Abstract—This paper describes the design of unified active safety framework that combines trajectory planning, threat assessment, and semi-autonomous control of passenger vehicles into a single constrained-optimal-control-based system. This framework allows for multiple actuation modes, diverse trajectory-planning objectives, and varying levels of autonomy. The vehicle navigation problem is formulated as a constrained optimal control problem with constraints bounding a navigable region of the road surface. A model predictive controller iteratively plans the best-case vehicle trajectory through this constrained corridor. The framework then uses this trajectory to assess the threat posed to the vehicle and intervenes in proportion to this threat. This approach minimizes controller intervention while ensuring that the vehicle does not depart from a navigable corridor of travel. Simulated results are presented here to demonstrate the framework's ability to incorporate multiple threat thresholds and configurable intervention laws while sharing control with a human driver.

Keywords—Semi-autonomous control, shared adaptive control, threat assessment, hazard avoidance, active safety, vehicle safety, vehicle autonomy, model predictive control, MPC, lane keeping, mobile robotics, human-machine interaction

I. INTRODUCTION

Recent traffic safety reports from the National Highway Traffic and Safety Administration show that in 2007 alone, over 41,000 people were killed and another 2.5 million injured in motor vehicle accidents in the United States [1]. The longstanding presence of passive safety systems in motor vehicles, combined with the ever-increasing influence of active systems, has contributed to a decline in these numbers from previous years. Still, the need for improved collision avoidance technologies remains significant.

Recent developments in onboard sensing, lane detection, obstacle recognition, and drive-by-wire capabilities have facilitated active safety systems that share steering and/or braking control with the driver [2,3]. These active safety systems operating with a “human in the loop” generally attempt to honor driver intentions, opposing them only when doing otherwise would lead to a potential collision or loss of control. This requires sensor systems that detect and identify potential objects in the host vehicle's path, then quantify the threat those objects pose to the host vehicle.

Among existing proposals for semi-autonomous vehicle navigation, lane-keeping systems using audible warnings [4], haptic alerts [5], steering torque overlays [6], and various combinations of these have been developed with mixed results [7]. In a recent subproject of the European PREVENT consortium, a lane-keeping system was designed to prevent lane departure by perceiving the environment, making heuristic-based trajectory planning decisions based on perceived threat, and implementing warning mechanisms or slight steering torque overlay when the vehicle drifts from the desired trajectory [8].

Many of the navigation systems developed in previous work address only one piece of the active safety problem. While some use planning algorithms such as rapidly-exploring random trees [3], evolutionary programming [9] or potential fields analysis [10] to plan a safe vehicle path, others simply begin with this path presumed [11]. The threat posed by a particular path is seldom assessed by the controller itself and is often only estimated by a simple threat metric such as lateral vehicle acceleration required to track the path [12]. Finally, hazard avoidance is commonly performed using one or more actuation methods (steering, differential braking, etc.) without explicitly accounting for the effect of driver inputs on the vehicle trajectory [8]. Such controllers selectively replace (rather than assist) the driver in performing the driving task.

Yu addressed this problem in mobility aids for the elderly by designing an adaptive shared controller which allocates control authority between the human user and a controller in proportion to the user's performance [13]. These metrics and the associated intervention are designed to act on current and past user performance, however, and do not anticipate future states or performance. This reactive approach to semi-autonomy, while sufficient to control low-speed mobility aids, is not well suited for higher-speed applications with significant inertia effects and no pre-planned trajectory.

In this paper, a framework for passenger vehicle active safety is developed that performs vehicle trajectory planning, threat assessment, and hazard avoidance in a unified manner. This framework leverages the predictive and constraint-handling capabilities of Model Predictive Control (MPC) to plan trajectories through a pre-selected corridor, assess the threat this path poses to the vehicle, and regulate driver and controller inputs to keep that threat below a given threshold.

A. Current Work

In this paper, a framework for passenger vehicle active safety is developed that performs vehicle trajectory planning, threat assessment, and hazard avoidance in a unified manner. This framework leverages the predictive and constraint-handling capabilities of MPC to plan trajectories through a pre-selected corridor, assess the threat this path poses to the vehicle, and regulate driver and controller inputs to maintain the threat below a given threshold.

Section II describes the semi-autonomous control framework and its associated trajectory prediction, control law, threat assessment, and intervention law. Section III discusses simulation setup and results. The paper then closes with general conclusions in Section V.

II. FRAMEWORK DESCRIPTION

The framework described below leverages the predictive- and constraint-handling capabilities of MPC to perform trajectory planning, threat assessment, and hazard avoidance. First, an objective function is established to capture desirable performance characteristics of a safe or “optimal” vehicle path. Boundaries tracing the edges of the drivable road surface are assumed to have been derived from forward-looking sensor data and a higher-level corridor planner. These boundaries establish constraints on the vehicle’s projected position. This constraint data, together with a model of the vehicle dynamics is then used to calculate an optimal sequence of inputs and the associated vehicle trajectory. The predicted trajectory is assumed to be a “best-case” scenario and used to establish the minimum threat posed to the vehicle given its current state and a series of best-case inputs. This threat is then used to calculate the intervention required to prevent departure from the navigable corridor and driver/controller inputs are scaled accordingly. Fig. 1 shows a block diagram of this system.

Figure 1. Diagram of an active safety system

A. Assumptions

In this paper it is assumed that road lane data is available and that road hazards have been detected, located, and mapped into a 2-dimensional navigable corridor of travel. Existing systems and previous work in onboard sensing and sensor fusion justify this as a reasonable assumption [14]. Radar, LIDAR, and vision-based lane-recognition systems [3,15], along with various sensor fusion approaches [16] have been proposed to provide the lane, position, and environmental information needed by this framework.

Additionally, where multiple corridor options exist (such as cases where the roadway branches or the vehicle must circumnavigate an obstacle in the center of the lane), it is

assumed that a high-level path planner has selected a single corridor through which the vehicle should travel.

B. Vehicle Path Planner

The best-case (or baseline) path through a given region of the state space is established by a MPC controller. As described in later sections, metrics from this predicted path are used to assess the threat posed to the vehicle.

Model Predictive Control is a finite-horizon optimal control scheme that iteratively minimizes a performance objective defined for a forward-simulated plant model subject to performance and input constraints. Stated another way, MPC uses a model of the plant to predict future vehicle state evolution and optimize a set of inputs such that this prediction satisfies constraints and minimizes a user-defined objective function. At each time step, t , the current plant state is sampled and a cost-minimizing control sequence spanning from time t to the end of a control horizon of n sampling intervals, $t+n\Delta t$, is computed subject to inequality constraints. The first element in this input sequence is implemented at the current time and the process is repeated at subsequent time steps. The basic MPC problem setup is described in [17].

1) Vehicle Dynamic Model

The vehicle model used by the controller accounts for the kinematics of a 4-wheeled vehicle, along with its lateral and yaw dynamics. Vehicle states include the position of its center of gravity $[x, y]$, the vehicle yaw angle ψ , yaw rate $\dot{\psi}$, and sideslip angle β , as illustrated in Fig. 2. Table 1 defines and quantifies this model’s parameters.

Figure 2. Vehicle model used in MPC controller

TABLE I. VEHICLE MODEL PARAMETERS

Symbol	Description	Value [units]
m	Total vehicle mass	2050 [kg]
I_z	Yaw moment of inertia	3344 [kg m ²]
x_f	C.g. distance to front wheels	1.43 [m]
x_r	C.g. distance to rear wheels	1.47 [m]
y_w	Track width	1.44 [m]
C_f	Front cornering stiffness	1433 [N/deg]
C_r	Rear cornering stiffness	1433 [N/deg]
μ	Surface friction coefficient	1

Tire compliance is included in the model by approximating lateral tire force (F_y) as the product of wheel cornering stiffness (C) and wheel sideslip (α or β) as in

$$F_y = C\alpha. \quad (1)$$

Linearized about a constant speed and assuming small slip angles, the equations of motion for this model are (where δ represents the steering angle input),

$$\dot{x} = V \quad (2)$$

$$\dot{y} = V(\psi + \beta) \quad (3)$$

$$\dot{\beta} = \frac{-(C_r + C_f)}{mV} \beta + \left(\frac{C_r x_r - C_f x_f}{mV^2} - 1 \right) \dot{\psi} + \frac{C_f}{mV} \delta \quad (4)$$

$$\dot{\psi} = \frac{(C_r x_r - C_f x_f)}{I_{zz}} \beta - \frac{(C_r x_r^2 + C_f x_f^2)}{I_{zz} V} \dot{\psi} + \frac{C_f x_f}{I_{zz}} \delta \quad (5)$$

where C_f and C_r represent the cornering stiffness of the lumped front wheels and the lumped rear wheels, and x_f and x_r are the longitudinal distances from the c.g. of the front and rear wheels, respectively.

2) Constraint Setup

This framework assumes that the environment has been delineated previously (see II. A. above). The boundaries of the navigable road surface at each timestep are then described by the constraint vectors

$$\begin{aligned} \mathbf{y}^y_{\max}(k) &= [y^y_{\max}(k+1) \ \cdots \ y^y_{\max}(k+p)]^T \\ \mathbf{y}^y_{\min}(k) &= [y^y_{\min}(k+1) \ \cdots \ y^y_{\min}(k+p)]^T \end{aligned} \quad (6)$$

In (6), \mathbf{y}^y_{\max} and \mathbf{y}^y_{\min} represent the upper and lower limits on the vehicle lateral position (y) and must satisfy

$$\mathbf{y}^y_{\max} - \mathbf{y}^y_{\min} > \mathbf{0} \quad (7)$$

in order for the constraint space to remain feasible.

By enforcing vehicle position constraints at the boundaries of the navigable region of the road surface (i.e. the lane edges on an unobstructed road), the controller forces the MPC-generated path to remain within the constraint-bounded corridor whenever dynamically feasible. Coupling this lateral position constraint with input constraints $\mathbf{u}_{\min/\max}$, input rate constraints $\Delta \mathbf{u}_{\min/\max}$, and vehicle dynamic considerations, the navigable operating corridor delineated by \mathbf{y}^y_{\max} and \mathbf{y}^y_{\min} translates to a safe operating region within the state space.

3) Objective Function Description

The controller's projected path through this constraint-imposed region is shaped by the performance objectives established in the MPC cost function. While many options exist for characterizing desirable vehicle trajectories, here, the total sideslip angle at the front wheels (α) was chosen as the trajectory characteristic to be minimized in the objective function. This choice was motivated by the strong influence front wheel sideslip has on the controllability of front-wheel-steered vehicles since cornering friction begins to decrease above critical slip angles. In [18] it is shown that limiting tire slip angle to avoid this strongly nonlinear (and possibly unstable) region of the tire force curve can significantly

enhance vehicle stability and performance. Further, the linearized tire compliance model described here does not account for this decrease, motivating the suppression of front wheel slip angles to reduce controller-plant model mismatch. Finally, trajectories that minimize wheel slip also tend to minimize lateral acceleration and yaw rates, leading to a safer and more comfortable ride.

The MPC objective function with weighting matrices $R_{(\cdot)}$ then takes the form

$$\begin{aligned} J_k &= \sum_{i=k+1}^{k+p} \frac{1}{2} \alpha_i^T R_\alpha \alpha_i + \sum_{i=k}^{k+p-1} \frac{1}{2} \delta_i^T R_\delta \delta_i \\ &\quad + \sum_{i=k}^{k+p-1} \frac{1}{2} \Delta \delta_i^T R_{\Delta \delta} \Delta \delta_i + \frac{1}{2} \rho_\varepsilon \varepsilon^2 \end{aligned} \quad (8)$$

where ε represents constraint violation and was included to soften select position constraints.

In summary, the MPC controller uses vehicle position, input magnitude, and input rate constraints to satisfy safety requirements, while minimizing front wheel slip to maximize controllability.

C. Threat Assessment

The vehicle path calculated by the MPC controller is assumed to be the best-case or safest path through the environment. As such, key metrics from this prediction are used to assess instantaneous threat posed to the vehicle. By setting constraint violation weights (ρ_ε) significantly higher than the competing minimization weight (R_α) on front wheel sideslip, a hierarchy of objectives can be created in order to force the optimal solutions to satisfy corridor constraints before minimizing front wheel sideslip. When constraints are not active, as illustrated by the gray vehicle in Fig. 3, front wheel sideslip – and the corresponding controllability threat – is minimized. When the solution is constrained, predicted front wheel sideslip increases with the severity of the maneuver required to remain within the navigable corridor.

The dark vehicle in Fig. 3 illustrates how the MPC-predicted optimal vehicle trajectory might appear as the tire slip angles and corresponding threat increase in the presence of an active constraint. As predicted sideslip approaches tire-cornering-friction-imposed limits, the threat of leaving the navigable corridor increases.

Figure 3. Obstacle avoidance scenario showing MPC trajectory plans with varying levels of required front wheel sideslip

Various approaches are available to reduce the vector α to a scalar threat metric Φ . In this work,

$$\Phi(k) = \max(\alpha_{k+1} \quad \alpha_{k+2} \quad \dots \quad \alpha_{k+p}) \quad (9)$$

was chosen for its good empirical performance (described in the next section).

D. Hazard Avoidance

Given a best-case vehicle path through the environment and a corresponding threat, desired inputs from the driver and controller are blended and applied to the vehicle. This blending is performed based on the threat assessment: a low predicted threat causes more of the driver's input and less of the controller's input to be applied to the vehicle, while high threat allows controller input to dominate that of the driver. This "scaled intervention" may thereby allow for a smooth transition in control authority from driver to controller as threat increases.

Denoting the current driver input by u_{dr} and the current controller input by u_{MPC} , the blended input seen by the vehicle, u_v , is defined as

$$u_v = K(\Phi)u_{MPC} + (1 - K(\Phi))u_{dr} \quad (10)$$

The intervention function K is used to translate predicted vehicle threat (Φ) into a scalar blending gain. This function is bounded by 0 and 1 and may be linear, piecewise-linear, or smooth as in

$$K = \begin{cases} 0 & 0 \leq \Phi \leq \Phi_{eng} \\ f(\Phi) & \Phi_{eng} < \Phi < \Phi_{aut} \\ 1 & \Phi_{aut} \leq \Phi \end{cases} \quad (11)$$

Where linear and piecewise-linear forms may be described by

$$f(\Phi) = \frac{\Phi_{aut} - \Phi}{\Phi_{aut} - \Phi_{eng}} \quad (12)$$

In (12), the shape of K is described by the threat level at which the semi-autonomous controller engages (Φ_{eng}) and the level at which it is given full control authority and effectively acts as an autonomous controller (Φ_{aut}). Fig. 4 illustrates this intervention function for various $f(\Phi)$.

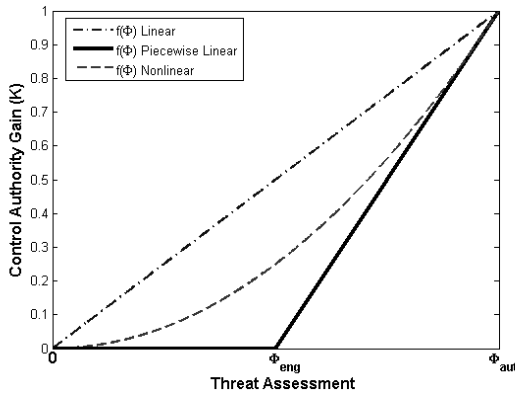

Figure 4. Intervention laws used to translate threat assessments into controller blending gains

Using predicted threat (Φ) as calculated in (9) with an appropriate cost function formulation of the form (8) ensures that 1) the threat metric regulating controller intervention is minimized in the path plan (and associated control calculation) and 2) the controller maintains complete control authority when constraints are binding.

Increasing Φ_{eng} widens the "low threat" band in which the driver's inputs are unaffected by the controller. While this provides greater driver freedom for low-threat situations, this freedom comes at the cost of increasing the rate of controller intervention when Φ_{eng} is exceeded.

Increasing the value of Φ_{aut} , on the other hand, delays complete controller intervention until more severe maneuvers are predicted. The friction-limited bounds on the linear region of the tire force curve (1) suggest a natural upper limit of $\Phi \leq 5$ degrees on surfaces with a friction coefficient of 1.0 in order to ensure that by the time the predicted maneuver required to remain within the safe region of the state space reaches this level of severity, the controller has full control authority and can – unless unforeseen constraints dictate otherwise – guide the vehicle to safety. The effect of varying threat thresholds on controller performance is discussed in the results below.

In some scenarios, driver input may differ significantly from controller input. Such cases can lead to abrupt adjustments to steering inputs as K increases. These abrupt changes may saturate steering rate constraints (which are limited by the available steering actuators) and may be uncomfortable and/or unnerving to the human driver. To account for differences between driver and controller input, K may be augmented by an additional term to increase controller intervention in proportion to the driver's deviation from the best-case input. This augmentation can be described by

$$K_{aug}(\Phi, u_{MPC}, u_{dr}) = f(\Phi) + (1 - f(\Phi)) \left(1 - e^{-\frac{|u_{MPC} - u_{dr}|}{\Delta u_{max}}} \right) \quad (13)$$

where Δu_{max} represents the maximum difference between driver and controller inputs.

III. SIMULATION RESULTS

A. Setup

Controller performance was simulated using a vehicle plant model provided by researchers at Ford (similar to the one described in [19]). This model uses a Pacejka tire model to describe longitudinal and cornering forces as a function of normal force, tire slip angle, surface friction, and longitudinal slip.

The vehicle model described by (2-5), with the parameters given in Table 1 was used in the receding horizon controller. Controller parameters are defined and quantified in Table 2. Vehicle velocity was 20 meters per second.

TABLE II. CONTROLLER PARAMETERS USED IN SIMULATOIN

Symbol	Description	Value [units]
p	Prediction horizon	35, 40
n	Control horizon	18, 20
$R_y^{(a)}$	Weight on front wheel slip	0.2657
R_u	Weight on steering input	0.01
$R_{\Delta u}$	Weight on steering input rate (Δ per Δt)	0.01
$u_{min/max}$	Constraints on steering input	± 10 [deg]
Δu_{min}	Constraints on steering input rate ($/\Delta t$)	± 0.75 [deg]
Δu_{max}		(15 deg/s)
y_{min}^y	Lateral position constraints	Scenario - dependent
y_{max}^y		
ρ_c	Weight on constraint violation	1×10^5
V	Variable constraint relaxation on vehicle position	$V(1...p-1) = 1.25$ $V(p) = 0.01$

B. Results

Simulation results were obtained for various maneuvers, driver inputs, objective function configurations, and intervention laws. Results below are shown for double lane change maneuvers with a driver steer input $\delta_{driver} = 0$. This driver behavior was chosen to simulate a drowsy or otherwise inattentive driver.

Semi-autonomous intervention was successfully shown to satisfy safety constraints while allowing significant driver control in low-threat scenarios. Intervention laws with varying threat thresholds for controller engagement (Φ_{eng}) and full autonomy (Φ_{aut}) were shown to satisfy lane constraints while honoring driver inputs whenever possible. Sideslip thresholds Φ_{eng} and Φ_{aut} (in units of degrees) are denoted in figure legends as $[\Phi_{eng} \ \Phi_{aut}]$.

Figure 5. Simulation results showing the effect of varying intervention thresholds ($[\Phi_{eng} \ \Phi_{aut}]$) on corridor-tracking performance

Figure 6. Simulation results showing the effect of varying intervention thresholds ($[\Phi_{eng} \ \Phi_{aut}]$) on corridor-tracking performance

As Fig. 5 and Fig. 6 illustrate, increasing Φ_{eng} delays controller intervention K at the cost of more rapid increases and more frequent saturation of the control authority allotment. This late intervention, while allowing the human driver greater autonomy far away from constraints/hazards, often requires slightly more control authority to regain control of the vehicle if the driver does not make the correction on their own. For example, increasing Φ_{eng} from 0 to 2 deg as shown in Fig. 6 ultimately increased the average intervention metric K over the entire maneuver by 0.9 %. Similar results were observed over the entire range of interest in Φ_{eng} and Φ_{aut} ($0 \leq \Phi_{eng} \leq 2$ and $2.5 \leq \Phi_{aut} \leq 5$), with average intervention K varying by less than 0.09. Fig. 7 shows how $mean(K)$ varies as a function of Φ_{eng} and Φ_{aut} for this maneuver.

Figure 7. Average intervention K for a double lane change maneuver as a function of intervention thresholds Φ_{eng} and Φ_{aut}

These results suggest that over the course of some maneuvers, this framework tends to average out controller intervention for various Φ_{eng} and Φ_{aut} settings, allowing for considerable driver preference tuning without dramatically changing average K .

Fig. 8 shows how augmenting K according to (12) affects the vehicle trajectory and controller intervention.

Figure 8. Simulation results showing the effect of augmenting K based on differences between driver and controller steering input.

Notice that for certain maneuvers, driver inputs, and intervention thresholds Φ_{eng} and Φ_{aut} , augmenting K does not necessarily result in more controller intervention. In the simulation shown above, the opposite is observed owing to the

slightly increased intervention early in the maneuver, which reduced the subsequent intervention at $x \sim 75\text{m}$.

Finally, in each of the above results, this shared-adaptive controller behaves as a stable closed-loop system. While this was also true of all of the other simulated results conducted to date, no rigorous stability proof is presented in this paper as it is a topic of current investigation.

IV. CONCLUSIONS

This paper presented a unified framework based on constrained optimal control that performs trajectory planning, threat assessment, and semi-autonomous control of passenger vehicles. This framework has been simulated and proven capable of satisfying position, input, and dynamic vehicle constraints using multiple threat metrics and intervention laws. Additionally, the framework has been shown in simulation to provide significant autonomy to a human driver, intervening only as necessary to keep the vehicle under control and within the navigable roadway corridor. Simulation results have also shown this control framework to be stable even in the presence of system-inherent time delays, though a rigorous stability proof is a topic of current investigation.

Finally, while human factors have not been studied in depth here, it is expected that with additional investigation, a best-case, or average driver-preferred intervention law may be described and intervention settings tuned accordingly.
