values of the elastic parameters are fixed by the mean atomic weight and density. For a particular oxide or silicate, temperature and pressure affect the elastic parameters only when a change in density occurs. Thus, the elastic parameters would not change if an increase in pressure were balanced by an increase in temperature so that the density remained unchanged. An equivalent statement of  $q = q(\bar{m}, \rho)$ , where  $q$  is an elastic parameter, is

$$V-1) \quad \left[ \frac{\partial q(\bar{m})}{\partial \rho} \right]_{\text{T}} = \left[ \frac{\partial q(\bar{m})}{\partial \rho} \right]_{\text{P}}$$

Data on 10 oxides and silicates are listed in table V-1. A test of equation V-1, using the data from table V-1, was conducted. The test data are presented in table V-2. Except for  $K_s$ , the requirement that  $q = q(\bar{m}, \rho)$  fails, particularly,  $v_p \neq v_p(\bar{m}, \rho)$ , which is a challenge to the validity of Birch's law. In chapter IV, Birch's law was the only universal law illustrated to be even marginally successful. A general conclusion, based on the arguments presented in chapter IV and on the failure of equation V-1, is that the universal equations of state are inadequate for reliable extrapolation to temperatures and pressures found in the mantle of the earth. The reliability of an extrapolation to mantle conditions is improved greatly if a theoretically sound equation of state tailored to a specific petrological model is used. The quasi-harmonic theory of lattice

dynamics is presently the only suitable theory. A development of the quasi-harmonic equation of state and an evaluation of the volume dependence of its key parameter, Gruneisen's ratio, is presented in this chapter.

### Background

Two problems are inherent in the formulation of an equation of state. A theoretical expression is needed for the dynamic atomic interactions, and values are required for the interatomic forces. Roughly, the temperature dependence of the equation of state is derived from the dynamic solution, and the pressure dependence is derived from the interatomic forces. Although the interatomic potentials of the general form

$$u = -\frac{a}{r^n} + \frac{b}{r^m} \quad (m > n)$$

may be justifiable for ionic crystals, the interatomic forces must be obtained empirically for most materials.

Born and Huang (1954), Maradudin, et al. (1963), and others have reviewed the harmonic theory of lattice dynamics. Leibfried and Ludwig (1961) have reviewed the quasi-harmonic theory and the general anharmonic effects. Those parts of the quasi-harmonic theory pertinent to the geophysical use of the equation of state are discussed in this study. The notation used here conforms generally to that used by Maradudin, et al.

Consider a lattice of  $N$  cells, each cell  $l$  having volume  $v$  and containing  $r$  atoms. The atoms oscillate about mean positions determined by temperature and pressure. This theory differs from the harmonic theory in which these positions are equilibrium atom sites at zero  $P$  and  $T$ .

If  $\phi$  is the potential energy of the crystal, a Taylor expansion of  $\phi$ , based on mean position, is

$$V-2) \quad \phi = \phi_0(V) + \left(\frac{1}{2}\right) \sum_{\substack{l's'i \\ l's'j}} \phi_{,ij} \left( \begin{smallmatrix} ll' \\ ss' \end{smallmatrix} \right) u_i \left( \begin{smallmatrix} l \\ s \end{smallmatrix} \right) u_j \left( \begin{smallmatrix} l' \\ s' \end{smallmatrix} \right) + \dots$$

where  $V$  is the total volume,  $V = Nv$ ,  $\phi_0(V)$  is the rest potential at volume  $V$ ,  $u_i \left( \begin{smallmatrix} l \\ s \end{smallmatrix} \right)$  is the displacement from equilibrium in the  $i^{\text{th}}$  direction of the  $s^{\text{th}}$  atom in the  $l^{\text{th}}$  cell, and

$$\phi_{,ij} \left( \begin{smallmatrix} ll' \\ ss' \end{smallmatrix} \right) \equiv \left[ \frac{\partial^2 \phi}{\partial u_i \left( \begin{smallmatrix} l \\ s \end{smallmatrix} \right) \partial u_j \left( \begin{smallmatrix} l' \\ s' \end{smallmatrix} \right)} \right].$$

Note that equilibrium requires the first-order term in equation V-2 to be zero. If the displacements are such that the third and higher terms are negligible (not the same as assuming that the displacements are small), V-2 becomes a simple quadratic equation. The kinetic energy for the crystal is

$$V-3) \quad K = \frac{1}{2} \sum_{l's'i} m_s \dot{u}_i \left( \begin{smallmatrix} l \\ s \end{smallmatrix} \right)^2$$

where  $\dot{u}_i \left( \begin{smallmatrix} l \\ s \end{smallmatrix} \right)$  is the time derivative of  $u_i \left( \begin{smallmatrix} l \\ s \end{smallmatrix} \right)$ . A solution for the equation of motion

$$V-4) \quad m_s \ddot{u}_i \left( \begin{smallmatrix} l \\ s \end{smallmatrix} \right) + \sum_{l's'j} \phi_{,ij} \left( \begin{smallmatrix} ll' \\ ss' \end{smallmatrix} \right) u_j \left( \begin{smallmatrix} l' \\ s' \end{smallmatrix} \right) = 0$$

is

$$V-5) \quad u_i \binom{1}{s} = m_s^{-1/2} u_i(s) e^{i[\omega t - \bar{k} \cdot \bar{x}(1)]}$$

where the amplitude  $u_i(s)$  is independent of  $l$  and  $V$ ,  $\bar{x}(1)$  is the position vector of the  $l^{\text{th}}$  cell,  $\omega$  is the angular frequency, and  $\bar{k}$  is the wave vector. The characteristic equation of equation V-4 is

$$V-6) \quad \sum_{s'j} \left[ D_{ij} \binom{\bar{k}}{ss'} - \omega^2 \delta_{ij} \delta_{ss'} \right] U_j(s') = 0$$

where

$$D_{ij} \binom{\bar{k}}{ss'} = \left( m_s m_{s'} \right)^{-1/2} \sum_{l'} \phi_{,ij} \binom{1l'}{ss'} e^{i\bar{k} \cdot [\bar{x}(1') - \bar{x}(1)]}.$$

The elements of the dynamical matrix are  $D_{ij} \binom{\bar{k}}{ss'}$ . This matrix reflects the symmetry of the crystal.

Equation V-6 has nontrivial solutions only if

$$V-7) \quad \left| D_{ij} \binom{\bar{k}}{ss'} - \omega^2 \delta_{ij} \delta_{ss'} \right| = 0$$

for any allowed choice of  $\bar{k}$ . Because  $s = 1, \dots$ , and  $i = 1, 2, 3$ , equation V-7 is the  $3r$ -degree equation in  $\omega^2$ . Thus,

$$\omega = \omega_p(\bar{k}) \quad (p = 1, 2, \dots, 3r).$$

Given boundary conditions for the oscillations, e.g., the displacement at the boundary is always zero,  $k$  may have only  $N$  discrete values.

Therefore,  $3rN$  solutions to equation V-6 exist. This situation might

have been anticipated from the three degrees of freedom of each of the  $3rN$  atoms in the crystal.

The solutions (eq. V-5) are wavelike. The crystal dynamics can be considered as a problem of  $3rN$  independent linear oscillators. The Helmholtz free energy for a set of oscillators is written as the sum of the equilibrium configurational energy, the zero point vibrational energy, and a term related to the thermal vibrational energy. Thus,

$$V-8) \quad A = \phi(V) + \sum_{\omega} \frac{\hbar\omega}{2} + kT \sum_{\omega} \ln \left( 1 - e^{-\hbar\omega/kT} \right).$$

Because  $\omega$  is strictly a function of the equilibrium configuration or volume  $V$ , a new function  $\psi(V)$  will be substituted for  $\phi(V) + \sum_{\omega} \frac{\hbar\omega}{2}$ .

The pressure is

$$V-9) \quad P = - \left( \frac{\partial A}{\partial V} \right)_T = -\psi_{,V} + \left( \frac{1}{V} \right) \sum_{\omega} \left( \frac{\hbar\omega}{e^{\hbar\omega/kT} - 1} \right) \gamma_{\omega}$$

where

$$V-10) \quad \gamma_{\omega} \equiv - \left( \frac{\partial \ln \omega}{\partial \ln V} \right).$$

The Gruneisen parameter  $\gamma_{\omega}$  for the eigenfrequency  $\omega$  is strictly a function of  $V$ . The quantity

$$\left( \frac{\hbar\omega}{e^{\hbar\omega/kT} - 1} \right) \equiv E_{\omega}$$

is the thermal vibrational energy of an oscillator having the eigenfrequency  $\omega$ . Equation V-9 becomes the quasi-harmonic equation of state

$$V-11) \quad P = -\psi_{,V} + \frac{1}{V} \sum_{\omega} \gamma_{\omega} E_{\omega}.$$

The only assumption to this point is that the third and higher order potential-energy terms are negligible to the formulation of the vibrational energy.

The Gruneisen assumption is that  $\gamma_{\omega}$  can be replaced by an average value  $\bar{\gamma}$  so that

$$V-12) \quad P = -\psi_{,V} + \frac{\bar{\gamma} E_{\text{vib}}}{V}$$

where  $E_{\text{vib}} = \sum_{\omega} E_{\omega}$ . Equation V-12 is the Mie-Gruneisen equation of state. Because

$$V-13) \quad \bar{\gamma} = \frac{\sum_{\omega} \gamma_{\omega} E_{\omega}}{E_{\text{vib}}},$$

$\bar{\gamma}$  is no longer strictly a function of volume but may also vary with the temperature. Because each  $E_{\omega}$  had its own temperature dependence, a variation of temperature at constant volume may change  $\bar{\gamma}$  even though each  $\gamma_{\omega}$  is fixed.

#### New Support for a Modified Quasi-Harmonic Equation of State

An alternative to the  $3rN$  distinct terms in  $\bar{\gamma}$  is to assume that the  $\gamma_{\omega}$  terms within each mode are identical. In terms of the mode  $n$ ,

equation V-13 is

$$V-14) \quad \bar{\gamma} = \frac{\sum_n \gamma_n E_n}{E_{\text{vib}}}$$

where  $E_n$  is the energy in mode  $n$ . Only three independent elastic modes exist for the cubic crystals. The temperature dependence of  $\bar{\gamma}$  becomes manageable. In the following discussion, it is shown that the Gruneisen's ratios within a mode are independent of  $\omega$  for covalently bonded crystals.

To illustrate a sufficient condition for  $\gamma_n \neq \gamma_n(\bar{k})$ , consider a crystal which has symmetry other than triclinic or monoclinic. The orientation of the eigenvectors for such a crystal is not dependent on  $|\bar{k}|$ . For this case, a transformation matrix  $A_{ni}$  exists (not dependent on  $|\bar{k}|$ ), so that entries in the orthogonalized dynamical matrix are

$$V-15) \quad D^n(\bar{k}_{ss'}) = \sum_{ij} A_{ni} A_{jn} D_{ij}(\bar{k}_{ss'}) \quad (n = 1, 2, 3).$$

If the order of summation is reversed, then

$$V-16) \quad D^n(\bar{k}_{ss'}) = \left( \begin{matrix} m & m \\ s & s' \end{matrix} \right)^{-1/2} \sum_{l'} e^{i\bar{k} \cdot [\bar{x}(l') - \bar{x}(l)]} \left\{ \sum_{ij} A_{ni} A_{jn} \Phi_{,ij} \left( \begin{matrix} ll' \\ ss' \end{matrix} \right) \right\}.$$

The quantity in braces is strictly a function of the indices  $n$ ,  $l$ ,  $l'$ ,  $s$ , and  $s'$ . By denoting the quantity in brackets as  $g^n \left( \begin{matrix} ll' \\ ss' \end{matrix} \right)$ , equation V-16 can be written as

$$V-17) \quad D^n(\bar{k}_{ss'}) = \left( \begin{matrix} m & m \\ s & s' \end{matrix} \right)^{-1/2} \sum_{l'} g^n \left( \begin{matrix} ll' \\ ss' \end{matrix} \right) e^{i\bar{k} \cdot [\bar{x}(l') - \bar{x}(l)]}.$$

Consider a lattice centered on the atom  $s_0$  ( $\bar{x}(1) = 0$ ) with the nearest neighbors of type  $s_1$ . If the nearest neighbor forces are identical and dominate the dynamical interactions, then

$$V-18) \quad D^n \begin{pmatrix} \bar{k} \\ s_0 \end{pmatrix} = \left( m_{s_0} m_{s_1} \right)^{-1/2} g^n(|\Delta|) \sum_{1'} e^{i\bar{k} \cdot \bar{\Delta}(1')}$$

where  $\bar{\Delta}(1')$  quantities are the vectors to the nearest neighbor forces.

Because the boundary conditions require that  $\bar{k} \cdot \bar{x}(1')$  be independent of volume, the volume derivatives of the solutions to the characteristic equation are

$$V-19) \quad \frac{d}{dV} \left( \omega_n^2 \right) = m_n \left[ \frac{dg^n(|\Delta|)}{dV} \right] \sum_{1'} e^{i\bar{k}_n \cdot \bar{\Delta}(1')}$$

where  $n$  has  $3r$  values for each eigenvector or a total of  $9r$  values.

From the definition of Gruneisen's ratio (eq. V-10),

$$V-20) \quad \gamma_n = - \frac{1}{2} \frac{d \ln g^n(|\Delta|)}{d \ln V}.$$

The assumption of dominant nearest neighbor forces yields mode gammas that are independent of frequency or, equivalently, independent of temperature. Because of the charge neutrality of atoms in covalently bonded crystals, the nearest neighbor forces dominate. In support, consider that the total energy of a covalent solid is very nearly the sum of the energies of the individual covalent bonds (Ziman, 1964). Much of the bonding in oxides and silicates is covalent, i.e., the mode gammas for much of the material in the mantle and crust of the earth are largely independent of

temperature. Thus, the geophysically appropriate quasi-harmonic equation of state is

$$V-21) \quad P = -\psi_{,V} + \frac{1}{V} \sum_n \gamma_n E_n$$

where the summation is over the  $9r$  modes.

To evaluate the mode gamma of an elastic branch  $n$ , consider the phase velocity  $\omega_n/k_n$ . The boundary conditions are that the crystal dimensions be an integral multiple of  $2\pi/k_n$ . The reciprocal of the round-trip travel time of a wave between two boundaries is

$$V-22) \quad F_n(\omega) = \frac{\omega_n}{2\pi s}$$

where  $s$  is an integer. The mode gamma, in terms of  $F_n(\omega)$ , is

$$V-23) \quad \gamma_n = - \frac{\partial \ln F_n(\omega)}{\partial \ln V}.$$

For those materials where  $\gamma_n \neq \gamma_n(\omega)$ ,  $\omega$  in the ultrasonic range may be chosen. Then,

$$V-24) \quad \gamma_n = -V \left[ \frac{\partial \left( \frac{F_n}{F_n^0} \right)}{\partial V} \right]_T$$

or

$$V-25) \quad \gamma_n = K_T \left[ \frac{\partial \left( \frac{F_n}{F_n^0} \right)}{\partial P} \right]_T$$

A measurement of the change in ultrasonic wave travel time with pressure yields Gruneisen's ratio for that mode (a direct application of the parameter  $(F_n/F_n^0)$  that was used in chapter III).

The wave velocities in the solution to the dynamical equation are observable, as indicated in equation V-25. The solution was based on completely decoupled oscillators. Because the elastic parameters in the dynamical equation are related more closely to the static rather than the dynamic elastic constants, the ultrasonic waves are not truly eigensolutions to the dynamical equation. If the ultrasonic waves were eigensolutions to the dynamical equation, the phase velocities would be dependent only on volume, i.e.,  $(\partial v_n/\partial \rho)_P = (\partial v_n/\partial \rho)_T$ . The data in table V-2 indicate that this is not true. Because the  $\gamma_n$  values in the quasi-harmonic equation of state were obtained from the volume derivative at constant temperature of the Helmholtz energy, the  $(\partial v_n/\partial \rho)_T$  values probably are more nearly related to the solutions for  $\gamma_n$ .

The omission of the optic modes at room temperature is not serious; however, at mantle temperature, much of the vibrational energy is in the higher frequency modes. An approximation of the effect of the optic modes may be obtained by ignoring the band gaps. Each optic branch becomes an extension of an acoustic branch. For dominant, nearest neighbor forces, the acoustic  $\gamma_n$  would be the same as that for the appropriate optic branch. The summation in the modified quasi-harmonic equation V-21 would be over nine values of  $n$  (three solutions to each of the three principal directions) rather than over  $9r$  values of  $n$ .

### A New Expression for the Volume Dependence of Gruneisen's Ratio

The quasi-harmonic equation of state is often used to reduce shock data (Duvall and Fowles, 1963; Rice, et al., 1958). Because the locus of possible P-V points (the Hugoniot) for a shocked material is assumed to be an isentrope, the data reduction involves an estimate of adiabatic heating in the shock front. If a reversible process is assumed, the thermodynamic identity

$$V-26) \quad T ds = C_V dT + T \left( \frac{\partial P}{\partial T} \right)_V dV = 0$$

can be integrated to yield

$$V-27) \quad T = T_i e^{-\int_{V_i}^V \frac{\bar{\gamma}}{V} dV} .$$

To reduce the Hugoniot to an isotherm, one must depend heavily on equation V-27 or on the volume dependence of  $\bar{\gamma}$ . The uncertainty caused by this dependence is discussed by Knopoff and Shapiro (1969). A common approach has been to accept either the Slater (SL) or the Dugdale-MacDonald (DM) expressions for  $\bar{\gamma}$ . Thus,

$$V-28) \quad \gamma_{SL} = -\frac{1}{6} + \frac{1}{2} \left( \frac{\partial K}{\partial P} \right) + \delta_{SL}$$

$$V-29) \quad \gamma_{DM} = -\frac{1}{2} + \frac{1}{2} \left( \frac{\partial K}{\partial P} \right) + \delta_{DM}$$

where the  $\delta_{SL,DM}$  are factors that force the  $\gamma_{SL,DM}$  to agree with the thermal Gruneisen's ratio. Knopoff and Shapiro observe that neither

expression is sound theoretically. As demonstrated in figure V-1, the correct volume dependence of  $\gamma_{SL}$  or  $\gamma_{DM}$  has considerable importance.

Anderson and Kanamori (1968) reduced the Hugoniot for several oxides and silicates, including those for spinel, alumina, magnesium oxide, and forsterite. They calculated the parameters in the Birch-Murnaghan equation (appendix A) for several densities along the Hugoniot. For the Birch-Murnaghan equation of state,

$$V-30) \quad P = \frac{3}{2} K_0 \left[ \rho/\rho_0^{7/3} - \rho/\rho_0^{5/3} \right] \left\{ 1 - \xi \left[ \left( \frac{\rho}{\rho_0} \right)^{2/3} - 1 \right] \right\},$$

the SL and DM Gruneisen's ratios are

$$V-31) \quad \gamma_{SL} = \frac{11}{6} - \frac{2}{3} \xi + \delta_{SL}$$

$$\gamma_{DM} = \frac{3}{2} - \frac{2}{3} \xi + \delta_{DM}$$

The initial volume dependence of these Gruneisen's ratios are

$$V-32) \quad \left( \frac{\partial \ln \gamma}{\partial \ln V} \right)_{SL}^{\circ} = \frac{2}{3} \frac{K_0}{\gamma} \left( \frac{\partial \xi}{\partial P} \right)_0$$

$$\left( \frac{\partial \ln \gamma}{\partial \ln V} \right)_{DM}^{\circ} = \left( \frac{\partial \ln \gamma}{\partial \ln V} \right)_{SL}^{\circ} - \frac{2}{3} \left( \frac{\gamma + \frac{1}{6}}{\gamma} \right).$$

Data from the Anderson and Kanamori paper are given in table V-3 to show

$\left( \frac{\partial \ln \gamma}{\partial \ln V} \right)_{SL}^{\circ}$  for several materials. The term  $\frac{2}{3} \left( \frac{\gamma + \frac{1}{6}}{\gamma} \right)$  is small compared to

$\left(\frac{\partial \ln \gamma}{\partial \ln V}\right)_{\text{SL}}^{\circ}$ . As observed by Takeuchi and Kanamori (1966), little difference

exists between the SL and DM formulations.

The following discussion is to determine whether  $\left(\frac{\partial \ln \gamma}{\partial \ln V}\right)_{\text{SL}}^{\circ}$  is reasonable. The difference between the ultrasonic  $(\partial K_s/\partial \rho)_{\text{T}}$  and  $(\partial k_s/\partial \rho)_{\text{P}}$  (table V-2) allows  $(\partial \ln \gamma/\partial \ln V)_{\circ}$  to be estimated. The volume derivative at constant entropy of the Mie-Gruneisen equation of state (eq. V-12) for  $\bar{\gamma} = \bar{\gamma}(V)$  is

$$\text{V-33)} \quad P - K_s = - \left( V\psi,_{\text{V}} \right)_{\text{V}} + \bar{\gamma},_{\text{V}} E_{\text{vib}} + \bar{\gamma} \left( \frac{\partial E_{\text{vib}}}{\partial V} \right)_{\text{S}}.$$

The internal energy  $U$  is  $\psi + E_{\text{vib}}$ . Because  $dU = -pdV$  at constant entropy, equation V-33 can be written as

$$\text{V-34)} \quad K_s = \left( P + \psi,_{\text{V}} \right) \left( 1 + \bar{\gamma} \right) + V\psi,_{\text{VV}} - \bar{\gamma},_{\text{V}} E_{\text{vib}}.$$

From the temperature derivative at constant volume,

$$\text{V-35)} \quad \bar{\gamma},_{\text{V}} = \frac{1}{C_V} \left[ \left( 1 + \bar{\gamma} \right) \left( \frac{\partial P}{\partial T} \right)_{\text{V}} - \left( \frac{\partial K_s}{\partial T} \right)_{\text{V}} \right].$$

Because  $(\partial P/\partial T)_{\text{V}} = K_{\text{T}}\alpha$ ,  $(\partial K_s/\partial T)_{\text{V}} = \rho\alpha(\partial K_s/\partial \rho)_{\text{T}} - \rho\alpha(\partial K_s/\partial \rho)_{\text{P}}$ ; and  $\bar{\gamma} = K_{\text{T}}\alpha/\rho C_V$ , then

$$\text{V-36)} \quad \frac{\partial \ln \gamma}{\partial \ln V} = (1 + \bar{\gamma}) + \frac{\rho}{K_{\text{T}}} \left[ \left( \frac{\partial K_s}{\partial \rho} \right)_{\text{P}} - \left( \frac{\partial K_s}{\partial \rho} \right)_{\text{T}} \right].$$

The value of  $(\partial \ln \gamma/\partial \ln V)_{\circ}$  for 10 compounds are listed in table V-4. Note that the values in table V-4 are an order of magnitude smaller than the values in table V-3. The assumed volume dependence of

the Gruneisen ratio used to reduce the shock-wave data is much too large. The isothermal equation, based on a constant Gruneisen's ratio, is probably closer to being correct than are the equations based on an SL or DM formula. The temperatures in a shock front are higher than were previously thought, and the isothermal P-V curves are not as steep. Because neither the SL nor the DM Formulations of Gruneisen's ratio is sound, the ultrasonic data should be used to obtain  $(\partial\gamma/\partial V)_0$ , and the linear approximation to  $\gamma$ , i.e.,  $\gamma = \gamma_0 + (\partial\gamma/\partial V)_0 \Delta V$  should be used for the reduction of the Hugoniot. This procedure is not practical for high-pressure polymorphs. In such cases,  $(\partial \ln \gamma / \partial \ln V)_0 = (1 + \gamma)$  might be a good alternative. For most of the compounds listed in table V-2, the second term in equation V-36 is small compared to  $(1 + \gamma)$ .

The  $(\partial \ln \gamma / \partial \ln V)_0$  values are plotted against the specific volume in figure V-2. The trend is that the  $(\partial \ln \gamma / \partial \ln V)_0$  value is less for the more dense materials, which is consistent with O. Anderson's (1968) contention that Gruneisen's ratios for higher density polymorphs are smaller. If  $(\partial \ln \gamma / \partial \ln V)_0 = (1 + \gamma)$  and  $\gamma$  is smaller for the high density polymorph, then  $(\partial \ln \gamma / \partial \ln V)_0$  is also smaller.

## VI. CONCLUSIONS

For an elastic parameter  $X$ , the effect of spherical pores on the parameter  $X$  is predicted adequately by Mackenzie's (1950) equations. However, the assumption of a linear dependence of  $X$  on pressure combined with the pressure derivatives of Mackenzie's equations is insufficient to predict reliably the effective  $\partial X/\partial P$  as a function of porosity. When the data of a study must be very accurate, the porosity will have to be reduced to nearly zero, which is very difficult with modern hot-pressing techniques.

Comparison of the elastic properties of four spinels ( $\text{Al}_2\text{O}_3/\text{MgO}$  ratios of 1.1, 2.61, 3.0, and 3.5) shows an almost negligible dependence on stoichiometry. Because the mean atomic weights and the densities of the spinels are nearly the same, the result is consistent with the universal equations of state.

The O. Anderson-Nafe, Birch, and D. Anderson relationships are tested against the new data on spinel, magnetite, and cadmium oxide plus data from the literature on the elastic properties of other oxides and silicates. Numerous exceptions to each exist, and none of the relationships appear to have general validity for oxides and silicates. However, the Birch relationship may be useful for predicting the properties of some materials with restricted compositions. If the phase and compositional changes are barred, the O. Anderson-Nafe law and the  $\phi$  law predict the strict dependence of an elastic property on density, i.e.,  $K_s = K_s(\rho)$ .

If the nearest neighbor atomic forces dominate the interatomic lattice interactions, mode Gruneisen's ratios are independent of frequency. This dominance is realized in covalently bonded solids. For such

materials, measurement of ultrasonic mode gammas are particularly pertinent. The quasi-harmonic equation of state becomes

$$\text{VI-1)} \quad P = -\psi_{,V} + \frac{1}{V} \sum_n \gamma_n E_n$$

where  $n$  is the elastic mode and  $\gamma_n$  is the ultrasonically determined mode gamma. Because most oxides and silicates are predominantly covalent, when possible, equation VI-1 should be used rather than the less accurate Mie-Gruneisen equation. Certainly, either equation VI-1 or the Mie-Gruneisen equation is preferable to any of the universal equations.

If the Gruneisen assumption that  $\bar{\gamma}$  is independent of temperature is accepted, the volume derivative of Gruneisen's ratio is obtained readily, i.e.

$$\text{VI-2)} \quad \left( \frac{\partial \ln \gamma}{\partial \ln V} \right)_O = (1 + \gamma) + \frac{\rho}{K_T} \left[ \left( \frac{\partial K_S}{\partial \rho} \right)_P - \left( \frac{\partial K_S}{\partial \rho} \right)_T \right].$$

New data for spinel and cadmium oxide along with data for eight other oxides and silicates indicate that  $(\partial \ln \gamma / \partial \ln V)_O$  is nearly  $(1 + \gamma)$ , which is an order of magnitude smaller than either the SL or DM approximation. Thus, equation VI-2 or, where ultrasonic data are unavailable,  $(\partial \ln \gamma / \partial \ln V)_O = (1 + \gamma)$  should be used in the reduction of shock data. The isotherm derived from the Hugoniot is strongly dependent on the variation of Gruneisen's ratio with volume. To assume either the SL or the DM formula is not sufficient.

## APPENDIX A

## DERIVATION OF THE BIRCH-MURNAGHAN

## EQUATION OF STATE

The development of the Birch-Murnaghan equation can be found in Birch (1947, 1952). However, the derivation presented here has the advantage of modern nomenclature and brevity without sacrificing rigor.

If each point in an undeformed body is designated by a position vector whose components are  $a_i$  ( $i = 1, 2, 3$ ), and  $x_i$  are the coordinates of the point after deformation, then each point before deformation is uniquely related to some point after deformation by a function

$$A-1) \quad a_i = a_i(x_1, x_2, x_3).$$

Consider an infinitesimal line segment  $da_i$  at a point  $a_i$ . The deformation transforms  $da_i$  to a line segment  $dx_i$  in the deformed body. By the functional relation of A-1,

$$A-2) \quad da_i = a_{i,j} dx_j$$

where use is made of the usual summation convention and  $a_{i,j}$  is  $\frac{\partial a_i}{\partial x_j}$ . The difference of the squares of this infinitesimal line before and after deformation is

$$A-3) \quad \Delta(ds^2) = dx_i dx_i - da_j da_j$$

or, from A-2, in terms of the final coordinates,

$$A-4) \quad \Delta(ds^2) = (\delta_{jk} - a_{i,j} a_{i,k}) dx_j dx_k,$$

where  $\delta_{jk}$  is the Kronecker delta. The quantity  $\epsilon_{jk}$ , defined as

$$\text{A-5)} \quad \epsilon_{jk} = (1/2) (\delta_{jk} - a_{i,j} a_{i,k}),$$

is called the Eulerian finite strain tensor. In terms of this strain tensor, equation A-4 becomes

$$\text{A-6)} \quad \Delta(ds^2) = 2\epsilon_{jk} dx_j dx_k.$$

We now want the constitutive relations. For a deformed body with surface  $S$ , volume  $V$ , and specific energy  $\phi$  (either internal energy or Helmholtz energy), the change in total energy (adiabatically for internal energy or with a constant temperature for Helmholtz energy) due to an arbitrary, reversible, virtual displacement,  $(\delta x)_i$ , is

$$\text{A-7)} \quad \int_V \rho \delta\phi dV = \int_S \sigma_{ij} (\delta x)_j n_i dS + \int_V F_j (\delta x)_j dV$$

where  $\sigma_{ij}$  are the stresses at the boundary,  $F_j$  are the body forces, and  $n_i$  is the unit normal to surface  $S$  with positive sense outward. Applying the divergence theorem and remembering the  $\sigma_{ij,j} + F_i = 0$  for stress equilibrium, one may write A-7 as

$$\text{A-8)} \quad \int_V \left( \rho \delta\phi - \sigma_{ij} \frac{\partial (\delta x)_j}{\partial x_i} \right) dV = 0$$

Since this is true for any region of  $V$ ,

$$\text{A-9)} \quad \rho \delta\phi - \sigma_{ij} \frac{\partial (\delta x)_j}{\partial x_i} = 0$$

It is generally assumed that the energy,  $\phi$ , is some function of the deformation. If the Eulerian strain tensor is chosen as representative of that deformation,  $\delta\phi$  can be expressed in terms of  $\delta\epsilon_{ij}$ , i.e.,

$$\text{A-10)} \quad \delta\phi = \frac{\partial\phi}{\partial\epsilon_{mn}} \delta\epsilon_{mn},$$

or, by definition A-5,

$$\text{A-11)} \quad \delta\phi = - \frac{\partial\phi}{\partial\epsilon_{mn}} a_{j,m} \delta a_{j,n}.$$

The operation of virtual displacement on A-2 yields

$$\text{A-12)} \quad 0 = a_{j,k} d(\delta x)_k + \delta a_{j,k} dx_k$$

since the operators  $d$  and  $\delta$  are commutative. Division of A-12 by  $dx_n$  yields

$$\text{A-13)} \quad 0 = a_{j,k} \frac{\partial(\delta x)_k}{\partial x_n} + \delta a_{j,k} \delta_{k,n},$$

or,

$$\text{A-14)} \quad \delta a_{j,n} = - a_{j,k} \frac{\partial(\delta x)_k}{\partial x_n}.$$

Therefore, by A-11,

$$\text{A-15)} \quad \delta\phi = \frac{\partial\phi}{\partial\epsilon_{mn}} a_{j,m} a_{m,k} \frac{\partial(\delta x)_k}{\partial x_n},$$

and A-9 becomes

$$A-16 \quad \left[ \rho \left( \frac{\partial \phi}{\partial \epsilon_{mn}} \right) a_{j,m} a_{j,k} - \sigma_{nk} \right] \frac{\partial (\delta x)_k}{\partial x_n} = 0.$$

Since  $(\delta x)_k$  is arbitrary, its partial derivative with respect to  $x_n$  is also arbitrary. Thus, A-16 requires that

$$A-17) \quad \sigma_{nk} = \rho \left( \frac{\partial \phi}{\partial \epsilon_{mn}} \right) a_{j,m} a_{j,k}.$$

One should note that this is an entirely general definition of stress in terms of the deformed body.

Expansion of  $\phi$  around zero deformation yields

$$A-18) \quad \phi = \phi_0 + \left( \frac{1}{2} \right) \left( \frac{\partial^2 \phi}{\partial \epsilon_{mn} \partial \epsilon_{pl}} \right)_0 \epsilon_{mn} \epsilon_{pl} + \dots,$$

where equilibrium required a zero linear term. Therefore, if the limiting approximation is made that third and higher order terms in  $\phi$  can be ignored,

$$A-19) \quad \sigma_{nk} = \rho \left( \frac{\partial^2 \phi}{\partial \epsilon_{mn} \partial \epsilon_{pl}} \right)_0 \epsilon_{pl} a_{j,m} a_{j,k}$$

which can be written

$$A-20) \quad \sigma_{nk} = \left( \frac{1}{2} \right) \left( \frac{\rho}{\rho_0} \right) C_{mnp1} (\delta_{pl} a_{j,m} a_{j,k} - a_{s,p} a_{s,l} a_{j,m} a_{j,k}),$$

where the constants  $C_{mnp1}$  are

$$A-21) \quad C_{mnp1} = \rho_o \left( \frac{\partial^2 \phi}{\partial \epsilon_{mn} \partial \epsilon_{p1}} \right)_o$$

and are the elements of the elastic stiffness tensor.

If instead of considering a general deformation, one assumed an isotropic deformation in a cubic or isotropic materials, then the second order equation, A-20, becomes the one parameter Birch-Murnaghan equation. For instance, assume

$$A-22) \quad a_i = \left( \frac{\rho}{\rho_o} \right)^{1/3} x_i$$

where  $\rho$  and  $\rho_o$  are the densities in the deformed and undeformed states, respectively. Note that the Eulerian strain becomes

$$A-23) \quad \epsilon_{jk} = (1/2) \left( 1 - (\rho/\rho_o)^{2/3} \right) \delta_{jk}.$$

Equation A-20 is easily written in the Birch-Murnaghan form

$$A-24) \quad P = 3/2 K_o \left[ \left( \frac{\rho}{\rho_o} \right)^{7/3} - \left( \frac{\rho}{\rho_o} \right)^{5/3} \right]$$

where  $P$  is hydrostatic pressure and

$$A-25) \quad K_o = 1/3 (C_{1111} + 2C_{1122}).$$

Since the instantaneous bulk modulus  $K$  is

$$A-26) \quad K \equiv \rho \frac{\partial P}{\partial \rho}$$

equation A-24 and this definition yields

$$\text{A-27} \quad K = 3/2 K_o \left[ (7/3) \left( \frac{\rho}{\rho_o} \right)^{7/3} - (5/3) \left( \frac{\rho}{\rho_o} \right)^{5/3} \right] .$$

## APPENDIX B

ULTRASONIC WAVE REFLECTION AND  
REFRACTION AT A SEAL

Figure B-1 shows an ultrasonic wave  $u_1$  traveling in a material  $g$  and impinging on a seal (designated by an  $o$ ) at  $x = 0$ . The seal is generally less than a wavelength thick ( $\Delta$ ), although this analysis is not thickness dependent. The  $u_3$  and  $u_4$  are, respectively, the transmitted and reflected waves in the seal while  $u_5$  is the transmitted wave in material  $m$ .  $u_2$  is the total of the waves reflected by the seal.  $k$  and  $z$  are the wave vector, and mechanical impedance, respectively.

The propagating waves can be written

$$\begin{aligned}
 u_1 &= A_1 e^{i(\omega t - k_g x)} \\
 u_2 &= A_2 e^{i(\omega t + k_g x)} \\
 u_3 &= A_3 e^{i(\omega t - k_o x)} \\
 u_4 &= A_4 e^{i(\omega t + k_o x)} \\
 u_5 &= A_5 e^{i(\omega t - k_m x)},
 \end{aligned}$$

B-1)

where the  $A_j$  are complex.

Continuity at  $x = 0$  and  $x = \Delta$  requires

$$\begin{aligned}
 A_2 - A_3 - A_4 + 0 &= -A_1 \\
 0 + A_3 e^{-ik_o \Delta} + A_4 e^{ik_o \Delta} - A_5 e^{-k_m \Delta} &= 0.
 \end{aligned}$$

B-2)

Force balance yields

$$\begin{aligned}
 & z_g A_2 + z_o A_3 - z_o A_4 + 0 = z_g A_1 \\
 \text{B-3)} \quad & -z_o A_3 e^{-ik_o \Delta} + z_o A_4 e^{ik_o \Delta} + z_m A_5 e^{-ik_m \Delta} = 0
 \end{aligned}$$

The solutions for  $\frac{A_2}{A_1}$  and  $\frac{A_5}{A_1}$  are easily derived by dividing equations B-2 and B-3 by  $A_1$  and solving the four linear independent equations. These equations are recast in matrix form as:

$$\text{B-4)} \quad \begin{bmatrix} 1 & -1 & -1 & 0 \\ 0 & e^{-ik_o \Delta} & e^{ik_o \Delta} & -e^{-ik_m \Delta} \\ z_g & z_o & -z_o & 0 \\ 0 & -z_o e^{-ik_o \Delta} & z_o e^{ik_o \Delta} & z_m e^{-ik_m \Delta} \end{bmatrix} \begin{bmatrix} A_2/A_1 \\ A_3/A_1 \\ A_4/A_1 \\ A_5/A_1 \end{bmatrix} = \begin{bmatrix} -1 \\ 0 \\ z_g \\ 0 \end{bmatrix}$$

By use of Cramer's rule,

$$\text{B-5)} \quad \frac{A_2}{A_1} = \frac{1}{D} \begin{vmatrix} -1 & -1 & -1 & 0 \\ 0 & e^{-ik_o \Delta} & e^{ik_o \Delta} & -e^{-ik_m \Delta} \\ z_g & z_o & -z_o & 0 \\ 0 & -z_o e^{-ik_o \Delta} & z_o e^{ik_o \Delta} & z_m e^{-ik_m \Delta} \end{vmatrix}$$

where  $D$  is the determinant of the coefficient matrix in B-4.

Similarly,

$$B-6) \quad \frac{A_5}{A_1} = \frac{1}{D} \begin{vmatrix} 1 & -1 & -1 & -1 \\ 0 & e^{-ik_o \Delta} & e^{ik_o \Delta} & 0 \\ z_g & z_o & -z_o & z_g \\ 0 & -z_o e^{-ik_o \Delta} & z_o e^{ik_o \Delta} & 0 \end{vmatrix} .$$

D is easily shown to be

$$B-7) \quad D = -2 \left[ (z_o z_g + z_o z_m) \cos k_o \Delta + i (z_g z_m + z_o^2) \sin k_o \Delta \right] \left( e^{-ik_m \Delta} \right) .$$

Similarly,

$$B-8) \quad \left( \frac{A_2}{A_1} \right) D = -2 \left[ (z_o z_g - z_o z_m) \cos k_o \Delta + i (z_g z_m - z_o^2) \sin k_o \Delta \right] \left( e^{ik_m \Delta} \right)$$

and

$$B-9) \quad \left( \frac{A_5}{A_1} \right) D = -4 z_o z_g .$$

B-8 can be written

$$B-10) \quad \frac{A_2}{A_1} = \frac{(z_o z_g - z_o z_m) + i (z_g z_m - z_o^2) \tan k_o \Delta}{(z_o z_g + z_o z_m) + i (z_g z_m + z_o^2) \tan k_o \Delta} .$$

In those instances where  $A_5/A_1$  is used, the origin will be moved to  $x = \Delta$ . Therefore,  $u_5$  should be multiplied by  $e^{-ik_m \Delta}$ .

B-9 becomes

$$\text{B-11)} \quad \frac{A_5}{A_1} = \frac{2z_o z_g}{\left(z_o z_g + z_o z_m\right) \cos k_o \Delta + i \left(z_g z_m + z_o^2\right) \sin k_o \Delta} .$$

Note that neither  $A_2/A_1$  nor  $A_5/A_1$  is symmetric with respect to switching materials  $g$  and  $m$ .

To obtain the phase lag  $\phi$  for each of the interactions, equations B-10 and B-11 will be cast in form  $|A_2/A_1|e^{+i\phi}$  for B-10 and  $|A_5/A_1|e^{-i\phi}$  for B-11. By multiplying both numerator and denominator by the conjugate of the denominator, one obtains for the phase angles

$$\text{B-12)} \quad \phi\left(\frac{A_2}{A_1}\right) = \tan^{-1} \left[ \frac{2 \left(z_o z_g z_m^2 - z_o^3 z_g\right) \tan k_o \Delta}{\left(z_o^2 z_g^2 - z_o^2 z_m^2\right) + \left(z_g^2 z_m^2 - z_o^4\right) \tan^2 k_o \Delta} \right]$$

and

$$\text{B-13)} \quad \phi\left(\frac{A_5}{A_1}\right) = \tan^{-1} \left[ \frac{\left(z_g z_m + z_o^2\right)}{\left(z_o z_g + z_o z_m\right)} \tan k_o \Delta \right] .$$

A similar manipulation yields the absolute values

$$\text{B-14)} \quad \left| \frac{A_2}{A_1} \right| = \left[ \frac{\left(z_o z_g - z_o z_m\right)^2 + \left(z_g z_m - z_o^2\right)^2 \tan^2 k_o \Delta}{\left(z_o z_g + z_o z_m\right)^2 + \left(z_g z_m + z_o^2\right)^2 \tan^2 k_o \Delta} \right]^{1/2}$$

and

$$\text{B-15)} \quad \left| \frac{A_5}{A_1} \right| = \frac{2z_o z_g}{\left[\left(z_o z_g + z_o z_m\right)^2 \cos^2 k_o \Delta + \left(z_g z_m + z_o^2\right)^2 \sin^2 k_o \Delta\right]^{1/2}} .$$

Note that while  $\phi(A_2/A_1)$  is not symmetric with respect to switching materials  $g$  and  $m$ ,  $|A_2/A_1|$  is symmetric. Conversely,  $\phi(A_5/A_1)$  is symmetric and  $|A_5/A_1|$  is not symmetric. The symmetries are used in evaluating the total phase lag  $\phi$  and the ratio of the reflected amplitudes off the two faces of the sample. (See section III.)

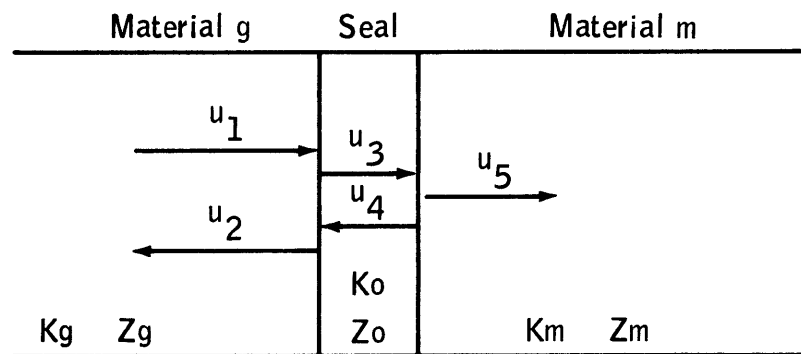

Figure B-1.- A schematic of the transmission  $u_5$  and reflection  $u_2$  of ultrasonic wave  $u_1$  as it interacts with a seal. The  $K_i$  and  $Z_i$  are the wave vector and mechanical impedance, respectively.

## APPENDIX C

WAVE PROPAGATION IN A CRYSTALLINE MEDIA,  
THE ELASTIC CONSTANTS, THE ISOTHERMAL CORRECTION  
AND THE ULTRASONIC ESTIMATE OF GRUNEISEN'S RATIO

The Christoffel relations are used to relate the ultrasonic velocities to single crystal elastic constants. A simple review is included here.

Given a crystalline material with density  $\rho$ , the time variation of the displacement vector  $u_i$  of a point in a volume  $dx dy dz$  under a stress field  $\sigma_{ij}$  is

$$C-1) \quad \rho \frac{\partial^2 u_i}{\partial t^2} dx dy dz = \frac{\partial \sigma_{ij}}{\partial x_j} dx dy dz.$$

Or, in terms of the usual constitutive relation,

$$C-2) \quad \sigma_{ij} = C_{ijkl} \epsilon_{kl},$$

where  $\epsilon_{kl}$  is defined as  $\frac{1}{2} \left( \frac{\partial u_k}{\partial x_l} + \frac{\partial u_l}{\partial x_k} \right)$ , C-1 becomes

$$C-3) \quad \rho \frac{\partial^2 u_i}{\partial t^2} = C_{ijkl} \frac{\partial^2 u_k}{\partial x_l \partial x_j}$$

since the elastic stiffness tensor  $C_{ijkl}$  is symmetric with respect to  $k$  and  $l$ . The material is assumed to be uniform though anisotropic. A body wave travels through the medium in a direction parallel to  $\bar{s}$

whose direction cosines are  $l_i$  and whose components are  $l_1x_1, l_2x_2, l_3x_3$ . The particle motion  $u_k$ , expressed in terms of  $\bar{s}$  is

$$C-4) \quad \frac{\partial u_k}{\partial x_1} = \left( \frac{\partial u_k}{\partial \bar{s}} \right) \left( \frac{\partial \bar{s}}{\partial x_1} \right)$$

and

$$C-5) \quad \frac{\partial^2 u_k}{\partial x_1 \partial x_j} = \left( \frac{\partial^2 u_k}{\partial \bar{s} \partial x_j} \right) \left( \frac{\partial \bar{s}}{\partial x_1} \right) + \left( \frac{\partial u_k}{\partial \bar{s}} \right) \left( \frac{\partial^2 \bar{s}}{\partial x_1 \partial x_j} \right).$$

The last term in C-5 is zero since  $\bar{s}$  is a linear function of the  $x_i$ .

C-5 can be written

$$C-6) \quad \frac{\partial^2 u_k}{\partial x_1 \partial x_j} = \left( \frac{\partial^2 u_k}{\partial \bar{s}^2} \right) \left( \frac{\partial \bar{s}}{\partial x_j} \frac{\partial \bar{s}}{\partial x_1} \right),$$

or

$$C-7) \quad \frac{\partial^2 u_k}{\partial x_1 \partial x_j} = \left( \frac{\partial^2 u_k}{\partial \bar{s}^2} \right) (l_j l_1).$$

C-3 becomes

$$C-8) \quad \rho \left( \frac{\partial^2 u_k}{\partial t^2} \right) = C_{ijkl} l_j l_l \left( \frac{\partial^2 u_k}{\partial \bar{s}^2} \right).$$

The elements  $\lambda_{ik}$  of a matrix defined by  $\lambda_{ik} = C_{ijkl} l_j l_l$  are called the Christoffel constants.

If a wavelength character is attributed to the  $u_k$ , i.e.,

$$C-9) \quad u_k = A_k e^{i(\omega t - \bar{k} \cdot \bar{s})}$$

where  $\bar{k}$  is a wave vector along  $\bar{s}$ , then solving C-8 involves finding the eigenvalues of

$$C-10) \quad (\lambda_{ik} - \rho v^2 \sigma_{ik}) u_k = 0$$

where the phase velocity  $v$  is defined as  $v = (\omega/k)$ . Equation C-10 is the Christoffel relation.

The measurements made in this study were on crystals with cubic symmetry and were such that  $\bar{s}$  was either in the [100] or the [110] direction. For the [100] case, C-10 becomes

$$C-11) \quad \begin{bmatrix} C_{11} - \rho v^2 & 0 & 0 \\ 0 & C_{44} - \rho v^2 & 0 \\ 0 & 0 & C_{44} - \rho v^2 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} = 0,$$

where the subscript notation  $23 = 4$ ,  $31 = 5$ ,  $12 = 6$  is used. Equation C-11 has three roots labeled

$$v_1 = \frac{C_{11}}{\rho} \quad \bar{u} \text{ along } [100]$$

$$v_s = \frac{C_{44}}{\rho} \quad \bar{u} \text{ along } [010]$$

$$v_s = \frac{C_{44}}{\rho} \quad \bar{u} \text{ along } [001]$$

The subscripts l and s refer to longitudinal and shear waves, respectively. For the [110] case, C-10 becomes

$$C-12) \begin{bmatrix} \frac{C_{11} + C_{44}}{2} - \rho v^2 & \frac{C_{12} + C_{44}}{2} & 0 \\ \frac{C_{12} + C_{44}}{2} & \frac{C_{11} + C_{44}}{2} - \rho v^2 & 0 \\ 0 & 0 & C_{44} - \rho v^2 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} = 0.$$

The three roots of equation C-12 are

$$\begin{aligned} v_1 &= \frac{C_{11} + C_{12} + 2C_{44}}{2\rho} & \bar{u} \text{ along } [110] \\ v_s(1) &= \frac{C_{44}}{\rho} & \bar{u} \text{ along } [001] \\ v_s(2) &= \frac{C_{11} - C_{12}}{2\rho} & \bar{u} \text{ along } [1\bar{1}0] \end{aligned}$$

These equations show that measurement of three velocities  $v_1$ ,  $v_s(1)$ , and  $v_s(2)$  in the [110] direction yield all three elastic constants of a crystal with cubic symmetry. Generally, measurements along a second direction, often the [100], are made to check consistency of results.

Stiffness constants  $C_{ijkl}$  measured ultrasonically apply to a dynamic situation. That is, adiabatic heat due to strain in the medium because of an elastic wave cannot flow distances on the order of the elastic wavelength. The passage of the wave is too rapid. Thus, in a lossless medium, ultrasonic velocity measurements determine the adiabatic or isentropic stiffness constants  $C_{ijkl}$ . A static measurement yields isothermal stiffness constants.

There are several situations where the distinction is important. Here, only the case of volume change under hydrostatic pressure is considered. The parameter expressing volume change with pressure  $P$  is the bulk modulus  $K$  and is defined as  $K = -V\left(\frac{dP}{dV}\right)$ . The adiabatic bulk modulus is labeled  $K_S$  and the isothermal modulus is labeled  $K_T$ .  $K_S$ , in terms of the dynamic  $C_{ijkl}$ , is

$$C-13) \quad K_S = \left( \frac{C_{11} + 2C_{12}}{3} \right).$$

A total differential of  $P$  is

$$C-14) \quad dP = \left( \frac{\partial P}{\partial V} \right)_T dV + \left( \frac{\partial P}{\partial T} \right)_V dT$$

Thus, the partial derivative of  $P$  with respect to  $V$  at constant entropy  $S$ , is

$$C-15) \quad V \left( \frac{\partial P}{\partial V} \right)_S = V \left( \frac{\partial P}{\partial V} \right)_T + V \left( \frac{\partial P}{\partial T} \right)_V \left( \frac{\partial T}{\partial V} \right)_S$$

where both sides have been multiplied by  $V$ . By definition of  $K$ ,

$$C-16) \quad K_S = K_T - V \left( \frac{\partial P}{\partial T} \right)_V \left( \frac{\partial T}{\partial V} \right)_S$$

Since

$$C-17) \quad \left( \frac{\partial P}{\partial T} \right)_V = - \left( \frac{\partial V}{\partial T} \right)_P \left( \frac{\partial P}{\partial V} \right)_T,$$

and since the definition for volume thermal expansion is  $\alpha = \frac{1}{V} \left( \frac{\partial V}{\partial T} \right)_P$ ,

C-16 becomes

$$C-18) \quad K_S = K_T - K_T \alpha V \left( \frac{\partial T}{\partial V} \right)_S .$$

Similarly,

$$\text{C-19)} \quad \left(\frac{\partial T}{\partial V}\right)_S = \left(\frac{\partial S}{\partial V}\right)_T \left(\frac{\partial T}{\partial S}\right)_V$$

Through use of the Maxwell relation

$$\text{C-20)} \quad \left(\frac{\partial S}{\partial V}\right)_T = \left(\frac{\partial P}{\partial T}\right)_V,$$

C-18 becomes

$$\text{C-21)} \quad K_S = K_T + V K_T^2 \alpha^2 \left(\frac{\partial T}{\partial S}\right)_V.$$

The differential of the internal energy  $U$  is

$$\text{C-22)} \quad dU = Tds - PdV$$

so that

$$\text{C-23)} \quad \left(\frac{\partial U}{\partial T}\right)_V = T \left(\frac{\partial S}{\partial T}\right)_V.$$

Since  $\left(\frac{\partial U}{\partial T}\right)_V$  is the specific heat at constant volume  $C_V$ , equations C-23 and C-21 yield

$$\text{C-24)} \quad K_S = K_T + V \left(\frac{K_T^2 \alpha^2}{C_V}\right)_T,$$

or,

$$K_S = K_T \left[ 1 + T\alpha \left(\frac{VK_T \alpha}{C_V}\right) \right].$$

Equation C-25 is used to calculate  $K_s/K_T$ ; however, the equation is often expressed in terms of Gruneisen's parameter  $\gamma$ . From the text, it is easily shown that  $\gamma = \frac{VK_T}{C_V}$ , therefore,

$$C-26) \quad K_s = K_T (1 + T\alpha\gamma) .$$

There are instances where the elastic compliances  $S_{ijkl}$  are more convenient to use than the elastic stiffnesses  $C_{ijkl}$ . If  $C$  is the stiffness matrix and  $S$  is the compliance matrix,

$$C-27) \quad S = C^{-1} .$$

Details of the element by element calculation are in Nye (1960). The results for materials having cubic symmetry are

$$C-28) \quad S_{11} = \frac{C_{11} + C_{12}}{(C_{11} - C_{12})(C_{11} + 2C_{12})}$$

$$S_{12} = \frac{-C_{12}}{(C_{11} - C_{12})(C_{11} + 2C_{12})}$$

$$S_{44} = \frac{1}{C_{44}}$$

To apply the harmonic theory to the single crystal oxides, the  $v_{p,s}$  must be related to measured ultrasonic velocities and estimates obtained for the thermal energy. If  $f_{p,s}$  is the fraction of the thermal energy in modes  $p$  or  $s$ , at sufficiently high temperatures (above the Debye temperature (Slater, 1939)),  $f_p = f_s = 1/3$ , i.e.,

$$C-29) \quad \gamma = \frac{\gamma_p + 2\gamma_s}{3} .$$

Also, from the Debye theory of specific heat, the vibrational energy at sufficiently low temperatures is proportional to  $(\omega_{\max})^{-1/3}$ . Since  $|\bar{k}|_{\max}$  is independent of mode,

$$(C-30) \quad E_{p,s} \propto \frac{1}{(v_{p,s})^3}$$

and

$$(C-31) \quad E_{\text{vib}} \propto \frac{1}{(v_p)^3} + \frac{1}{(v_s)^3}.$$

Therefore,

$$(C-32) \quad \bar{\gamma} = \frac{\gamma_p + 2\gamma_s \left(\frac{v_p}{v_s}\right)^3}{1 + 2\left(\frac{v_p}{v_s}\right)^3}$$

Experimental temperatures usually lie between the extremes of these assumptions. However, equations (C-29) and (C-32) are effective bounds for  $\bar{\gamma}$ . There is a method based on the Debye theory where the  $f_{p,s}$  could be calculated directly. The complication is usually not warranted.

The  $v_p$  and  $v_s$  may best be obtained from an integration of the solutions to the Christoffel relation. As we have seen, velocity solutions  $v$  for a wave traveling in a direction with cosines  $l_i$  must satisfy

$$(C-33) \quad |C_{ijkl}l_jl_k - \rho v^2\delta_{ik}| = 0.$$

which is a third order determinant in  $v^2$ . For an eigenvector  $l_i$ , the square roots of the three solutions are labeled  $v_p(l_i)$ ,  $v_{s(1)}(l_i)$ , and  $v_{s(2)}(l_i)$ , where subscript  $p$  is attached to the highest velocity. If the average of a value  $v$ , over the three principal directions, is denoted by  $\langle v \rangle$ , then

$$(C-34) \quad v_p = \langle v_p(l_i) \rangle$$

$$v_s = \frac{1}{2} \langle v_{s(1)}(l_i) + v_{s(2)}(l_i) \rangle.$$

An additional assumption implicit in equation C-31 is that the concentration of allowed wave vectors is independent of direction. This is so for crystals having cubic symmetry.

Although the  $v_p$  and  $v_s$  in equation C-34 are the appropriate parameters for the modified quasi-harmonic model, it is probably adequate to consider only the isotropic elastic properties of an aggregate of the single crystals. Hill (1952) has shown that the so called Voigt elastic constants

$$(C-35) \quad K_v = \left(\frac{1}{3}\right)(c_{1111} + 2c_{1122})$$

$$G_v = \left(\frac{1}{5}\right)(c_{1111} - c_{1122} + 3c_{1212})$$

and the Reuss elastic constants

$$(C-36) \quad K_R = \frac{3}{(s_{1111} + 2s_{1122})}$$

$$G_R = \frac{5}{(4s_{1111} - 4s_{1122} + 3s_{1212})}$$

are upper and lower bounds, respectively, for the bulk and shear moduli of a polycrystal. This polycrystal has an isotropic distribution of single crystals with elastic stiffnesses  $C_{ijkl}$  and elastic compliances  $S_{ijkl}$ . Hill suggests that measured elastic constants fall near the averages of the Voigt and Reuss limits. Although there are closer but more complex bounds (Hashin and Shtrikman, 1962), the Hill averages will suffice. The result is

$$(C-37) \quad v_p = \left( \frac{K_H + \frac{4}{3} G_H}{\rho} \right)^{1/2}$$

$$v_s = \left( \frac{G_H}{\rho} \right)^{1/2}$$

Equation C-37 was used to estimate the  $\gamma_{p,s}$  in chapter III.

## APPENDIX D

## CRYSTAL CUTTING AND POLISHING TECHNIQUES

Rough orientations of the magnetite and the spinel crystals were estimated from their morphologies. With the desired faces thus identified, the crystals were embedded in paraffin on a goniometer supplied as part of the Laue X-ray camera. A series of patterns were made with successive adjustments of the goniometer until the desired orientation was achieved to  $\pm 1/2$  degree.

The goniometer was then mounted on the bed of a surface grinder. The faces were ground with a 400 grit wheel and finished with a 600 grit wheel. The crystals were cooled during grinding by a water-rust inhibitor mixture.

The samples were ground with some trepidation since in previous experience with fused quartz and polycrystalline alumina, uneven frictional heating had resulted in cracking of the surfaces. Undoubtedly, the greater care taken grinding the magnetite and spinel crystals was warranted.

After being ground, the samples were mounted in the end of a one-inch inside diameter stainless steel tube, that slid freely, but without wobble, in an aluminum frame. Figure D-1 is a cross section of the apparatus as it sits on a polishing wheel. So that the bottom of the aluminum frame would not be worn by the polishing wheel, three 1/2-inch-diameter alumina (Luca-lox) legs were inset into the frame's base. Although automatic polishing systems were tried, this hand-held aluminum frame and piston worked best.

After mounting the sample in the piston, the crystal faces were polished on a piece of plate glass with  $8\mu$  alumina. Finally,  $1\mu$  alumina was used on a hard silk wheel. Although a slight tendency for the edges to round might have been reduced by a careful matching of the polishing powder

to the crystal, the method as outlined yielded surfaces on the spinel with less undulation than a wavelength of light to within a millimeter of the edges. In the case of magnetite, several flaws in the crystal made polishing the surface to less than a few wavelengths of light impossible. The lower estimates of accuracy of velocity given in the text for magnetite are, in part, a reflection of these surface flaws.

Figure D-1.- Frame for holding sample during polishing. The stainless steel piston floats freely in the cylinder. The polishing force can be varied by changing the length of the piston since the piston's weight is on the surface being polished.

## APPENDIX E

## THE PHASE COMPARISON TECHNIQUE AND ERROR ANALYSIS

There are several reviews of methods for measuring sound velocity, e.g., McSkimin (1964) and Simmons (1965). The phase comparison technique, developed by McSkimin (1953), lends itself to high precision measurements with relatively simple electronics. Figure E-1 is a schematic of the hardware and figure E-2 shows the wave trajectory in the buffer rod and sample. The buffer rod permits removal of the active element, the quartz transducer, from elastic interactions with and the environment of the sample. The equipment built for this study at moderate pressures was to be used in studies at high temperature as well. Above 500° C, a quartz crystal loses its piezoelectric character so that isolation of the transducer from the furnace is essential. The assembly shown in Figure E-2 was inside the pressure vessel.

The buffer and reflecting rods were made of fused quartz obtained from Syncor, Inc. Their cylindrical surfaces were threaded on a cylindrical grinder to reduce surface waves and to scatter side reflections. The end of the buffer rod were polished by the A. D. Jones Optical Co. of Burlington, Massachusetts, to less than a wavelength of sodium light and the ends made parallel to 15 seconds of arc. Aluminum was evaporated onto the blunt end of the rod to form an electrically conducting layer under the quartz transducer. (Previously, evaporated gold had been tried but was found to be less durable.) The 1/2-inch-diameter quartz transducer was epoxied to the aluminum film. Removal of the transducer simply lifted the film under the transducer. Redeposition of the film is a simple process. Only transducers polished to the fundamental frequency were used. X-cut transducers were used to generate compressional waves and AC-cut to generate shear waves.

In the phase comparison technique, a continuous (cw) burst (shown as a in figure E-2) is sent down the buffer rod so that reflections off the two sample faces interfere. Ultrasonic interferometry is a more descriptive term than phase comparison. The frequency  $f_1$  of the cw is varied until either a maximum (constructive interference) or a minimum (destructive interference) is obtained for the overlap portion of the resulting envelope (wave c and pattern iv in figure E-2). The minimum or null was arbitrarily used. The condition for a null is that the travel time be

$$E-1) \quad \left(n + \frac{1}{2}\right) \frac{1}{f_1} = \frac{2L}{v} + \left(\frac{\phi}{2\pi}\right) \frac{1}{f_1}$$

where  $n$  is an integer,  $L$  is the length of the sample,  $v$  is phase velocity in the sample, and  $\phi$  is the phase lag of reflections or transmissions at seals caused by impedance mismatches and finite seal thicknesses.

$n$  may be found by measuring velocity  $v_{\text{approx}}$  by the pulse travel time method (Birch, 1960) and finding the number of wavelengths at frequency  $f_1$  in the distance

$$E-2) \quad 2L + \left(\frac{\phi}{2\pi} - \frac{1}{2}\right) \frac{v_{\text{approx.}}}{f_1} .$$

This method was used in the case of magnetite.

$n$  may also be obtained by finding the next higher frequency  $f_2$  that results in a null. The condition for this is

$$E-3) \quad \left(n + 1 + \frac{1}{2}\right) \frac{1}{f_2} = \frac{2L}{v} + \left(\frac{\phi_2}{2\pi}\right) \frac{1}{f_2} .$$

For the first approximation the travel times are assumed to be independent of frequency. Thus,

$$E-4) \quad \left(n + 1 + \frac{1}{2}\right) \frac{1}{f_2} = \left(n + \frac{1}{2}\right) \frac{1}{f_1}$$

or,

$$E-5) \quad n = \frac{1}{2} + \frac{1}{\left(\frac{f_2}{f_1} - 1\right)}$$

The electronics system, similar to that used by McSkimin (1953), Verma (1960), and others is shown in figure E-3. The low drift (less than 0.005% over 10 minutes) 606A signal generator supplied a continuous RF sine wave variable over the desired 5- to 20-MHz range. Frequency was measured with a digital counter to seven significant figures. The signal was amplified and gated by an Arenberg PG-650C. A wide band amplifier was used between the source and the gated amplifier for isolation and to drive the gated amplifier to its design limit of about 100 volts peak-to-peak into 50 ohms for small duty cycles. The internal gate of the PG-650C was set for about 80 bursts per second. Pulse lengths were varied between 3 and 10  $\mu$ sec. The electrical signal passed through a discriminator to the quartz transducer. This discriminator behaved electrically (fig. E-4(a)) to reduce the escape of low level ringing in the tank circuit of the gated amplifier and present a high impedance to the low level signals coming from the transducer. The network between B and C (fig. E-4(b)) limited the voltages seen at input of the preamplifier PA-620-SN. This preamplifier had an adjustable bandwidth which was set at 1.3 MHz. Maximum gain of the preamplifier and the amplifier, WA-600-E, was 120 dB. This gain was never needed. The usual setting

was at about 90 dB. The preamp was necessary more for its filter characteristics than for gain. The signal was rectified in the last stages of the WA-600-E and displayed on the Tektronix 585A oscilloscope.

#### EVALUATION OF PHASE ANGLE

The seals,  $s(1)$  and  $s(2)$ , form a mechanical link between the buffer rod and sample. To avoid many of the seal problems normally incurred, the assembly was mechanically loaded. A force of 15 lb was applied between the quartz transducer and the fused quartz reflecting rod. With nothing between the buffer rod and sample, submicroscopic variations in surfaces were still sufficient to eliminate sound transmission. Gold foil only 0.00005 inch thick inserted between the buffer rod and sample as well as between the sample and reflecting rod permitted the 20 MHz compressional waves to pass. The malleability of gold allowed it to absorb irregularities in the surfaces. Copper also worked but could not be obtained sufficiently thin. Platinum made a poor seal.

For shear wave transmission more adhesion was needed between the buffer rod and sample. Because petroleum ether, the pressure medium, dissolves the resins or vacuum greases that have previously been used, a new type seal was developed. Clear Seal, a silicone rubber made by GE, worked quite well.

$\phi$  is written

$$E-6) \quad \phi = \phi \begin{pmatrix} a \\ c \end{pmatrix} + \phi \begin{pmatrix} c \\ d \end{pmatrix} + \phi \begin{pmatrix} d \\ e \end{pmatrix} - \phi \begin{pmatrix} a \\ b \end{pmatrix}$$

where  $\phi \begin{pmatrix} i \\ j \end{pmatrix}$  is the phase lag between the elastic waves  $i$  and  $j$  in figure E-2. Mathematical expressions in terms of the thickness of the seal and the mechanical impedances of the buffer rod, seal, and sample can be assigned each  $\phi \begin{pmatrix} i \\ j \end{pmatrix}$  (appendix B). The thickness of the gold foil is

supplied by the manufacturer and the mechanical impedance of gold is about  $62.5 \times 10^5 \text{ g/sec-cm}^2$ . Changes with pressure were ignored.

In the case of shear wave seals, neither the seal thickness nor the mechanical impedance of the Clear Seal were known. A special plug (fig. E-5) for the pressure vessel was fabricated and the amplitude of a wave reflected off the end of the plug was noted before and after coating it with a thick layer of Clear Seal. This amplitude was recorded as a function of pressure to 10 kilobars. If  $R$  is the ratio of reflected to transmitted wave amplitudes, then the mechanical impedance,  $z_o$ , of the Clear Seal is

$$\text{E-7)} \quad z_o = z_p \left( \frac{1 - R}{1 + R} \right)$$

where  $z_p$  is the shear wave mechanical impedances of the steel plug. The results of these measurements are shown in figure E-6. For the pressure range of 1 to 10 kilobars, the shear wave mechanical impedance of the Clear Seal is approximately

$$\text{E-8)} \quad z_o = [1.45 - 0.11P(\text{kb})] \times 10^5 \text{ g/sec-cm}^2.$$

In addition to mechanical impedance, the thickness of the Clear Seal bond is needed. Or, as shown in appendix B, the quantity  $\tan k_o \Delta$  is needed rather than the thickness.  $k_o$  is the wave vector in the seal and  $\Delta$  is the seal thickness.  $(k_o \Delta)$  is obtained from the ratio of amplitudes

of reflected waves off seals s(1) and s(2) (fig. E-2). Using the equations in appendix B, one obtains

$$E-9) \quad \sin^2 k_o \Delta = \left[ \frac{4z_b z_s \left( \frac{A_b}{A_e} \right) - (z_b + z_s)^2}{\left( \frac{z_b z_s}{z_o} + z_o \right)^2 - (z_b + z_s)^2} \right]$$

where  $z_b$ ,  $z_s$ , and  $z_o$  are the mechanical impedances of the buffer rod, sample, and seals, respectively, and  $\left( \frac{A_b}{A_e} \right)$  is the ratio of amplitudes of reflected waves b and e. Values for seal thicknesses of the Clear Seal bond were around 0.00004 inch at 10 kilobars. Although  $z_o$  was corrected for pressure,  $k_o \Delta$  was not. The value at 10 kilobars was used throughout. This resulted in a large uncertainty for shear wave studies of  $\pm 20\%$  in  $k_o \Delta$ .

## ERROR ANALYSIS

Equation E-1 recast as

$$E-10) \quad v = \frac{2Lf}{\left(n + \frac{1}{2} - \frac{\phi}{2}\right)}$$

lends itself to error analysis. That is,

$$E-11) \quad \frac{\delta v}{v} = \pm \frac{\delta L}{L} + \frac{\delta f}{f} + \frac{v}{2Lf} \left(\frac{\phi}{2\pi}\right).$$

The precision micrometer allows a  $\delta L$  of  $\pm 5 \times 10^{-5}$  cm. For magnetite ( $f = 5 \times 10^6$ /sec),  $\Delta f$  could be found to  $\pm 200 \text{ sec}^{-1}$ .  $\frac{\delta f}{f} = \frac{v}{2Lf} \left(\frac{h}{360}\right)$  where  $h$  is the uncertainty in degrees of picking a minimum. For  $v_p$  (110) of magnetite  $2L = 2.7$  cm,  $v = 7.4 \times 10^5$  cm/sec. This results in a  $\frac{\delta f}{f}$  of  $10^{-3}h$ , or  $h \approx y$ . The sensitivity of  $\pm 200 \text{ sec}^{-1}$  in  $f$  yields a precision of 4 parts in  $10^4$ . Since the magnetite data was extrapolated to room pressure, this should be doubled to  $\pm 8$  parts in  $10^4$ . An additional limit of accuracy lies in  $\phi$ . From appendix B, the terms in equation E-6 are

$$E-12) \quad \begin{aligned} \phi \left( \begin{matrix} a \\ c \end{matrix} \right) &= \phi \left( \begin{matrix} d \\ e \end{matrix} \right) = \tan^{-1} \left[ \frac{\left( z_b z_s + z_o^2 \right)}{\left( z_o z_b + z_o z_s \right)} \tan k_o \Delta \right] \\ \phi \left( \begin{matrix} c \\ d \end{matrix} \right) &= \tan^{-1} \left[ \frac{2 \left( z_o z_s z_b^2 - z_o^3 z_s \right) \tan k_o \Delta}{\left( z_o^2 z_s^2 - z_o^2 z_b^2 \right) + z_s^2 z_b^2 - z_o^4} \tan^2 k_o \Delta \right] \\ \phi \left( \begin{matrix} a \\ b \end{matrix} \right) &= \tan^{-1} \left[ \frac{2 z_o z_b z_s^2 - z_o^3 z_b \tan^2 k_o \Delta}{\left( z_o^2 z_b^2 - z_o^2 z_s^2 \right) + \left( z_b^2 z_s^2 - z_o^4 \right) \tan^2 k_o \Delta} \right] \end{aligned}$$

where, again, o, b, and s refer to the seal, buffer rod, and sample, respectively. Roughly,  $z_s = z_b$  so that  $\phi\left(\frac{c}{d}\right) = \phi\left(\frac{a}{b}\right)$ . Therefore,

$$\text{E-13)} \quad \phi \approx 2\phi\left(\frac{a}{c}\right).$$

Since  $k_o \Delta$  is much less than  $2\pi$ ,

$$\text{E-14)} \quad \phi \approx 2 \left( \frac{z_b z_s + z_o^2}{z_b z_o + z_o z_s} \right) k_o \Delta.$$

For  $z_b \approx z_s$ ,

$$\text{E-15)} \quad \left( \frac{\phi}{2\pi} \right) \approx \left( \frac{z_s}{z_o} + \frac{z_o}{z_s} \right) \frac{f}{v_o} \Delta$$

since  $k_o = \frac{2\pi f}{v_o}$ .  $\Delta$  is about  $10^{-4}$  cm and is known to better than  $\pm 20\%$ ,  $z_s$  and  $z_o$  are known to about 1%. Therefore,

$$\text{E-16)} \quad \delta \left( \frac{\phi}{2\pi} \right) = 10^{-5} \left( \frac{z_s}{z_o} + \frac{z_o}{z_s} \right) \frac{f}{v_o}.$$

The total error, equation E-11, is

$$\text{E-17)} \quad \frac{\delta v}{v} = \pm \left( \frac{5 \times 10^{-5}}{L} + 4 \times 10^{-4} + \frac{10^{-5}}{L} \left( \frac{v}{v_o} \right) \left( \frac{z_s}{z_o} + \frac{z_o}{z_s} \right) \right).$$

or,

$$\text{E-18)} \quad \frac{\delta v}{v} \approx \pm \left( 4 \times 10^{-5} + 4 \times 10^{-4} + 6 \times 10^{-5} \right),$$

or about 5 parts in  $10^4$ . Doubling this because of the extrapolation yields 1 part in  $10^3$  accuracy in velocity for the magnetite.

The error in the pressure derivative of velocity is

$$E-19) \quad \frac{\delta \left( \frac{\partial v}{\partial P} \right)}{\left( \frac{\partial v}{\partial P} \right)} = \pm \left( 2 \left( \frac{\delta v}{v} \right) + 0.005 \right).$$

0.005 reflects the uncertainty in pressure  $\frac{\delta P}{P}$ . The  $2 \left( \frac{\delta v}{v} \right)$  is 0.001 from equation E-18 so that  $\frac{\delta \left( \frac{\partial v}{\partial P} \right)}{\left( \frac{\partial v}{\partial P} \right)}$  for magnetite was  $\pm 0.006$ .

The uncertainties in velocities for the single-crystal spinel and the polycrystalline cadmium oxide were  $\pm 0.03\%$  (Chap. III). In their cases

$\frac{\delta \left( \frac{\partial v}{\partial P} \right)}{\left( \frac{\partial v}{\partial P} \right)}$  was  $\pm 0.005$ . The temperatures were accurate to  $\pm 0.1^\circ$  C yielding an inaccuracy in the temperature derivatives of 0.004. Often, the inaccuracies in the temperature derivatives were controlled by scatter in the data. The uncertainties listed in chapter III reflect both factors.

The data on magnetite was reduced on the Univac 1108 at NASA's Manned Spacecraft Center. The programs were written in FORTRAN V and are included in Appendix F.

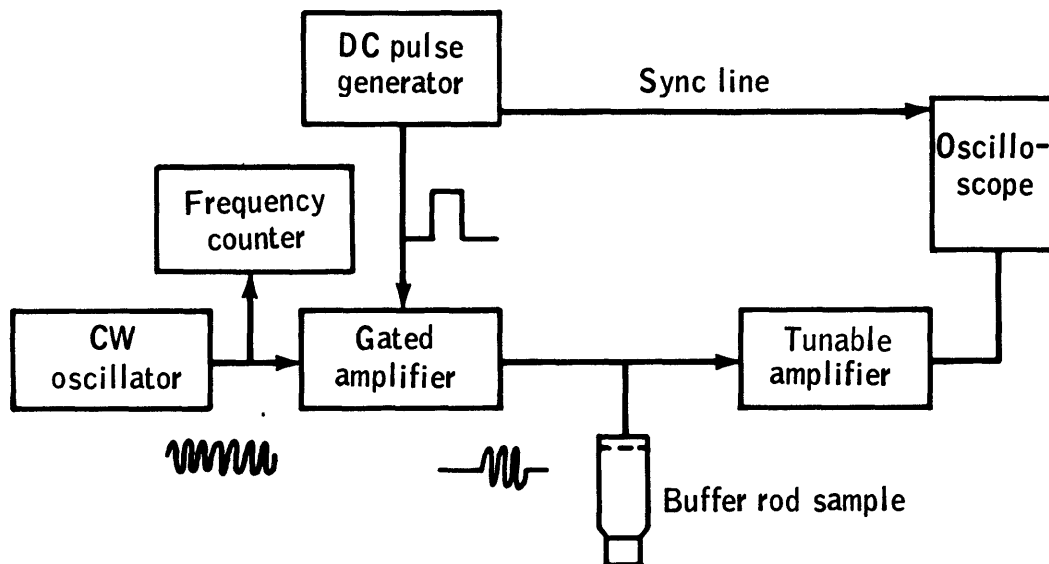

Figure E-1.- Circuit for the measurement of ultrasonic velocity.  
Adapted from McSkimin (1964).

Figure E-2.- Diagram of the buffer rod and sample assembly and a schematic of the traveling elastic waves. Multiple reflections are ignored in the drawing for conceptual simplicity. Note that everything shown in the assembly is inside the pressure vessel.

Figure E-3.- Block diagram of the electronics used.

Figure E-4.- Idealizations of the two electrical networks in figure III-3;  $v$  and  $i$  are the voltage and current between points A and B;  $V_B$  and  $V_C$  are voltages with respect to ground at points B and C.

ZB = impedance of buffer rod

ZO = impedance of seal

DEAL = thickness of seal in cm.

KAPPA = bulk modulus of specimen, in kb.

RHOS = density of specimen

LEN = length of specimen

FO NE, FTWO = adjacent frequencies for null

PHIP = phase lag ( $\phi/2\pi$ )

WNUM =  $(n+1/2)$  as in equation III-1

PNUM = associate with P

P(L) = conversion PNUM to P

VZERO = velocity if  $\phi = 0$

VPHIP = velocity

The last two lines refer to a least squares fit to a binomial in P

## APPENDIX G

## ELASTICITY DATA OF THE POROUS GLASS SAMPLES

Included here are the data obtained on the porous glass samples. Pressure  $P$  is in bars, sample length  $L$  is in centimeters, and the reciprocal of travel time  $F_{p,s}$  is in  $\text{sec}^{-1}$ . (The subscripts  $p$  or  $s$  refer to compressional or shear wave, respectively.)

Sample F,  $L = 1.3160$

## BIOGRAPHICAL NOTE

Anthony Wayne England was born May 15, 1942, in Indianapolis, Indiana. He graduated from West Fargo High School, West Fargo, North Dakota, in May 1959 and the following September entered The Massachusetts Institute of Technology. He was accepted into the Five Year Honors Program in Geology and Geophysics and received the Bachelor of Science and Master of Science degrees simultaneously in February 1965.

His field experience includes a summer of geological mapping in Montana, a summer of exploration seismology in the Southwest United States with Texaco, a summer measuring heat flow in the South and Central United States, and a month assisting in the deployment of a magnetic array in Montana. He is presently involved with pilot and space systems training as a scientist astronaut with NASA.

He has published:

Walsh, J. B., W. F. Brace, and A. W. England, Effect of porosity on compressibility of glass, J. Am. Ceram. Soc., 48, 605, 1965.

England, A. W., Gene Simmons, and D. Strangway, Lunar electrical conductivity, J. Geophys. Res., 1968.
