## Elasticity of Some Mantle Crystal Structures

by Herbert Fan Wang

Submitted to the Department of Earth and Planetary Sciences in August, 1971 in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

### Abstract

The elasticity of high-pressure mantle phases may be characterized by crystal chemically similar compounds. Analogue compounds available as single crystals yield the most reliable elastic constant data. The single-crystal elastic constants of pleonaste and hercynite spinel, rutile-structure germanium dioxide, and spessartite-almandine garnet are studied, in most cases as a function of pressure and temperature. High-pressure phases of olivine, silica, and pyroxene occur in the spinel, rutile, and garnet structures, respectively.

The pressure derivative of the shear mode  $(C_{11} - C_{12})/2$  is slightly negative for pleonaste. Small shear moduli pressure derivatives are characteristic of the spinel structure and imply a low kinetic barrier to phase transformations and diffusion. The pleonaste and hercynite elastic constant data determine the compressional and shear velocities as a function of mean atomic weight for the spinel phase of olivine. The compressional velocity data indicate an increase in mean atomic weight in the transition zone while the shear velocity data indicate no increase.

The bulk modulus pressure derivative,  $\partial K/\partial P$ , of rutile-structure germanium dioxide is about 6.2. It is likely that  $\partial K/\partial P$  of stishovite is between 6 and 7. The seismic parameter  $\Phi$  of stishovite is not well-determined at present and its use in a molar averaging scheme to deduce the iron and silicon content of the lower mantle contains inconsistencies. There is no strong evidence for enrichment of either component in the lower mantle.

The elastic constant pressure derivatives of spessartite-almandine garnet are similar to almandine-pyrope. The elastic velocities of garnet-transformed pyroxenes may be estimated from an inverse proportionality relation between the seismic parameter  $\Phi$  and mean atomic weight  $M$ . The velocity change over the pyroxene  $\rightarrow$  garnet transformation is then 20% for compressional waves and 10% for shear waves.

Thesis Supervisor: Gene Simmons

Title: Professor of Geophysics

### Acknowledgments

There would have been no thesis without the single-crystal samples. The pleonaste and hercynite were given to me by Dr. Glen Slack of the General Electric Research and Development Center. The  $\text{GeO}_2$  crystal was given to me by Capt. John Goodrum and C. Dugger of the Air Force Cambridge Research Laboratories. Several people contributed to the experimental work. Dr. A. Reid of the NASA Manned Spacecraft Center did the microprobe analyses of the pleonaste and garnet samples. P. McFarlin measured the lattice parameter of the pleonaste sample. J. Kalnajs and E. Farrell of the MIT Crystal Physics Laboratory taught me how to determine precision hydrostatic densities and how to orient my crystals. Dr. E. Papadakis used his equipment at Panametrics, Inc. to measure the elastic constants of the extremely small hercynite sample. A.W. England and D.H. Chung showed me how to use the ultrasonic equipment. D. Silversmith helped me understand some of the subtleties of the equipment via telephone conversations. My advisor, Gene Simmons, gave encouragement and advice from the beginning of the study through the preparation of the manuscript. I had many discussions with D. Weidner and T. Todd. C. Sande and R. Fitterman did typing and organizational work. I thank my wife, Rosemary, for her patience and understanding over the last couple of years.

The experimental costs of my study were absorbed by NASA Contract NAS9-8102. Money is not without value.

## Introduction

### I. Introduction.

Laboratory ultrasonic experiments on oxides and silicates provide basic data for the interpretation of seismic velocity profiles in the earth's mantle. The mineral phases hypothesized to be stable in the transition zone and lower mantle are usually not available in quantities sufficient for elasticity experiments. Ultrasonic measurements on compounds which are crystal structure analogues to high pressure mineral phases then become important.

#### A. Statement of thesis problem.

I studied the single-crystal elastic constants of pleonaste spinel and hercynite spinel (Chapter II), rutile-structure germanium dioxide (Chapter III), and spessartite-almandine garnet (Chapter IV). Ringwood [1970] reviewed the depths where these structures are expected. The major phases of the upper mantle are olivine and pyroxene. Between 300 and 450 km depth pyroxene transforms into the garnet structure and olivine transforms into the spinel structure. At 650 km olivine and pyroxene are expected to further transform, possibly into an isochemical mixture of oxides. The stable form of  $\text{SiO}_2$  at this depth would be stishovite which has the rutile structure. If  $\text{SiO}_2$  were chemically combined with other oxides, the silicon would probably also be in 6-fold coordination like in stishovite.

## Introduction

The new elastic constant data lead to a consideration of aspects of the following questions: Are negative values of the pressure derivatives of some shear constants related to phase transformation or diffusion kinetics? Is there evidence for iron or silicon enrichment in the lower mantle? Do density - mean atomic weight - velocity relations fit the data for spinel, rutile, and garnet structure compounds? Can the velocities of high-pressure mantle phases be estimated?

### B. Background literature.

Two comprehensive review papers [Birch, 1952; Ringwood, 1970] provide the basic background for understanding my thesis study. Birch [1952] reviewed the application of solid state physics to the elasticity and constitution of the earth's interior. He concluded that phase transitions to close-packed oxides such as periclase, rutile, spinel, or corundum were required to explain the elasticity of the 400 to 1000 km depth region of the mantle. Direct confirmation of the importance of phase transitions was made from high pressure and high temperature phase studies on silicates and their crystal chemical analogues [reviewed by Ringwood, 1970]. Other useful review papers on the constitution of the earth's mantle are Clark and Ringwood [1964], Ringwood [1966], and D.L. Anderson et al. [1971].

## Spinel

### II. Elastic constants of pleonaste and hercynite spinel.

Pleonaste and hercynite are iron-bearing spinels [see Deer et al., 1962, Vol. 5, p.62] whose elastic properties are of interest for two reasons: (1) Iron-bearing spinel is present as a minor phase in the upper mantle and (2) Iron-bearing spinel serves as an analogue to the spinel phase of olivine. This chapter emphasizes the analogue aspect, particularly in considering the shear behavior of pleonaste as a function of pressure and the effect of iron substitution in the spinel structure.

#### A. Sample descriptions.

##### 1. Pleonaste.

The natural pleonaste sample was obtained from Dr. Glen Slack of the General Electric Company. Its location of origin was Queensland, Australia and its surface had a stream-worn appearance before cutting. The pleonaste was black and opaque because of the iron content. The polished faces gave mirror-like reflections and no flaws were visible under 3X magnification.

The microprobe analysis shown in Table II.1 was done by A. Reid of the NASA Manned Spacecraft Center. The weight percentages have been recalculated into the molecular formula  $Mg_{0.75}Fe_{0.36}Al_{1.90}O_4$ , assuming an ideal four oxygens and neglecting the minor elements. If the titanium is  $Ti^{4+}$ , then the iron is all  $Fe^{2+}$  since the total charge balance is

## Spinel

satisfied almost exactly [see also Slack, 1962, p.430].

The pleonaste spinel is essentially  $\text{MgAl}_2\text{O}_4$  with 25% of the  $\text{Mg}^{2+}$  and 5% of the  $\text{Al}^{3+}$  replaced by  $\text{Fe}^{2+}$ .

The hydrostatically determined density of the pleonaste was  $3.817 \text{ g/cm}^3$  [for a description of the method see Smakula and Sils, 1955]. A density of  $3.836 \text{ g/cm}^3$  was calculated from the molecular weight based on the microprobe analysis of Table II.1 and a lattice parameter of  $8.1225 \text{ \AA}$ . An average value of  $3.826 \text{ g/cm}^3$  was used in the determination of the elastic constants.

A mean atomic weight of 21.9 was calculated directly from the formula

$$\bar{M} = (\sum (x_i/m_i))^{-1} \quad (\text{Eqn. II.1})$$

where  $x_i$  = wt. % of oxide

and  $m_i$  = mean atomic weight of oxide.

On the other hand  $\bar{M} = 21.6$  from the approximate chemical formula. There is an excess of cations compared to the number expected for 4 oxygens ( $\sum$  cations = 3.03 versus ideal  $\sum = 3.00$ ).

After X-ray orientation the pleonaste sample appeared as sketched in Fig. II.1. Its weight was 1.234 g, the [100]-path length was 4.933 mm, and the [110]-path length was 6.645 mm.

## Spinel

### 2. Hercynite, $\text{FeAl}_2\text{O}_4$ .

The hercynite sample was also obtained from Dr. Glen Slack of General Electric. The synthetically grown  $\text{FeAl}_2\text{O}_4$  is actually sample R75 described in Slack [1964].  $\text{FeAl}_2\text{O}_4$  is basically a normal spinel ( $\text{Fe}^{2+}$  in tetrahedral sites) but Slack found indications for 15%  $\text{Fe}^{2+}$  in octahedral sites since annealing at  $1200^\circ\text{C}$  introduced some disorder.

The  $\text{FeAl}_2\text{O}_4$  sample came as a rectangular bar about  $4 \times 4 \times 10$  mm with all sides  $\{100\}$ -faces. The end face of the bar was X-ray oriented and the bar was cut in half. The end  $\{100\}$ -faces of one-half of the bar were then polished flat and parallel. A pair of  $45^\circ$  cuts were then made on the remaining half of the bar to obtain  $\{110\}$ -faces. The cuts are shown in Fig. II.2. The  $[100]$ -path length was 4.104 mm and the  $[110]$ -path length was just 1.763 mm.

An X-ray density of  $4.280 \text{ g/cm}^3$  was calculated from a lattice parameter of  $8.140 \text{ \AA}$  [Slack, 1964]. The mean atomic weight  $\bar{M} = 24.8$ .

## Spinel

### B. Experimental method and results.

#### 1. Pleonaste.

The elastic constants of the pleonaste spinel were measured to 5 kb at room temperature (20 °C) by the pulse-echo-overlap technique [Papadakis, 1967; Chung *et al.*, 1969]. The pleonaste was oriented to  $1/2^\circ$  with a Laue back-reflection camera in the [110] and [100]-directions. The two sets of faces were optically polished flat and parallel to  $10^{-4}$  in/in by the A.D. Jones Optical Works of Burlington, Mass.

For compressional wave modes, the travel time was only slightly longer than one microsecond and there was a little difficulty in damping one echo before the next arrived. Also since the {110} and {100}-faces were mutually perpendicular and since there were over fifty echoes in a pulse train, guided-wave mode effects existed, particularly for compressional waves in the [110]-direction at 20 MHz. The measurements in this direction were done at 30 MHz by driving the third overtone of a 10 MHz transducer. The guided-wave effect was reduced enough to select a pair of early, unmodulated echoes. Papadakis [1969] discussed the precautions to be taken in the pulse-echo-overlap method when guided-wave effects are present.

## Spinel

On the basis of pressure runs for modes (Table II.2 and Fig. II.3) yielding  $C_{11}$ ,  $C_S = 1/2 (C_{11} - C_{12})$ ,  $C_{44}$ , and  $C_L = 1/2 (C_{11} + C_{12} + 2C_{44})$ , the  $C_{ij}$  are considered to be accurate to 0.5% and the  $\partial C_{ij}/\partial P$  accurate to 5%. Temperature runs to 100 °C were made for the two shear constants  $C_{44}$  and  $C_S$ . No compressional wave temperature runs were successful due to the short path lengths and bonding difficulties. The  $\partial C_{ij}/\partial T$  are considered to be accurate to 10%.

The raw frequency versus pressure data were fitted by a least squares linear relation from which the derivative of the "effective elastic constant" [Thurston, 1965a] was obtained either by computing the elastic constant  $C_{ij}$  at different pressures and finding the slope, or by differentiating the expression

$$C_{ij} = 4 \rho l^2 f^2 \quad (\text{Eqn. II.2})$$

where  $\rho$  = density

$l$  = path length

$f$  = reciprocal round trip travel time

with respect to pressure and evaluating it at  $P = 0$ . The adiabatic rather than isothermal bulk modulus was used in calculating  $\partial C_{ij}/\partial P$  since the difference does not effect the result within the stated 5% accuracy. Temperature derivatives were obtained by the slope method.

## Spinel

The results of the single crystal measurements are tabulated in Table II.3 and calculated aggregate properties are tabulated in Table II.4. The  $\partial S_{ij}/\partial P$  were calculated from the matrix relation

$$\frac{\partial S}{\partial X} = - S \frac{\partial C}{\partial X} S \quad (\text{Eqn. II.3})$$

[see, for example, Finkbeiner, 1960, Theorem 10.8, p.203]. For the cubic case the  $\partial S_{ij}/\partial P$  may be obtained from direct differentiation of formulas for  $S_{ij}$  in terms of the  $C_{ij}$ . For lower symmetries the matrix multiplication method becomes most convenient [see also Thurston, 1965b]. The alternative would be to compute  $S_{ij} = C_{ij}^{-1}$  as a function of pressure and to obtain  $\partial S_{ij}/\partial P$  by finding the slope. Explicit expressions become quite messy because of the triple matrix product, and in fact the expressions for the orthorhombic case given by Kumazawa and Anderson [1969] are not even dimensionally correct.

The calculated averages are based on the schemes of Voigt [1928], Reuss [1929], Hashin and Shtrikman [1962a, 1962b], and Kröner [1967]. The larger of the Hashin-Shtrikman bounds has been called Hashin and the smaller Shtrikman. The calculated averages for the derivatives are to be considered simply as the derivatives of the zero pressure formulas [see Chung, 1967 for "Voigt" and "Reuss" applications to cubic, hexagonal, trigonal, and tetragonal symmetries] and not

## Spinel

an extension of these averaging methods to third order elastic constants [Barsch, 1968; Hamilton and Parrott, 1968]. No bounds for these derivative averages are implied [for a discussion see Knopoff and Shapiro, 1969].

### 2. Hercynite, $\text{FeAl}_2\text{O}_4$ .

Because of the extremely small size of the  $\text{FeAl}_2\text{O}_4$  sample combined with relatively high velocities, the rf-pulse-echo-overlap method of the previous section could not be used. The rf-pulse had a nominal 0.5  $\mu\text{sec}$  width but in practice it was difficult to resolve echoes separated by less than 1.0  $\mu\text{sec}$ . For the longitudinal mode in the [100]-direction, echoes were separated by about 0.4  $\mu\text{sec}$ .

The velocity measurements were made by E. Papadakis of Panametrics, Inc., Waltham, Mass. by a digital-pulse-echo-overlap method using an assembly containing a highly damped 20 MHz ceramic transducer and fused quartz delay line. The digital pulse width was 25 nsec, which was equivalent to one-half the transducer resonance width. Echoes every 0.4  $\mu\text{sec}$  were then clearly resolved and overlapped (Fig. II.4). Measurements were made for all modes shown in Table II.2. The [110]-direction measurements were more reliable since some phasing effects occurred in the [100]-direction. Cross checks were good to 1% and the  $C_{ij}$  are considered to be accurate to 1%. The single crystal and calculated aggregate values for  $\text{FeAl}_2\text{O}_4$  are given in Table II.5.

## Spinel

### C. Comparison with other experimental and theoretical work.

Current experimental and theoretical interest exists for the elastic constants of spinel structure compounds, and particularly for various stoichiometries of  $\text{MgO}:\text{xAl}_2\text{O}_3$  spinels (Table II.6). Because stoichiometric spinels ( $x = 1.0$ ) are more difficult to grow, only room condition values for the elastic constants [Lewis, 1966] are presently available. However, during the preparation of this chapter O'Connell and Graham [1971] published an abstract on the elastic constants of stoichiometric spinel to 800 °K and 8 kb. Another paper on the pressure dependence of the elastic constants of stoichiometric spinel is in preparation by Chang and Barsch [Chang, personal communication].

Theoretical work on the elasticity of  $\text{MgAl}_2\text{O}_4$  includes a Born model calculation for the pressure dependence of the elastic constants [Sammis, 1970] and an 11-parameter rigid ion model calculation for both acoustic and optic frequency modes as a function of pressure [Striefler and Barsch, 1971 (abstract)]. Also an oxygen framework model [Leibfried, 1955; O.L. Anderson, 1965; Gieske and Barsch, 1968] may be considered for spinels.

## Spinel

## 1. Effect of stoichiometry.

The elastic constants of the stoichiometric  $\text{MgO:1.0Al}_2\text{O}_3$  are 5 to 10% lower than those with excess alumina  $x\text{Al}_2\text{O}_3$  ( $2.6 \leq x \leq 3.5$ ). The elastic constants of the non-stoichiometric spinels agree to 1%.

Suppose the differences between the elastic constants of the stoichiometric and non-stoichiometric spinels are due only to the difference in density. That is, apply a law of corresponding states [O.L. Anderson, 1966] and consider  $\text{MgO:2.6Al}_2\text{O}_3$  ( $\rho = 3.62 \text{ g/cm}^3$ ) to be  $\text{MgO:1.0Al}_2\text{O}_3$  ( $\rho = 3.58 \text{ g/cm}^3$ ) compressed 20.2 kb. Decompressing the  $\text{MgO:2.6Al}_2\text{O}_3$  to  $\rho = 3.58 \text{ g/cm}^3$  gives the following values for the elastic constants compared to those for stoichiometric  $\text{MgO:1.0Al}_2\text{O}_3$ . Schreiber's [1967] values for the pressure derivatives of the elastic constants of  $\text{MgO:2.6Al}_2\text{O}_3$  are used.

"Decompressed"	$\text{MgO:1.0Al}_2\text{O}_3$
$\text{MgO:2.6Al}_2\text{O}_3$	
$K = 1.935 \text{ Mb}$	$K = 1.950 \text{ Mb}$
$C_S = 0.716 \text{ Mb}$	$C_S = 0.630 \text{ Mb}$
$C_{44} = 1.559 \text{ Mb}$	$C_{44} = 1.530 \text{ Mb}$

where  $K =$  bulk modulus

$$\text{and } C_S = 1/2 (C_{11} - C_{12})$$

## Spinel

The bulk modulus  $K$  has been slightly over corrected and the shear moduli  $C_S$  and  $C_{44}$  have been more significantly under corrected. In other words an excess alumina spinel cannot be regarded as a compressed stoichiometric one, particularly for the shear moduli.

The excess  $Al_2O_3$  structure results in additional cation vacancies in order to maintain charge neutrality within the nearly perfect cubic close packed arrangement of the oxygen anions (Fig. II.5). Jagodzinski and Saalfeld [1958] determined the deviation from a cubic close packed oxygen lattice for natural and synthetic spinels of various  $MgO:Al_2O_3$  ratios (Table II.7). The distortion of the cubic close packed oxygen lattice becomes smaller with increasing excess  $Al_2O_3$ . Thus on a crystallographic structure basis the non-stoichiometric spinel is expected to be weaker in bulk modulus because of more cation vacancies, yet stronger in shear because there is less distortion of the oxygen framework than a law of corresponding states with stoichiometric spinel would indicate.

### 2. Born model.

The last line of Table II.6 shows the results of a Born model lattice calculation for the pressure dependence of the elastic constants made by Sammis [1970] who used the method of homogeneous static deformations due to Fuchs [1936]. The

## Spinel

elastic energy density was written as the sum of the electrostatic energy and the repulsive energy. The repulsive term between nearest neighbors was of the form  $\lambda \exp(-r/\rho)$  where  $\lambda$  and  $\rho$  were parameters determined from the bulk modulus and lattice parameter (note that  $\rho$  is not the density here). Sammis claimed consistency was found in determining the four repulsive parameters for the Mg - O and Al - O interactions from the bulk moduli and lattice parameters of MgO,  $\text{Al}_2\text{O}_3$ , and  $\text{MgAl}_2\text{O}_4$ . Two additional adjustable parameters were the shear moduli Madelung constants arising from the electrostatic forces present in a shear static deformation. Their values were chosen to fit the zero pressure moduli.

One feature of Sammis' calculation was that at some pressure greater than 400 kb,  $\partial C_{44}/\partial P$  became negative while evidently  $\partial C_S/\partial P$  remained positive since no mention was made of it. Since  $\partial C_S/\partial P$  is negative for pleonaste while  $\partial C_{44}/\partial P$  is about 0.8 for both pleonaste and  $\text{MgO}:2.6\text{Al}_2\text{O}_3$ , it seems more likely that at high pressure  $\partial C_S/\partial P$  will be negative for  $\text{MgAl}_2\text{O}_4$  rather than  $\partial C_{44}/\partial P$ . Note in Table II.6 that the theoretical  $\partial C_S/\partial P$  is greater than  $\partial C_{44}/\partial P$ , while the inequality is just the other way around for both  $\text{MgO}:2.6\text{Al}_2\text{O}_3$  and pleonaste.  $\partial C_S/\partial P$  will become negative for  $\text{MgAl}_2\text{O}_4$  when  $P \approx 150$  kb on the assumption it becomes negative when  $\text{MgAl}_2\text{O}_4$  is compressed to the density of pleonaste.

## Spinel

## 3. Oxygen framework model.

Another theoretical approach is to calculate the elastic properties on the assumption that they are determined by the cubic close packed framework of oxygen anions [O.L. Anderson, 1965]. The theory [Leibfried, 1955] predicts ratios  $C_{ij}/K$  and  $(\partial C_{ij}/\partial P)/(\partial K/\partial P)$ . The oxygen framework scheme was applied to  $Al_2O_3$  and  $MgO$  by Gieske and Barsch [1968], to  $Mg_2SiO_4$  (olivine) by Graham and Barsch [1969], and to orthopyroxene by Frisillo and Barsch [1971].

For the cubic close packing of spinel define  $A_{11} = 3/2$ ,  $A_{12} = 3/4$ , and  $A_{44} = 3/4$ , where the  $A_{ij}$  have the same matrix properties as the cubic symmetry elastic constants  $C_{ij}$ . Then  $C_{ij} = K A_{ij}$  and  $\partial C_{ij}/\partial P = (\partial K/\partial P) A_{ij}$ . First the effective elastic constant derivatives must be converted into thermodynamic elastic constant derivatives [Thurston, 1965a]. The predicted and measured values are shown in Table II.8. As in the previous comparisons on  $Al_2O_3$ ,  $MgO$ , and  $Mg_2SiO_4$ , the predicted zero pressure ratios are fairly good for pleonaste ( $\pm 10\%$ ) and excellent for  $MgO:2.6Al_2O_3$  ( $\pm 4\%$ ). The agreement of the predicted pressure derivatives corresponds except for a 50% deviation in  $(\partial C_{44}/\partial P)/(\partial K/\partial P)$ . The lack of agreement can be attributed to many-body forces and the influence of the cations [Gieske and Barsch, 1968].

## Spinel

### 4. Critique of theoretical models.

Though the Born type or oxygen framework lattice calculations based on nearest neighbor interactions yield zeroth order and qualitative results, predictions for pressure derivatives are unreliable. At present, too little is known about solving the full quantum mechanical problem of complex oxides (or "simple" oxides such as MgO [La and Barsch, 1968]). The differences between the experimental and theoretical results indicate the difficulty. Semi-empirical factors to simulate such phenomena as many-body and exchange forces lead to results for which there are no theoretical means of distinguishing between right and wrong results. The reader is also referred to a recent paper by Leigh et al. [1971]. The paper concluded that experimental lattice frequency determinations are never sufficient to determine the atomic force constants uniquely.

## Spinel

### D. Lattice modes, crystal stability, and phase transformations.

Shock wave studies on  $\text{MgAl}_2\text{O}_4$  imply that it has undergone a transition by 700 kb to a phase 2 to 9% denser than an iso-chemical mixture of  $\text{MgO}$  and  $\text{Al}_2\text{O}_3$  [D.L. Anderson and Kanamori, 1968; Ahrens et al., 1969; and Davies and D.L. Anderson, 1971]. The high pressure phase has been interpreted as  $\text{MgAl}_2\text{O}_4$  going into a  $\text{CaFe}_2\text{O}_4$  or related structure where the  $\text{Mg}^{2+}$  becomes 8-coordinated [Reid and Ringwood, 1969, p.206]. Static compression of  $\text{FeAl}_2\text{O}_4$  at 120 kb and 1000 °C [Ringwood and Reid, 1969] yielded  $\text{FeO}$  and  $\text{Al}_2\text{O}_3$ . Therefore, pleonaste which is intermediate between these end members in composition can also be expected to undergo some type of spinel  $\rightarrow$  post-spinel transition. In this section the nature of the spinel  $\rightarrow$  post-spinel transition will be interpreted from the available information: thermochemical data, elastic stability criteria, and shock and static experiments.

#### 1. Elastic stability criteria.

First the implications of the negative value for the pressure derivative  $\partial C_S / \partial P = -0.05$  of pleonaste will be discussed in terms of the crystal's shear stability. With increasing pressure the shear modulus decreases so that the crystal becomes weaker to a  $C_S$ -type shear ( $\epsilon_{11} = -\epsilon_{22}$ ; all other strains equal zero). If the shear modulus  $C_S$  were to decrease to a negative value, then the lattice is unstable

## Spinel

since  $(C_{11} - C_{12}) < 0$ . Discussions of lattice stability and particularly shear stability in terms of the Born criteria [  $(C_{11} + 2C_{12}) < 0$ ,  $(C_{11} - C_{12}) < 0$ , or  $C_{44} < 0$  ] have been the subject of some recent papers [Thomsen, 1971; O.L. Anderson and Demarest, 1971]. Using his fourth-order anharmonic theory and O'Connell's [1970]  $\text{MgO:2.6Al}_2\text{O}_3$  data, Thomsen concluded that none of the Born criteria will be met before megabar pressures. The magnitude of the negative  $\partial C_S / \partial P$  in pleonaste is not large enough to bring  $C_S$  to zero until megabar pressures, unless  $\partial C_S / \partial P$  becomes increasingly negative with pressure. However, the possibility exists that lattice vibrational modes other than those in the long wavelength and non-dispersive elastic region become negative.

## 2. A case study: rubidium iodide.

Rubidium iodide transforms from the sodium chloride to cesium chloride structure at a pressure of about 4 kb at 300 °K [see, for example, Pistorius, 1965]. The transition is reviewed since it is instructive on the role of lattice modes [Musgrave, 1970, p.274].

Buerger [1948] suggested from crystallographic considerations a  $C_{44}$ -type shear along the [111]-direction as the mechanism for the sodium chloride to cesium chloride transition (Fig. II.6). Daniels and Smith [1963] noted that though

## Spinel

a negative  $\partial C_{44}/\partial P$  was measured for RbI at room pressure, its magnitude was such as to decrease the initial value of  $C_{44}$  by only 10% at the observed transition pressure. They suggested, however, that a transverse acoustic (TA) mode frequency in the [100]-direction became negative and was the mechanism of instability. This TA mode would be in the dispersive region of the spectrum and hence not observable in the 10 MHz region of elastic measurements. They schematically pictured the Brillouin zone-boundary frequency dropping off more rapidly with pressure than the low frequency acoustic mode (Fig. II.7).

Hardy and Karo [1965] agreed with this conclusion on the basis of a lattice dynamical calculation which took into account next-nearest neighbors and non-central forces. Saunderson [1966] performed a neutron scattering experiment on RbI that actually measured these zone-boundary modes as a function of pressure. The decrease with pressure, however, was still too small to bring the zone-boundary modes to zero at the transition pressure.

### 3. Lattice modes, metastability, and activation energy.

In interpreting the neutron scattering experiment Saunderson [1966] pointed out that the mode instability theory imposed the stringent condition that at the transition pressure the sodium chloride phase of rubidium iodide

## Spinel

could not exist even metastably. If the mode was not actually unstable but had a near zero positive value, the implication would be that a low activation energy was required for the transition.

Musgrave [1970, p.274] summarized the situation in the following way: "If phase A effects a transition to phase B, then phase A must in some way have been able to sample condition B in order to 'decide' in terms of a free-energy criterion. Consequently, where kinematic paths prove easily identifiable in terms of lattice modes, the possibility that the instability of these modes may provide the path to the new structure has been suggested." The sampling of the new phase should be regarded on a statistical basis. Thermal fluctuations of the lattice near a pressure transition enable the formation of an "embryo" of the new phase [see, for example, Smoluchowski, 1948 on the embryo concept].

If a lattice mode is actually unstable, the resistance to formation of the new phase is zero. If a lattice mode is stable but weak, the resistance to formation of the new phase is also weak but the old phase may still exist metastably. Thus, a zero shear constant is a sufficient but not necessary condition for a phase transition.

## Spinel

### 4. Shock-wave experiments.

The occurrence of an unstable lattice mode in the microsecond time scale of a shock-wave experiment implies that an instantaneous phase transition will take place, i.e., the transition cannot be overdriven beyond the mode-failure pressure [Barsch, 1965; Roy, 1969]. Roy suggested that in high bond strength materials (such as the alkali halides and oxides) one should look for the correlation of breaks in the shock-wave Hugoniot and predicted mode failures. One might also look for the correlation of limited metastable persistence and weak modes before any mode failure is expected to occur.

Plotted in Figs. II.8 and II.9 are the pressure-density Hugoniots for  $\text{MgAl}_2\text{O}_4$  (ceramic) and  $\text{Fe}_3\text{O}_4$  which have been taken from Birch's [1966] compilation and D.L. Anderson and Kanamori's [1968] figures. Recall that magnetite has the inverse spinel structure and exhibits negative pressure coefficients for both shear moduli [England, 1970]. In both figures the spinel structure has gone completely into a new high-pressure phase by pressures of 700 kb. The situation is ambiguous at lower pressures and subject to different interpretations. However, the suggestion is that the 200 to 600 kb data represent a mixed-phase region for the  $\text{MgAl}_2\text{O}_4$ . The number of data points seems sufficient to say that the

## Spinel

Hugoniot is linear between 200 and 500 kb with a possible negative curvature leading into an inflection at 600 kb.

The linear relation between pressure and density means a linear relation between bulk modulus and density which is not consistent with the expected equation of state for

$\text{MgAl}_2\text{O}_4$ .

From thermochemical data the pressure at which  $\text{MgAl}_2\text{O}_4$  would break down to its component oxides may be calculated through the relation  $P = -\Delta G_0 / \Delta V$  [Ringwood, 1966].  $\Delta G_0$  is the free energy of the reaction at zero pressure and  $\Delta V$  is the molar volume change of the reaction. Approximately,  $\Delta G_0^{1400^\circ\text{C}}$  is 8.4 kcal/mole [Rosén and Muan, 1966] and  $\Delta V$  is  $-3 \text{ cm}^3/\text{mole}$  to give  $P = 120 \text{ kb}$ . Ringwood and Reid [1969] did not observe any disproportionation of  $\text{MgAl}_2\text{O}_4$  at 120 kb and 1000 °C but the nature of the calculation does not allow detailed comparison. Several possibilities exist to fill the gap between the static experiments at 120 kb and the shock-wave experiments beginning at 200 kb. For example, the  $\text{MgAl}_2\text{O}_4$  might partially disproportionate and then begin to transform to a denser state. Or the  $\text{MgAl}_2\text{O}_4$  might remain metastably and then begin to transform directly to the denser high-pressure state in the mixed-phase region.

## Spinel

Inferences about the nature of the spinel  $\rightarrow$  post-spinel transition may now be drawn in terms of the previous discussion on lattice modes, metastability, and activation energy. By a pressure of 200 kb the shear modulus  $C_S$  will have increased a few percent for  $MgAl_2O_4$  and it will have decreased a few percent for pleonaste. In either case considering the compression involved, there is evidence of a weak  $C_S$ -mode so that in the microsecond duration of the shock wave the activation energy is sufficiently low for transformation to begin. On this microsecond time scale the mixed-phase 200 to 700 kb region represents a metastable range. At 700 kb either the superpressure is sufficient to cause complete transformation, or indeed a lattice mode has gone to zero at this pressure.

The effect of iron substitution is to reduce the value of the elastic constant  $C_S$  and apparently also to reduce the value of  $\partial C_S / \partial P$ .  $FeAl_2O_4$  may be expected to have a weaker  $C_S$ -mode than  $MgAl_2O_4$ . Perhaps Ringwood and Reid's [1969] observed disproportionation of  $FeAl_2O_4$  compared with no reaction in  $MgAl_2O_4$  at 120 kb and 1000 °C is explained by the  $FeAl_2O_4$  being more readily able to tunnel (via the  $C_S$ -mode) under the kinetic barrier required for unmixing.

Now consider the shock-wave data on olivines as compiled by Ahrens and Petersen [1969] in Fig. II.10. The 200 to

## Spinel

780 kb region is one of mixed phase. It is generally agreed that the olivine is in a post-spinel phase above 780 kb and that nowhere is there a clear indication of the presence of just the spinel phase. Note the similarity of the Hugoniot in Fig. II.10 for olivine and Fig. II.8 for  $\text{MgAl}_2\text{O}_4$ . The 200 to 700 kb region of both Hugoniot is interpreted as being one of mixed phase. For olivine the possibility exists that the mixed-phase region contains some spinel just as the possibility exists for  $\text{MgAl}_2\text{O}_4$  that the mixed-phase region contains a mixture of  $\text{MgO}$  and  $\text{Al}_2\text{O}_3$ .

From the pressure derivatives of the elastic constants of olivine [Graham and Barsch, 1969; Kumazawa and Anderson, 1969], Thomsen [1971] tentatively concluded that there will be no failure of the elastic stability criteria. Without a weak mode path for the transformation, the activation energy barrier is sufficiently high that the olivine form remains metastably for a range of superpressures. With the overshoot in pressure the spinel field is also overdriven. The expected shear mode weakness for the spinel form of olivine implies that the spinel phase will tend not to remain metastably above its transition pressure. Thus the high olivine  $\rightarrow$  spinel barrier and the low spinel  $\rightarrow$  post-spinel barrier combine to prevent the observation of the spinel phase in a

## Spinel

shock-wave experiment. The combination high/low barriers are observed as the large mixed-phase region. Other factors such as the non-hydrostatic nature of shock waves also have a large influence on whether or not a transformation will take place, but the above story seems to be consistent with the ultrasonic data.

## Spinel

## E. Diffusion kinetics.

Stresses in a descending lithospheric slab depend on the creep behavior of the material in the transition zone. For high temperatures ( $> 1/2$  the melting temperature) the creep rate is determined by the diffusion coefficient of the slowest moving atomic species in the material [see, for example, Weertman, 1970, p.146]. Keyes [1963] has proposed an elastic strain-energy model for diffusion.

$$K \frac{V^*}{G^*} = \frac{K}{\mu} \frac{\partial \mu}{\partial P} - 1 \quad (\text{Eqn. II.4})$$

where  $G^*$  = activation energy for diffusion

$V^*$  = activation volume for diffusion =  $\partial G^*/\partial P$

$K$  = bulk modulus

$\mu$  = shear modulus

Eqn. II.4 is plotted in Fig. II.11 for several values of  $K/\mu$ . The model gives the result that for small or negative values of the shear modulus pressure derivative, the diffusion rate increases with pressure ( $V^* < 0$ ). Such behavior is not intuitive. The strain-energy model is a semi-empirical theory which considers the activation energy for diffusion as work done against the elastic forces. The model does a fair job of explaining existing diffusion data.

## Spinel

Other diffusion theories might give a conflicting result. Weertman [1970] advocates the theory where the diffusion coefficient

$$D = D_0 \exp(-gT_m/T) \quad (\text{Eqn. II.5})$$

is an implicit function of pressure through the melting temperature  $T_m(P)$ .  $D_0$  and  $g$  are constants and  $T$  is the temperature. The activation volume in this theory is negative only if  $dT_m(P)/dP < 0$  and there is no clear correlation between the signs of  $dT_m(P)/dP$  and  $\partial\mu/\partial P$  [Keyes, 1963]. No conflict occurs for rutile- $\text{GeO}_2$  (next chapter).  $dT_m(P)/dP$  does not seem to be available for  $\text{MgAl}_2\text{O}_4$  to check.

A negative activation volume for the spinel structure implies a decrease in viscosity with depth in the transition region of the mantle rather than the increase usually calculated [Gordon, 1965; Weertman, 1970]. Postglacial uplift calculations do not resolve the viscosity profile within the transition zone. The calculations show a slightly lower viscosity for the lower mantle (below 1000 km) than for the transition zone [Cathles, 1971].

If the viscosity in the transition zone is constant or decreasing, a mechanism other than increasing strength is needed to explain the compressional axis parallel to the lithospheric slab for deep focus earthquakes [Isacks and Molnar, 1971]. For example, the density of the slab might remain lighter than the surrounding mantle.

## Spinel

### F. Iron substitution and the Jahn-Teller effect.

The ground state spin configuration of  $\text{Fe}^{2+}$  ( $3d^6$ ) in a tetrahedral site is degenerate. The Jahn-Teller effect is the distortion of the site which lowers the energy. The degeneracy is removed by the splitting of the  $t_2$  and  $e$  orbital groups.

The soft mode  $C_S = 1/2 (C_{11} - C_{12})$  in ulvöspinel,  $\text{Fe}_2\text{TiO}_4$ , was attributed to the Jahn-Teller effect for tetrahedral  $\text{Fe}^{2+}$  by Ishikawa and Syono [1971] and Syono et al. [1971]. Syono [personal communication, 1971] suggested that the "acoustic" Jahn-Teller effect should also be present in pleonaste and  $\text{FeAl}_2\text{O}_4$ . Previously, the elastic properties of the Jahn-Teller ions  $\text{Mn}^{3+}$  and  $\text{Ni}^{3+}$  in  $\text{YIG}:\text{Mn}^{3+}$  and  $\text{Al}_2\text{O}_3:\text{Ni}^{3+}$  were studied by Gyorgy et al. [1966] and Sturge et al. [1967], respectively.

Syono et al. [1971] found values of  $C_{11} = 1.39$ ,  $C_{12} = 1.12$ , and  $C_{44} = 0.396$  Mb for  $\text{Fe}_2\text{TiO}_4$ .  $\text{Fe}_2\text{TiO}_4$  is an inverse spinel in which one-half of the  $\text{Fe}^{2+}$  ions are in tetrahedral sites and one-half are in octahedral sites. The measured values for  $C_S = 0.132$  Mb and  $C_{44} = 0.396$  Mb are smaller than other spinels by a factor of five (Table II.6). Such a drastic reduction in  $C_S$  and  $C_{44}$  is not the case for  $\text{FeAl}_2\text{O}_4$  which has the same molar concentration of tetrahedral

## Spinel

$\text{Fe}^{2+}$  as  $\text{Fe}_2\text{TiO}_4$ . Rather there is only a gradual decrease in  $C_S$  and  $C_{44}$  with increasing iron substitution. Since the decrease in  $C_{11}$  is smaller than the decrease in  $C_S$ ,  $C_{12}$  increases and so does the bulk modulus  $K$ .

Thus there is a gradual softening of the  $C_S$ -mode with increasing iron content which may be due to a Jahn-Teller effect. However, with 100% iron substitution in the  $\text{MgAl}_2\text{O}_4$  -  $\text{FeAl}_2\text{O}_4$  system, the reduction is about 35% and not a factor of five as found in  $\text{Fe}_2\text{TiO}_4$ . The great reduction in the elastic constants of  $\text{Fe}_2\text{TiO}_4$  is not due solely to the presence of Jahn-Teller  $\text{Fe}^{2+}$  ions in the tetrahedral site. Perhaps magnetoelastic coupling between the Jahn-Teller distortion and the long-range magnetic ordering in  $\text{Fe}_2\text{TiO}_4$  [Ishikawa and Syono, 1971] is responsible for the difference.  $\text{FeAl}_2\text{O}_4$  shows no signs of magnetic ordering down to 11 °K [and probably 1.9 °K, Slack, 1964] while  $\text{Fe}_2\text{TiO}_4$  becomes weakly ferromagnetic below 142 °K. The low temperature dependence of the elastic constants of  $\text{FeAl}_2\text{O}_4$  will be needed to resolve the theoretical discussion since the effect is enhanced as  $1/T$  [Gyorgy *et al.*, 1966; Syono *et al.*, 1971].

## Spinel

G. Iron substitution, velocity-density relations, and the transition zone.

A variety of velocity-density relations [for a critical review see Simmons and England, 1969] have appeared since Birch [1961] proposed his linear relation

$$V_p = a(\bar{M}) + b\rho \quad (\text{Eqn. II.6})$$

where  $V_p$  = compressional wave velocity

$\rho$  = density

$\bar{M}$  = mean atomic weight

$a(\bar{M}), b$  = constants .

Birch used his velocity-density relation in the mantle's transition zone to test density models for consistency [1961], to examine the question of a change in iron content [1961], and to construct density models [1964]. The necessary parameters to know were  $dV_p/d\bar{M}$ ,  $(\partial V_p/\partial\rho)_{\bar{M}}$ , and  $(\partial\rho/\partial\bar{M})_y$  where  $y$  represents a constant phase and  $\Delta y$  is the change of density arising from a phase transition. Birch [1961] used values:  $dV_p/d\bar{M} = -0.36$ ,  $(\partial V_p/\partial\rho)_{\bar{M}} = 3.31$ , and  $(\partial\rho/\partial\bar{M})_y = 0.13$ .\* These values were also applied to the question of iron content in the transition zone by D.L. Anderson [1968, p.92] and Press [1970, p.18].

---

\*All numbers given in this section are based on units where  $V_p$  or  $V_s$  is in km/sec,  $\rho$  is in g/cm<sup>3</sup>, and  $\bar{M}$  is in g/mole/atom.

## Spinel

The new data in the  $\text{MgAl}_2\text{O}_4 - \text{FeAl}_2\text{O}_4$  system allow redetermination of the parameters

$$dV_p/d\bar{M} = (\partial V_p/\partial \rho)_{\bar{M}}(\partial \rho/\partial \bar{M})_Y + (\partial V_p/\partial \bar{M})_{\rho} \quad (\text{Eqn. II.7})$$

and  $(\partial V_p/\partial \rho)_{\bar{M}}$  for use in considering the olivine  $\rightarrow$  spinel transition which is one of the major phase changes in the 300 to 1000 km region. Also the data determine the corresponding parameters  $dV_s/d\bar{M}$  and  $(\partial V_s/\partial \rho)_{\bar{M}}$  for shear wave velocities.

## 1. Velocity-density relation for spinels.

First the  $\text{MgAl}_2\text{O}_4 - \text{FeAl}_2\text{O}_4$  system will be tested in a velocity-density relation proposed for spinel structure compounds [Liebermann, 1970].

$$V_p = 15.66 - 1.59 \rho \quad (\text{Eqn. II.8a})$$

$$V_s = 9.88 - 1.17 \rho \quad (\text{Eqn. II.8b})$$

$V_p$  and  $V_s$  are in km/sec and  $\rho$  is in  $\text{g/cm}^3$ . The heavy lines in Fig. II.12 represent Eqns. II.8. The newly measured values for  $V_p$  and  $V_s$  on pleonaste and hercynite fall 5 to 10% below the predicted values. The slope of the light line connecting  $\text{MgAl}_2\text{O}_4$  to  $\text{FeAl}_2\text{O}_4$  for  $V_p$  is the same as Liebermann's. However, the slope of the light line connecting  $\text{MgAl}_2\text{O}_4$  to  $\text{FeAl}_2\text{O}_4$  for  $V_s$  is steeper than Liebermann's, and in fact is the same as the slope of both  $V_p$  lines.

## Spinel

It appears as if  $V_p$  and  $V_s$  might be linear with composition in the  $MgAl_2O_4 - FeAl_2O_4$  system. The  $MgAl_2O_4 - FeAl_2O_4$  system would be expected to serve as a better elastic analogue to the spinel phase of the  $Mg_2SiO_4 - Fe_2SiO_4$  system than the assortment of spinels used in Liebermann's relation. The densities, mean atomic weights, and molar volumes of  $(Mg_{1-x}Fe_x)Al_2O_4$  and  $(Mg_{1-z}Fe_z)_2SiO_4$  where  $z = x/2$  are compared in Table II.9. Note that 100% Fe substitution for Mg in  $MgAl_2O_4$  is equivalent to about 50% Fe substitution for Mg in  $Mg_2SiO_4$ . For example, 100% Fe substitution in  $MgAl_2O_4$  increases  $\bar{M}$  by 4.5 which is exactly one-half the increase in  $\bar{M}$  for 100% Fe substitution in spinel- $Mg_2SiO_4$ . The densities for  $(Mg_{1-x}Fe_x)Al_2O_4$  and spinel- $(Mg_{1-z}Fe_z)_2SiO_4$  were calculated from a linear volume versus composition relation. The molar volumes for spinel- $Mg_2SiO_4$  and spinel- $Fe_2SiO_4$  were taken from Ringwood and Major [1970].

Assume that  $V_p$  and  $V_s$  are linear with composition in the  $(Mg_{1-x}Fe_x)Al_2O_4$  and  $(Mg_{1-z}Fe_z)_2SiO_4$  systems and that the elastic properties in the two systems are exactly similar for  $z = x/2$ . Then

$$V_p = 9.73 - 1.03 x \quad (\text{Eqn. II.9a})$$

$$V_s = 5.49 - 1.03 x \quad (\text{Eqn. II.9b})$$

where  $V_p$  and  $V_s$  are in km/sec and  $0 \leq x \leq 1$ . Uncertainties are about 3%.

## Spinel

## 2. Redetermination of Birch's parameters.

The parameters  $dV_p/d\bar{M}$ ,  $(\partial V_p/\partial \rho)_{\bar{M}}$ , and  $(\partial \rho/\partial \bar{M})_Y$  will now be considered in turn.

a. The value of  $dV_p/d\bar{M}$  is  $-1.03/4.5 = -0.23$  based on the  $MgAl_2O_4 - FeAl_2O_4$  data (Eqns. II.9). Birch's value for  $dV_p/d\bar{M}$  was  $-0.36$ . For reference,  $dV_s/d\bar{M}$  is  $-0.23$  based on the  $MgAl_2O_4 - FeAl_2O_4$  data. Recall that  $V_p$  and  $V_s$  are in km/sec,  $\rho$  is in  $g/cm^3$ , and  $\bar{M}$  is in g/mole/atom.

b. For consideration of the olivine  $\rightarrow$  spinel transition, it seems proper to consider the value of  $(\partial V_p/\partial \rho)_{\bar{M}}$  to be

$$(\partial V_p/\partial \rho)_{\bar{M}} = \frac{V_p^{\text{spinel}} - V_p^{\text{olivine}}}{\rho^{\text{spinel}} - \rho^{\text{olivine}}} \quad (\text{Eqn. II.10})$$

where the superscripts "spinel" and "olivine" refer to the respective phases of  $Mg_2SiO_4$ . The Hill averages for olivine- $Mg_2SiO_4$  [Graham and Barsch, 1969; Kumazawa and Anderson, 1969] are used to obtain  $(\partial V_p/\partial \rho)_{\bar{M}} = 3.45$  and for reference  $(\partial V_s/\partial \rho)_{\bar{M}} = 1.41$ . Birch's value for  $(\partial V_p/\partial \rho)_{\bar{M}}$  was 3.31. Neither  $(\partial V_p/\partial \rho)_{\bar{M}}$  nor  $(\partial V_s/\partial \rho)_{\bar{M}}$  calculated over the transition by Eqn. II.10 is consistent with that calculated from the pressure or temperature derivatives of olivine- $Mg_2SiO_4$  or  $MgO:2.6Al_2O_3$  [C. Wang, 1970, p.3265; England, 1970, p.95].

## Spinel

c. The parameter  $(\partial\rho/\partial\bar{M})_y$  for different Mg/Fe solid solution series is given below.

System	$(\partial\rho/\partial\bar{M})_y$
Olivine- $(\text{Mg}_{1-z}\text{Fe}_z)_2\text{SiO}_4$	0.130
Spinel- $(\text{Mg}_{1-z}\text{Fe}_z)_2\text{SiO}_4$	0.143
$(\text{Mg}_{1-x}\text{Fe}_x)\text{Al}_2\text{O}_4$	0.156

## 3. Transition zone.

a. To indicate the vagaries that remain on the question of iron content change in the transition zone, I will rework Birch's [1961] example where he used Jeffreys' 1939 seismic velocities and Bullen's Model A. I use the values

$$(\partial\rho/\partial\bar{M})_y = 0.14, \quad (\partial V_p/\partial\rho)_{\bar{M}} = 3.45, \quad dV_p/d\bar{M} = -0.23$$

which were determined in the previous section. The equations to be solved are [Birch, 1961, p.308]:

	Seismic change		Adiabatic compression		Phase change		Iron content change
$\Delta V_p$	= 2.32	=	1.14	+	3.45 $\Delta y$	-	0.23 $\Delta\bar{M}$
$\Delta\rho$	= 0.95	=	0.33	+	$\Delta y$	+	0.14 $\Delta\bar{M}$

The solution is  $\Delta\bar{M} = 1.4$  and  $\Delta y = 0.43 \text{ g/cm}^3$ . Birch obtained  $\Delta\bar{M} = 1.0$  and  $\Delta y = 0.48 \text{ g/cm}^3$ .

## Spinel

However, if shear velocity values are used, the equations become:

$$\Delta V_s = 1.33 = 0.46 + 1.41 \Delta y - 0.23 \Delta \bar{M}$$

$$\Delta \rho = 0.95 = 0.33 + \Delta y + 0.14 \Delta \bar{M}$$

The solution is  $\Delta \bar{M} = 0$  and  $\Delta y = 0.62 \text{ g/cm}^3$ . Thus the  $V_p$  solution indicates some iron increase while the  $V_s$  solution indicates that phase changes account for the entire density increase.

b. Some recent seismic shear velocity profiles have either a constant velocity gradient [Ibrahim and Nuttli, 1967] or a negative velocity gradient [D.L. Anderson and Julian, 1969] between 500 and 650 km. The small positive and slightly negative pressure derivatives of  $V_s$  for  $\text{MgO}:2.6\text{Al}_2\text{O}_3$  and pleonaste, respectively, suggest that the seismically determined  $V_s$  versus depth are indicative of the spinel structure.

The smaller value of  $\partial V_s / \partial P$  obtained on pleonaste compared to  $\text{MgO}:2.6\text{Al}_2\text{O}_3$  suggests this reduction in  $\partial V_s / \partial P$  may generally be true for iron substitution. When more confidence is gained in seismic shear wave gradients as well as in laboratory data on the effects of iron substitution, changes in the  $\text{FeO}/(\text{FeO} + \text{MgO})$  ratio in the transition zone may be estimated. An observed decrease in the slope of the shear wave gradient might mean an increase in the  $\text{FeO}/(\text{FeO} + \text{MgO})$  ratio.

Table II.1

Pleonaste microprobe analysis\* (wt. %).

Approximate chemical formula:  $(\text{Mg}_{0.75}\text{Fe}_{0.36})\text{Al}_{1.90}\text{O}_4$ .

	Wt. % oxide
$\text{SiO}_2$	0.1
$\text{TiO}_2$	0.5
$\text{Al}_2\text{O}_3$	63.8
$\text{Cr}_2\text{O}_3$	0.3
FeO	17.2
MnO	0.1
MgO	<u>19.9</u>
	101.9

\* Microprobe analysis by A. Reid of the NASA  
Manned Spacecraft Center, Houston, Texas.

$\rho$ , g/cm <sup>3</sup>	3.826
$a_0$ , Å	8.1225
$\bar{M}$ , g/mole/atom	21.8

Table II.2

Elastic constants determined from different propagation modes shown in Fig. II.3 for a cubic crystal.

Propagation direction	Path length (mm)	Vibration direction	Vibration mode	Elastic constant
$\alpha$ or [100]	4.933	[100]	L	$C_{11}$
$\alpha$ or [100]	4.933	Any	T	$C_{44}$
$\gamma$ or [110]	6.645	[110]	L	$C_L$
$\gamma$ or [110]	6.645	[ $\bar{1}10$ ]	T	$C_S$
$\gamma$ or [110]	6.645	[001]	T	$C_{44}$

$$\text{where } C_L = 1/2 (C_{11} + C_{12} + 2C_{44})$$

$$C_S = 1/2 (C_{11} - C_{12})$$

Also L = longitudinal

T = transverse

Table II.3

Pleonaste single crystal elastic constants.

(Based on density  $\rho = 3.826 \text{ g/cm}^3$ )

	11	12	44
$C_{ij}$ (Mb)	2.695	1.633	1.435
$\partial C_{ij}/\partial P$	4.85	4.95	0.75
$S_{ij}$ ( $\text{Mb}^{-1}$ )	0.684	-0.258	0.697
$\partial S_{ij}/\partial P$ ( $\text{Mb}^{-2}$ )	-0.079	-0.168	-0.364

Shear mode temperature derivatives:

$$\partial C_S/\partial T = +0.067 \text{ kb}/^\circ\text{K} \quad \text{and} \quad \partial C_{44}/\partial T = -0.080 \text{ kb}/^\circ\text{K}$$

$$\text{where } C_S = 1/2 (C_{11} - C_{12})$$

Based on thermal expansion  $\alpha = 22 \times 10^{-6} / ^\circ\text{C}$  used also by Schreiber [1967].

Table II.4

Pleonaste calculated aggregate elastic constants.  
(Based on density  $\rho = 3.826 \text{ g/cm}^3$ )

Zero pressure aggregate constants							
	E	$\mu$	$\sigma$	K	$\beta$	$V_s$	$V_p$

Fig. II.4. (a) Echo train in hercynite for a compressional wave in the  $[110]$ -direction. The first echo on the left is the reflection from the interface between the quartz buffer rod and the sample. Later echoes that have made round trips in the sample are inverted in phase with respect to the reflection from the end of the buffer rod. The time scale is  $0.2 \mu\text{sec/cm}$ . (b) Overlap of two echoes. The overlap frequency is  $2.60 \text{ MHz}$  for a sample path length of  $1.763 \text{ mm}$ .

Fig. II.5. Spinel structure [after Fyfe, 1964, p.106]. The unit cell contains 32 oxygens in cubic closest packing with cations in (a) 16 of the 32 octahedral sites and (b) 8 of the 64 tetrahedral sites. For the general formula,  $\text{AB}_2\text{O}_4$ , the spinel is termed normal when the A ions occupy the tetrahedral sites and the B ions occupy the octahedral sites. When the A ions and  $1/2$  the B ions occupy the tetrahedral sites, the spinel is termed inverse.

Rutile-GeO<sub>2</sub>III. Elastic constants of rutile-structure GeO<sub>2</sub>.

Germanium dioxide (germania) and germanate compounds have been used in geochemistry as a means of studying high pressure structures of silica and silicates [see reviews by Ringwood, 1966, 1970].\* The germanium ion (radius = 0.40 Å) is somewhat larger than the silicon ion (radius = 0.26 Å) when both are in tetrahedral coordination [radii from Shannon and Prewitt, 1969]. The germanate crystal isostructural to a silicate crystal is expected to go into a high pressure modification at a pressure below that of the silicate (see Table III.1 [after Ringwood, 1970]), because the oxygen framework will collapse around the germanium ion relatively sooner than around the silicon ion [Bernal, 1936]. The chemical similarity has been exploited by geochemists to estimate phase boundaries of the corresponding silicate through extrapolation in systems such as Mg<sub>2</sub>GeO<sub>4</sub> - Mg<sub>2</sub>SiO<sub>4</sub> [Dachille and Roy, 1960], Ni<sub>2</sub>GeO<sub>4</sub> - MgSiO<sub>4</sub> [Ringwood and Seabrook, 1962], and presently Mn<sub>2</sub>GeO<sub>4</sub> - Mg<sub>2</sub>SiO<sub>4</sub> [Ringwood, 1970, p. 116]. The Mg<sub>2</sub>GeO<sub>4</sub> - Mg<sub>2</sub>SiO<sub>4</sub> and Ni<sub>2</sub>GeO<sub>4</sub> - Mg<sub>2</sub>SiO<sub>4</sub> systems gave early estimates of the olivine-spinel phase boundary which

---

\* I have thought that this similarity between germanates and silicates could be exploited in the following examination question: "Describe the evolution and present state of the earth if the abundances of germanium and silicon were reversed."

## Rutile-GeO<sub>2</sub>

has recently been determined directly [Ringwood and Major, 1970]. The Mn<sub>2</sub>GeO<sub>4</sub> - Mg<sub>2</sub>SiO<sub>4</sub> system is in early stages of study to estimate the boundary of the spinel → post-spinel (strontium plumbate) transition [Ringwood, 1970].

Even though some of these high-pressure silicate phases are being synthesized, they are recovered in milligram proportions. Present ultrasonic techniques require close to one gram of material for polycrystalline samples. Single crystals are out of the question (unless General Electric becomes interested). So the germanium analogue technique may also be used to understand the elasticity of high-pressure silicate phases.

I add that though grams of stishovite are recoverable from Meteor Crater, phase studies [Holm et al., 1967] show that stishovite spontaneously transforms to a glass indistinguishable from ordinary SiO<sub>2</sub> glass at 800 °K in 15 to 20 minutes. Sample synthesis by hot-pressing might lead to an undesired finished product.

Quite recently some elastic property work on germanate compounds was reported by Soga [1969, 1971] and Mizutani [1970]. Soga measured the pressure dependence of the elastic moduli on germania glass and he measured the room condition values on a series of nearly dense polycrystalline samples of quartz-structure GeO<sub>2</sub>, rutile-structure GeO<sub>2</sub>, and

Rutile-GeO<sub>2</sub>

olivine-structure Mg<sub>2</sub>GeO<sub>4</sub>. Mizutani [1970] reported in abstract form shear velocity measurements on very thin samples of Mn<sub>2</sub>GeO<sub>4</sub> (olivine, spinel, and strontium plumbate structures) and MnGeO<sub>3</sub> (ilmenite structure).

In this chapter I report the pressure and temperature dependence of the single crystal elastic constants of rutile-structure (Fig. III.1) GeO<sub>2</sub>. This form of GeO<sub>2</sub> is isostructural to stishovite [Stishov and Popova, 1961], the 6-coordinated polymorph of SiO<sub>2</sub>. Similar measurements for the elastic constants as a function of pressure and temperature have been made for rutile (TiO<sub>2</sub>) by Manghnani [1969]. Since silica constitutes 33 to 50 mole percent of the transition zone and lower mantle, information gained from analogue studies will be important.

Rutile-GeO<sub>2</sub>A. GeO<sub>2</sub> phase diagram and thermochemical data.

Germanium dioxide can exist at room conditions in either the low-quartz or rutile structure [for an early comprehensive paper, see Laubengayer and Morton, 1932]. The densities of the two polymorphs are shown in Table III.2. The cation/anion ratio is right on the boundary between 4:2 and 6:3 coordination. At room conditions the rutile form of GeO<sub>2</sub> is the thermodynamically stable phase. At zero pressure the rutile-GeO<sub>2</sub> transforms to quartz-GeO<sub>2</sub> at 1002 °C. The quartz form is quite stable at room conditions, however. In fact when one buys GeO<sub>2</sub> one obtains the quartz phase. It is made at high temperatures from the ignition of GeCl<sub>4</sub> and maintains this metastable state. Thus the quartz-GeO<sub>2</sub> → rutile-GeO<sub>2</sub> transformation is quite sluggish in the absence of catalysts. A hydrothermally determined phase diagram is shown in Fig. III.2 [Hill and Chang, 1968].

The thermochemical data for germania is fairly complete (Table III.2). I have included the values for the analogous but metastable transition SiO<sub>2</sub> (quartz) → SiO<sub>2</sub> (stishovite) [Holm et al., 1967].

Rutile-GeO<sub>2</sub>

## B. Sample description.

The synthetically grown rutile-GeO<sub>2</sub> sample was obtained from Capt. John Goodrum and C. Dugger of the Air Force Cambridge Research Laboratories, Bedford, Mass. The sample was slightly less than 1 cm<sup>3</sup> in size and weighed 4.94 g. It was transparent and yellow. A sketch of the sample as grown is shown in Fig. III.3a. The four vertical sides were {110}-faces and the pyramid top pointed in the C-axis direction. The crystal was grown by a top-seeding method in an Na<sub>2</sub>O flux [Goodrum, 1970, 1971]. The only noticeable internal flaw was some small bubbles near the seed. Comparison of the X-ray density (6.2857 g/cm<sup>3</sup>) and hydrostatic weighing density (6.2718 g/cm<sup>3</sup>) showed less than 0.2% deviation and the bubbles were ignored. An average density of 6.279 g/cm<sup>3</sup> was used in the determination of the elastic constants. The only other flaw was that the initial {110}-faces showed apparent dislocation etch pits in reflected light. This caused some difficulty in the optical polishing of these faces until enough of the surface was ground away to remove the pits. The {110}-faces as grown were within 1/2° of the true orientation. Since the symmetry of Laue back-reflection photographs does not distinguish between {100} and {110}-faces for tetragonal symmetry, the distinction was made by means of a diffraction scan. When compared against the powder pattern, the scan showed missing {100}-peaks which confirmed the {110}-orientation.

Rutile-GeO<sub>2</sub>

## C. Experimental method and results.

In order to obtain a complete set of six elastic constants with reasonable cross checks, four sets of parallel faces were required. The normals to the four sets of faces are shown in Fig. III.4. Polarization directions for shear modes are also indicated and each mode is labelled. The exact combination of elastic constants determined for each mode is indicated in Table III.3.

## 1. Sample cutting procedure.

The four sets of parallel faces were obtained from the single sample described in the previous section. Initially one pair of {110}-faces was polished and pressure and temperature runs were made. Since the two shear modes were non-degenerate, three independent elastic constant combinations were determined. Then the pyramid was cut off and the set of {001}-faces polished. The pressure and temperature dependence of  $C_{33}$  and  $C_{44}$  were obtained from this direction. Note that  $C_{44}$  had previously been determined from the [110]-direction. At this point it was necessary to lose the {110}-faces. Namely, in order to obtain {100}-faces, cuts had to be made at a 45° angle to the {110}-face. Though the {110}-faces were not completely destroyed, a perpendicular path connecting them was lost. With the {100}-faces the crystal looked as in

Rutile-GeO<sub>2</sub>

Fig. III.3b. The pressure and temperature dependence of  $C_{11}$ ,  $C_{66}$ , and  $C_{44}$  were obtained from the [100]-direction. At this point five of the six elastic constants had been determined. Only  $C_{13}$  remained. It could be obtained from a set of {101}-faces, i.e., a cut had to be made at 45° to both the {100} and {001}-faces. The {001}-face was oriented so that the spots representing the mirror planes pointed in the [100]-direction. Then swinging the goniometer 45° in the horizontal plane and making a pair of vertical saw cuts yielded the {101}-faces (Fig. III.3c). The [001]-path direction was now lost. However, the [100]-path direction remains and in theory all six elastic constants may still be determined from just the [100] and [101]-directions. Table III.3 summarizes the final path lengths in the different directions. All the pairs of faces were optically polished flat and parallel to  $10^{-4}$  in/in by the A.D. Jones Optical Works, Burlington, Mass.

Rutile-GeO<sub>2</sub>

## 2. Ultrasonic measurements.

The elastic constants of rutile-GeO<sub>2</sub> were measured to 5 kb at room temperature (20 °C) and to 100 °C at zero pressure by the pulse-echo-overlap technique [Papadakis, 1967; Chung et al., 1969]. The measurements were mostly made at 20 MHz with coaxially plated X-cut and AC-cut quartz transducers. Some measurements were made at 30 MHz by driving the third harmonic of a 10 MHz transducer to reduce the beam spreading and guided-wave mode effects. A total of 22 pressure runs and 20 temperature runs were made. A summary of the average values for each mode is shown in Table III.4. The cross checks for the room condition elastic constants are all good to better than 0.2%. The values shown for C<sub>44</sub> are the average of runs in different directions. Mode cross checks for the pressure derivatives show agreement within 5% and mode cross checks for the temperature derivatives show agreement within 10%. The pressure and temperature derivatives are considered accurate to 5% and 10%, respectively.

Since the different modes listed in Table III.4 overdetermine the six independent elastic constants, an arithmetic average weighted by the number of runs was used in some cases. C<sub>33</sub>, C<sub>44</sub>, and C<sub>66</sub> were taken simply as their value in Table III.4. C<sub>11</sub> and C<sub>12</sub> were determined from the three modes C<sub>11</sub>, C<sub>S</sub>, and C<sub>L<sub>1</sub></sub>. Finally C<sub>13</sub> was determined from the difference 1/2 (C<sub>L<sub>2</sub></sub> - C<sub>T<sub>2</sub></sub>) and from the values for C<sub>11</sub>, C<sub>33</sub>,

Rutile-GeO<sub>2</sub>

and  $C_{44}$ . Since  $1/2 (C_{L_2} - C_{T_2}) = 1/4 [(C_{11} - C_{13})^2 + 4 (C_{13} + C_{44})^2]^{1/2}$ , the magnitude of  $(C_{13} + C_{44})$  was determined but not its sign. The two choices for  $C_{13}$  were  $C_{13} = 1.874$  Mb or  $C_{13} = -5.104$  Mb. The proper choice was  $C_{13} = 1.874$  Mb in order to satisfy the inequality  $C_{11}C_{33} > C_{13}^2$ . The inequality comes from the requirement that the strain energy density be positive definite, i.e.,

$$\sum_{i=1}^6 \sum_{j=1}^6 C_{ij} \varepsilon_i \varepsilon_j > 0.$$

A theorem of linear algebra [see, for example, Hausner, 1965, p.127] says the energy density will be positive definite if all the determinants

$$\left| C_{11} \right|, \quad \begin{vmatrix} C_{11} & C_{12} \\ C_{12} & C_{11} \end{vmatrix}, \quad \begin{vmatrix} C_{11} & C_{12} & C_{13} \\ C_{12} & C_{11} & C_{13} \\ C_{13} & C_{13} & C_{33} \end{vmatrix}, \quad \dots$$

are greater than zero. The inequality  $C_{11}C_{33} > C_{13}^2$  follows after some algebra. The resulting final values for the single crystal elastic constants, their pressure derivatives, and their temperature derivatives are tabulated in Table III.5. In addition the linear compressibilities and the volume compressibility are tabulated. Calculated aggregate properties are tabulated in Table III.6.

Rutile-GeO<sub>2</sub>

## D. Comparison with other work.

In this section the present results will be compared with the polycrystalline rutile-GeO<sub>2</sub> values of Soga [1971], the single crystal TiO<sub>2</sub> values of Manghnani [1969], the stishovite shock-wave reductions of Ahrens et al. [1970], and the stishovite isothermal compression measurements of Bassett and Barnett [1970]. Soga's values for the bulk modulus and compressional wave velocity of rutile-GeO<sub>2</sub> appear to be 20% and 7% too low, respectively. The pressure derivative of the bulk modulus,  $\partial K/\partial P$ , for rutile-GeO<sub>2</sub> is about 10% lower than for TiO<sub>2</sub>. The values are close enough that it is probable  $\partial K/\partial P$  for stishovite is between 6 and 7.

1. Comparison with polycrystalline rutile-GeO<sub>2</sub>.

Soga studied the elastic properties of polycrystalline quartz-GeO<sub>2</sub>, rutile-GeO<sub>2</sub>, and olivine-Mg<sub>2</sub>GeO<sub>4</sub>. He synthesized four rutile-GeO<sub>2</sub> polycrystalline samples of different porosity, the densest of which was 96% theoretical density. He then estimated the following values for the compressional wave velocity  $V_p$  and the shear wave velocity  $V_s$ . The corresponding values for the bulk modulus  $K$  and seismic parameter  $\phi$  are also given.

Polycrys-	$V_p = 7.90$ km/sec	$V_s = 4.85$ km/sec
talline		
values	$K = 1.950$ Mb	$\phi = 31.0$ km <sup>2</sup> /sec <sup>2</sup>

Rutile-GeO<sub>2</sub>

The values for  $K$  and  $V_p$  fall considerably outside the calculated Voigt and Reuss bounds shown in Table III.6. The Hill averages for the single crystal rutile-GeO<sub>2</sub> measurements are shown below.

Hill	$V_p = 8.55$ km/sec	$V_s = 4.90$ km/sec
averages	$K = 2.576$ Mb	$\phi = 41.0$ km <sup>2</sup> /sec <sup>2</sup>

The cause of the discrepancies is in Soga's value for  $V_p$ . His Table 1 is plotted in Fig. III.5. Perhaps the type of porosity present in the sample reduced the compressional wave velocity but not the shear wave velocity.

2. Comparison with single crystal rutile-TiO<sub>2</sub>.

- a. Both GeO<sub>2</sub> and TiO<sub>2</sub> exhibit a negative value for the pressure derivative of the shear modulus  $C_s = 1/2 (C_{11} - C_{12})$ .
- b. Both compounds show marked anisotropy. The ratio of linear compressibilities parallel and perpendicular to the C-axis are 0.449 for TiO<sub>2</sub> and 0.369 for GeO<sub>2</sub>.
- c. The "Hill" averages for the bulk modulus pressure derivatives are  $(\partial K/\partial P)_{TiO_2} = 6.76$  and  $(\partial K/\partial P)_{GeO_2} = 6.16$ . Although the value is about 10% lower for GeO<sub>2</sub> than for TiO<sub>2</sub>, it is still relatively higher than those for other oxides and silicates.

Rutile-GeO<sub>2</sub>

d. The "Hill" averages for the shear modulus pressure derivatives are  $(\partial\mu/\partial P)_{\text{TiO}_2} = 0.78$  and  $(\partial\mu/\partial P)_{\text{GeO}_2} = 1.22$ . Note that the individual "Voigt" and "Reuss" values are far apart. For TiO<sub>2</sub> the "Voigt" and "Reuss" values for  $\partial\mu/\partial P$  are 1.88 and -0.34, respectively. For GeO<sub>2</sub> the "Voigt" and "Reuss" values for  $\partial\mu/\partial P$  are 1.78 and 0.67, respectively. The shear modulus pressure derivative for GeO<sub>2</sub> is apparently larger than for TiO<sub>2</sub>.

e. The "Hill" averages for the bulk modulus temperature derivatives are  $(\partial K/\partial T)_{\text{TiO}_2} = -0.41 \text{ kb}/^\circ\text{K}$  and  $(\partial K/\partial T)_{\text{GeO}_2} = -0.36 \text{ kb}/^\circ\text{K}$ . As for  $\partial K/\partial P$ , the value of  $\partial K/\partial T$  is about 10% lower (in magnitude) for GeO<sub>2</sub> than for TiO<sub>2</sub>, but it is still relatively higher (in magnitude) than those for other oxides and silicates.

### 3. Comparison with stishovite (shock-wave and isothermal compression measurements).

Stishovite is the rutile modification of SiO<sub>2</sub>. Its bulk modulus has been determined from shock-wave [Wackerle, 1962; McQueen et al., 1963; D.L. Anderson and Kanamori, 1968; Ahrens et al., 1970; Davies and D.L. Anderson, 1971] and isothermal compression measurements [Ida et al., 1967; Liu et al., 1969; Bassett and Barnett, 1970]. In some cases a value for

Rutile-GeO<sub>2</sub>

the pressure derivative of the bulk modulus is quoted. The more recent (1970 - 1971) determinations will be considered in this section.

## a. Shock-wave measurements.

Ahrens et al. [1970] fitted the raw high pressure (> 400 kb) Hugoniot points of quartz to a third-order Birch-Murnaghan equation. The Hugoniot was reduced to a room-condition stishovite adiabat, where the adiabat was also given a Birch-Murnaghan form. The initial volume of quartz, the initial volume of stishovite, and the internal energy of the quartz → stishovite transformation were assumed to be known (Table III.3). The volume dependence  $V/V_0$  of the thermodynamic Grüneisen ratio,  $\gamma = \alpha K_S / C_P \rho_0$ , was given the form  $\gamma = \gamma_0 (V/V_0)^A$ .  $\alpha$  is the thermal expansion,  $K_S$  is the adiabatic bulk modulus,  $C_P$  is the specific heat at constant pressure,  $\rho_0$  is the initial density, and A is an adjustable parameter. The preferred solution of Ahrens et al. [1970] was

$$\gamma_0 = 1.58$$

$$A = 6$$

$$C_0 \equiv \sqrt{\phi} = 8.37 \text{ km/sec}$$

$$K_0 = 3.0 \text{ Mb}$$

$$(\partial K / \partial P)_{P=0} = 6.86$$

$$\partial K_0 / \partial T = -0.50 \text{ kb/}^\circ\text{K.}$$

Rutile-GeO<sub>2</sub>

The distinction between adiabatic and isothermal values is not indicated since the differences are more than adequately covered by uncertainties. Previously, Ahrens et al. [1969] obtained  $K_0 = 3.6$  Mb and  $\partial K/\partial P = 3$  by using the Dugdale-MacDonald relation for the volume dependence of  $\gamma$  along the Hugoniot. The 1970 reduction yielding  $\partial K/\partial P = 6.86$  seems appropriate in keeping with similar values found ultrasonically for TiO<sub>2</sub> and rutile-GeO<sub>2</sub>.

## b. Grüneisen's ratio.

Grüneisen's ratio  $\gamma$  is an important parameter in the reduction of shock-wave data. It is generally regarded to be only a function of volume and not explicitly a function of temperature. There is evidence that the room condition  $\gamma$  ( $1.5 \pm 0.3$ ) for stishovite determined from thermodynamic data is much higher than the high temperature  $\gamma$  (0.8 to 0.9) determined from the pressure offsets of fused quartz and porous quartz (Coconino sandstone) Hugoniots [Ahrens et al., 1970].

Because both Grüneisen's ratio and pressure derivatives of elastic constants are a measure of the anharmonicity of lattice vibrations, various relationships exist between them. Acoustic Grüneisen parameters associated with shear and longitudinal modes may be defined by [Schuele and Smith, 1964]:

$$\gamma_s = 1/3 + K_T (\partial \ln V_s / \partial P)_T \quad (\text{Eqn. III.1})$$

$$\gamma_p = 1/3 + K_T (\partial \ln V_p / \partial P)_T \quad (\text{Eqn. III.2})$$

Rutile-GeO<sub>2</sub>

The definitions are for the case of an isotropic solid.

If Hill averages are used, Eqns. III.1 and III.2 may also be applied to single crystal elastic constants.

For high temperatures when all modes are excited

$$\gamma_{HT} = (\gamma_p + 2\gamma_s)/3 \quad (\text{Eqn. III.3})$$

since there exist twice as many shear modes as longitudinal modes. The low temperature (where the specific heat associated with each mode is inversely proportional to the velocity cubed) value is given by

$$\gamma_{LT} = \frac{v_p^{-3} \gamma_p + 2v_s^{-3} \gamma_s}{v_p^{-3} + 2v_s^{-3}} \quad (\text{Eqn. III.4})$$

For reference purposes, the various  $\gamma$ 's for GeO<sub>2</sub> are given below:

$$\begin{array}{ll} \gamma_s = 0.87 & \gamma_p = 2.02 \\ \gamma_{LT} = 0.97 & \gamma_{HT} = 1.25 \\ \gamma_{thermo} = 1.16 & \gamma_{elastic} = 1.06 \end{array}$$

The room condition thermodynamic  $\gamma_{thermo} = \alpha K / C_p \rho_o = 1.16$  based on  $\alpha = 13.6 \times 10^{-6} / ^\circ K$  [Rao et al., 1968] and  $C_p = 12 \text{ cal/mole}^\circ K$  [Counsell and Marin, 1967]. Since the

Rutile-GeO<sub>2</sub>

Debye temperature for GeO<sub>2</sub> calculated from  $V_p$  and  $V_s$  is 773 °K,  $\gamma_{HT}$  and  $\gamma_{LT}$  may be averaged to obtain  $\gamma_{elastic} = 1.06$  for room conditions (300 °K). The value compares favorably with  $\gamma_{thermo}$  but is lower. Manghnani found that for TiO<sub>2</sub>,  $\gamma_{elastic} = 0.88$  while  $\gamma_{thermo} = 1.28$ .

## c. Static compression measurements.

Bassett and Barnett [1970] measured the change in X-ray lattice parameter of stishovite to 85 kb at 25 °C in a tetrahedral press. NaCl mixed with the stishovite was used to calibrate the pressure. The compressibilities parallel to the a-axis and c-axis are given below when linear fits were made to the lattice parameter versus pressure data.

$$\beta_a = \frac{-1}{a_0} \frac{\Delta a}{\Delta P} = 0.138 \text{ Mb}^{-1}$$

$$\beta_c = \frac{-1}{c_0} \frac{\Delta c}{\Delta P} = 0.057 \text{ Mb}^{-1}$$

The ratio  $\beta_c/\beta_a$  is equal to 0.41 which is intermediate between the ratios found for TiO<sub>2</sub> and rutile-GeO<sub>2</sub>. The volume compressibility  $\beta_v$  is 0.333 Mb<sup>-1</sup> which gives a bulk modulus  $K = 3.0 \text{ Mb}$ . However, if the volume versus pressure data were fit by the Birch-Murnaghan equation,  $K = 2.76 \text{ Mb}$  for  $\partial K/\partial P = 4$  and  $K = 2.69 \text{ Mb}$  for  $\partial K/\partial P = 6$ . The different values suggest that a 10% uncertainty may be placed on the value for the bulk modulus.

Rutile-GeO<sub>2</sub>

## d. Discussion.

A value of  $(\partial K/\partial P)_{P=0}$  between 6 and 7 should be used in reductions of shock-wave or isothermal compression data for stishovite which involve that parameter. The similar  $\partial K/\partial P$  values for TiO<sub>2</sub> and rutile-GeO<sub>2</sub> make such a requirement reasonable and seem to rule out the possibility that the high  $\partial K/\partial P$  for TiO<sub>2</sub> is due to some peculiarity of the electronic structure. In fact the Ti<sup>4+</sup> ion is 3p<sup>6</sup> in its outermost shell and is exactly isoelectronic to Si<sup>4+</sup> which is 2p<sup>6</sup>. Ge<sup>4+</sup> is 3d<sup>10</sup> and hence might be considered more likely to show any electronic structure bonding differences. Recall, however, that the silicon atom and the germanium atom are isoelectronic, and that in oxides they show more crystal chemical similarities because their ionic radii are closer. Thus TiO<sub>2</sub> and rutile-GeO<sub>2</sub> together indicate that stishovite will have a value of  $\partial K/\partial P$  between 6 and 7 because of their similar crystal structures.

## e. Some suggestions.

Much effort has gone into the shock-wave work on quartz. Some of the assumptions used in the reduction of the data may perhaps be checked by performing shock-wave experiments on polycrystalline GeO<sub>2</sub>, both in the quartz and rutile structures. The synthesis of such samples to a density between 90 and 95% theoretical density should provide no special difficulty. Such synthesis has been done by Soga [1971].

Rutile-GeO<sub>2</sub>

The thermochemical data for both the quartz and rutile structures are fairly complete. Reliable single crystal elastic constants, their pressure derivatives, and their temperature derivatives for rutile-GeO<sub>2</sub> have been presented. Single crystal data for quartz-GeO<sub>2</sub> may also be expected to be available in the future. Single crystal quartz-GeO<sub>2</sub> samples of limited size have been grown already [Roy and White, 1967; Finch and Clark, 1968; Theokritoff, 1970]. A 1 cm<sup>3</sup> size sample would be sufficient for an ultrasonic study. Complete sets of elastic constants for both structures along with shock-wave measurements would be an opportunity to study the lattice dynamics over this geophysically interesting phase transition.

Rutile-GeO<sub>2</sub>

## E. Phase transformation and diffusion kinetics.

The kinetics of the quartz-GeO<sub>2</sub> → rutile-GeO<sub>2</sub> transformation as a function of pressure (10 to 30 kb) and temperature (380 to 600 °C) were studied by Zeto and Roy [1969]. The transformation is of the metastable-to-stable type with a large volume decrease (50%) and thus is of the type one might associate with a phase transformation source for deep focus earthquakes [Evison, 1963; Randall, 1964; Holstrom, 1968].

The experimentally determined rate curves are shown in Fig. III.6. Zeto and Roy in their discussion of the rate curves divided the transformation kinetics into three stages.

Stage 1. The initial growth of the rutile phase was relatively rapid and was increased by both pressure and temperature. This stage was interpreted as the nucleation of rutile growth sites over the surfaces of individual grains.

Stage 2. After the formation of nuclei on grain surfaces, the growth of the nuclei took place preferentially over further nucleation. This mechanism represented the rate curve up to the "knee."

Stage 3. Beyond the knee of the curve the rate behavior was somewhat unusual. The interpretation was that inhibition of the growth of the rutile phase occurred due to the formation of a product layer of the phase surrounding the individual grains.

Rutile-GeO<sub>2</sub>

Zeto and Roy continued their discussion by writing the rate of transformation in the general form:

$$\alpha = 1 - \exp(-bt^n) \quad (\text{Eqn. III.5})$$

where  $\alpha$  = volume fraction transformed

t = time

b, n = constants

The portion of the rate curves before the knee yielded  $n = 0.5$ . A value of  $n = 0.5$  had been suggested for diffusion controlled growth. An empirical activation energy of  $29 \pm 9$  kcal/mole and an activation volume between  $-15$  and  $-25$  cm<sup>3</sup>/mole were obtained for the transformation before the knee. The negative activation volume meant that the activation energy decreased as a function of pressure, i.e., the rate constants increased as a function of pressure. Since diffusion rate constants normally are decreased by pressure, a diffusion mechanism for the transformation became questionable. Zeto and Roy did not rule out the possibility since they indicated that pressure might have reduced the particle size and hence increased the transformation rate.

Rutile-GeO<sub>2</sub>

## a. Keyes' strain energy model.

In terms of Keyes' [1963] strain energy model presented in the previous chapter, the diffusion rate constant might actually be expected to increase a little with pressure.

Keyes' relation is

$$V^* = \frac{G^*}{K} \left[ \frac{K}{\mu} \frac{\partial \mu}{\partial P} - 1 \right] \quad (\text{Eqn. III.6})$$

where  $V^*$  = activation volume for diffusion

$G^*$  = activation energy for diffusion

$K$  = bulk modulus

$\mu$  = shear modulus.

From Soga's values of  $V_p = 4.1$  km/sec and  $V_s = 2.55$  km/sec for quartz-GeO<sub>2</sub>, the bulk modulus  $K$  is 0.348 Mb and the shear modulus  $\mu$  is 0.278 Mb so that  $K/\mu = 1.25$ . The ratio  $K/\mu$  is 0.82 for  $\alpha$ -quartz [based on Hill averages for  $K$  and  $\mu$  from the single crystal values of McSkimin et al., 1965].  $\alpha$ -quartz is apparently the only oxide known for which the bulk modulus is smaller than the shear modulus. Soga's quartz-GeO<sub>2</sub> does not show such behavior. Single crystal elastic constants to confirm the  $K/\mu$  ratio for quartz-GeO<sub>2</sub> would be desirable.

Since the pressure derivative  $\partial\mu/\partial P$  for quartz-GeO<sub>2</sub> is not available, a value of 0.5 is estimated from the quartz-SiO<sub>2</sub> data [McSkimin et al., 1965]. Then the factor in brackets in Eqn. III.6 is negative and so is  $V^*$ .

Rutile-GeO<sub>2</sub>

## b. Empirical melting temperature relationship.

Now consider the empirical diffusion relationship advocated by Weertman [1970].

$$D = D_0 \exp(-gT_m/T) \quad (\text{Eqn. III.7})$$

where  $D$  = diffusion coefficient

$D_0$  = constant

$g$  = constant

$T_m$  = melting temperature as function  
of pressure

$T$  = temperature

The general relationship for the diffusion coefficient under pressure is given by

$$D = D_0 \exp(-G^*/kT) \exp(-PV^*/kT) \quad (\text{Eqn. III.8})$$

where  $G^*$  = activation energy for diffusion

$V^*$  = activation volume for diffusion

$k$  = Boltzmann's constant.

For small pressures  $T_m = T_{m_0} + (dT_m/dP)_0 P$ , where  $T_{m_0}$  = melting temperature at  $P = 0$ . Then near  $P = 0$  the constant  $g$  of Eqn. III.7 should satisfy both  $g = G^*/kT_{m_0}$  and  $g = V^*/(k(dT_m/dP)_0)$  [Weertman, 1970]. If the two expressions for  $g$  are assumed to be equal, then

Rutile-GeO<sub>2</sub>

$$V^* = G^* (dT_m/dP)_O / T_{m_0} . \quad (\text{Eqn. III.9})$$

A value of  $(dT_m/dP)_O = -0.5 \text{ } ^\circ\text{C}/\text{bar}$  is obtained from the GeO<sub>2</sub> phase diagram (Fig. III.2). Then  $V^*$  is negative. Quantitative agreement between Eqn. III.6 and III.9 is lacking ( $V^*/G^* \approx -1.0 \text{ Mb}^{-1}$  and  $V^*/G^* \approx -0.5 \text{ kb}^{-1}$ , respectively) but the signs do agree.

## c. Summary.

The negative sign of the experimentally determined activation volume for the quartz-GeO<sub>2</sub> → rutile-GeO<sub>2</sub> transformation is predicted by Keyes' strain energy model for diffusion and the empirical melting temperature relation favored by Weertman. For quartz-GeO<sub>2</sub> there does not seem to be a conflict between the two theories. Since the theories predict an increase in diffusion rate with pressure, it may not be necessary to suppose a particle size effect in order to have the quartz → rutile transformation kinetics be controlled by a diffusion process.

Rutile- $\text{GeO}_2$ F.  $\text{FeO}$  and  $\text{SiO}_2$  in the lower mantle.

The composition of the lower mantle was inferred from seismic data and ultrasonic, shock wave, isothermal compression, petrologic, crystal chemical, and high-pressure/high-temperature phase equilibria studies by Ringwood [1970] and D.L. Anderson [1970]. Ringwood concluded that the mineral assemblage was denser than an isochemical mixture of oxides due to phase transitions and that no change in chemical composition was required. D.L. Anderson concluded that the lower mantle was richer in  $\text{FeO}$  and  $\text{SiO}_2$  than in the upper mantle.

In my opinion the discussion of the lower mantle given by Ringwood [1970] was well-reasoned and consistent with the available data. The reader is referred to his paper for the details. The methods by which D.L. Anderson reached his conclusions on the composition of the lower mantle will be critically reviewed in this section.

1. D.L. Anderson's three methods for estimating the composition of the lower mantle.

Method 1. Since the lower mantle (1000 to 2900 km) is basically homogeneous and adiabatic, the third-order Birch-Murnaghan equation and its density derivative may be least squares fit to different density and seismic velocity models.

Rutile-GeO<sub>2</sub>

The final parameters determined are a room condition density  $\rho_0$  and seismic parameter  $\phi_0$ . The mean atomic weight  $\bar{M}$  (i.e., iron content) is determined from the seismic equation of state [D.L. Anderson, 1967].

Method 2. The assumption is made that the room condition molar volumes and seismic parameters of the high-pressure phases of olivine, pyroxene, and garnet are molar sums and molar averages of the constituent oxides, respectively. Then the  $\rho_0$  and  $\phi_0$  found for the lower mantle determine molar percentages of the oxides MgO, FeO, and SiO<sub>2</sub> (stishovite).

Method 3. A direct comparison is made between the lower mantle's pressure versus density curve and that of shocked dunites of different FeO/(FeO + MgO) ratios.

## 2. Discussion.

Methods 1 and 3 marginally favored the case for iron-enrichment. The uncertainties in the seismic equation of state were duly noted [D.L. Anderson and Jordan, 1970]. Ringwood [1970] discussed the shock-wave evidence with the conclusion that iron-enrichment was possible but not required. My discussion then concentrates on Method 2 -- the molar averaging scheme.

Rutile-GeO<sub>2</sub>

## a. Assumption of an isochemical mixture of oxides.

Note immediately that an isochemical mixture of oxides has been assumed since the molar volumes of the high-pressure phases of olivine, pyroxene, and garnet are considered to be the molar sum of the oxides. The lower mantle density referred to room conditions is generally conceded to be greater than an isochemical mixture of oxides of upper mantle composition. Is the greater density due to phase transitions and/or iron enrichment? Assuming an isochemical mixture of oxides begs the question in favor of iron enrichment since phase transformations to a denser state are precluded. (Previously, D.L. Anderson [1968] also made the assumption of an isochemical mixture of oxides. In that paper (p. 94) he explicitly stated that his conclusions involved only the region between the top of the mantle and 800 km depth and that he did not rule out the possibility of further phase changes below 800 km. In D.L. Anderson and Jordan [1970], however, their discussion dealt only with the lower mantle at depths greater than 1000 km.)

b. Uncertainties in  $\Phi(\text{SiO}_2)$ .

Anderson and Jordan [1970] apparently used a value  $\Phi(\text{SiO}_2) = 85 \text{ km}^2/\text{sec}^2$  while Anderson *et al.* [1971] used  $\Phi(\text{SiO}_2) = 70 \text{ km}^2/\text{sec}^2$ . One wonders, of course, what the effect is of the change in values. The change is summarized in Fig. III.7. In Fig. III.7 the dashed lines represent the

Rutile-GeO<sub>2</sub>

original figure from Anderson and Jordan [1970] while the solid lines represent the revision to  $\phi(\text{SiO}_2) = 70 \text{ km}^2/\text{sec}^2$ . The garnet line has not been reproduced for simplicity.

In the figure's original form the lower mantle  $\rho_0$  and  $\phi_0$  solutions fell between the dashed "pyroxene" and "olivine" lines. The molar averaging scheme gave a composition (in mole percent):

Model 200204	0.38 MgO + 0.16 FeO + 0.46 SiO <sub>2</sub> (82% "pyroxene")
--------------	---

Birch 2	0.49 MgO + 0.12 FeO + 0.39 SiO <sub>2</sub> (43% "pyroxene")
---------	---

By way of comparison Ringwood's pyrolite [Ringwood, 1966] is:

Pyrolite	0.54 MgO + 0.06 FeO + 0.40 SiO <sub>2</sub> (50% "pyroxene")
----------	---

However, in its revised form, the lower mantle solutions no longer fall between the "pyroxene" and "olivine" lines.

But now the triangle determined by the points SiO<sub>2</sub>, Mg<sub>2</sub>SiO<sub>4</sub>, and (Mg<sub>0.5</sub>Fe<sub>0.5</sub>)<sub>2</sub>SiO<sub>4</sub> is almost the same as that in Fig. 4 of Anderson et al. [1971]. They evidently used this triangle in the sense of a petrologic composition indicator. For example, a perpendicular is dropped to the  $\rho$ -axis from the point representing Model 200204. The point at which the perpendicular to the  $\rho$ -axis intersects the Mg<sub>2</sub>SiO<sub>4</sub> -

Rutile-GeO<sub>2</sub>

(Mg<sub>0.5</sub>Fe<sub>0.5</sub>)<sub>2</sub>SiO<sub>4</sub> base side determines the MgO/FeO ratio. The (MgO + FeO)/SiO<sub>2</sub> ratio is determined by the ratio of lengths along the vertical between  $\phi(\text{SiO}_2)$  and the "olivine" line with Model 200204 as the dividing point. The triangle of Fig. III.7 gives a 100% "pyroxene" component (Mg<sub>0.7</sub>Fe<sub>0.3</sub>)SiO<sub>3</sub> with 15% excess silica. D.L. Anderson et al. [1971] found a 100% "pyroxene" component (Mg<sub>0.64</sub>Fe<sub>0.36</sub>)SiO<sub>3</sub>.

## c. Summary.

Consistency of the petrologic triangle interpolation scheme with the molar averaging scheme is lacking when the same  $\phi(\text{SiO}_2)$  is used in both cases. All the lower mantle solutions fall above the revised "pyroxene" and "olivine" lines (Fig. III.7). Presumably, no one will consider the revised figure to be an argument for a lower mantle richer in silica than "pyroxene."

## Garnet

## IV. Elastic constants of spessartite-almandine garnet.

The word "garnet" is used in two different ways. First, it represents the six natural silicate garnets with the general formula  $A_3^{\text{VIII}}B_2^{\text{VI}}\text{Si}_3^{\text{IV}}\text{O}_{12}$ \* (Table IV.1). Second, it represents the complex structure (Fig. IV.1) which these natural garnets possess. The context in which the word "garnet" is used should keep the meaning clear.

The elastic properties of garnet are of geophysical interest in both senses of the word. (1) Garnet is important in distinguishing between a peridotitic (olivine + pyroxene) or eclogitic (pyroxene + garnet) upper mantle. Even for the predominant view of a peridotitic upper mantle, garnet is an important accessory phase. For example, if garnet pyrolite is taken to represent the upper mantle at a depth of 150 to 250 km, then garnet represents 14 weight percent [Ringwood, 1970]. (2) Beginning at about 350 km depth pyroxene gradually transforms into the garnet structure [Ringwood, 1967]. For example,  $\text{MgSiO}_3$  has the garnet structural formula  $\text{Mg}_3^{\text{VIII}}(\text{Mg},\text{Si})^{\text{VI}}\text{Si}_3^{\text{IV}}\text{O}_{12}$ . "Such garnets, characterized by partial octahedral coordination of silicon, are fundamentally different from the common garnet family of minerals in which silicon is always in tetrahedral coordination" [Ringwood, 1967, p.258]. The density increase over the pyroxene  $\rightarrow$  garnet

---

\*The Roman numeral superscripts indicate coordination number.

## Garnet

transformation is about 10% [Ringwood, 1969, p. 406]. Because of the high pressures and temperatures required for synthesis, garnet-transformed pyroxenes will not be readily available in amounts necessary for ultrasonic experiments. So perhaps the partial octahedral coordination of the silicon may be understood through a combination of analogue studies, namely, ordinary garnets and six-coordinated silica analogues such as rutile- $\text{GeO}_2$ .

Ultrasonic measurements on garnet in this country have been limited. Verma [1960] measured the room condition elastic constants of an almandine-pyrope garnet and a spessartite-almandine garnet. (Table IV.1 is a reminder list of common end member names of natural garnets and synthetic or rare-earth garnets as well as their chemical formulas.) Soga [1967] measured the pressure and temperature dependence of the elastic constants of another almandine-pyrope garnet. In Russia Ryzhova et al. [1966] ultrasonically measured the elastic constants of a number of natural garnets. Several synthetic garnet measurements and older determinations of garnets of unspecified composition exist [see the compilation by Simmons and Wang, 1971].

## Garnet

### A. Sample description.

Table IV.2 lists the chemical analyses, densities, and mean atomic weights of the present garnet and others considered in this chapter. The analysis of Verma's spessartite-almandine garnet and the present one agree in all oxides to 1.5 weight percent. The present garnet was purchased from the International Mineral Corp., 44 Maiden Lane, New York, New York, as a cut stone (Fig. IV.2a) with Brazil as its likely source of origin. Its original weight was 7.58 g. After X-ray orientation, it appeared as in Fig. IV.2b and its weight was 1.865 g. Only the {110}-faces were polished. The path length was 6.217 mm. Verma's garnet was obtained from the Harvard collection with Brazil as its origin. His [110]-path length was 8.79 mm.

The hydrostatically determined density of the present spessartite-almandine garnet was  $4.2374 \text{ g/cm}^3$  while the X-ray density was  $4.2597 \text{ g/cm}^3$ . An average value of  $4.249 \text{ g/cm}^3$  was used in the determination of the elastic constants.

A mean atomic weight of 25.0 was calculated directly from the chemical analysis while  $\bar{M}$  from the approximate chemical formula (based on the ideal 12 oxygens in the garnet formula) was 24.7. There is a deficiency of cations compared to the number expected for 12 oxygens ( $\Sigma$  cations = 7.95 versus ideal  $\Sigma = 8.00$ ).

## Garnet

It is worth emphasizing the optical purity of the present garnet sample. Under a microscope with a strong light source, the garnet transmits like a medium red glass with absolutely no visible flows or inclusions. By way of contrast, Soga's almandine sample contained five volume percent ilmenite inclusions [Takahashi and Liu, 1970].

## Garnet

## B. Experimental method and results.

The elastic constants of the spessartite-almandine garnet were measured to 5 kb at room temperature (20 °C) by the pulse-echo-overlap technique [Papadakis, 1967; Chung et al., 1969]. The garnet was oriented to 1/2° with a Laue back-reflection camera in the [110] and [100]-directions. However, only the {110}-faces were optically polished flat and parallel to  $10^{-4}$  in/in by the A.D. Jones Optical Works of Burlington, Mass. In this direction there exist three independent pure modes which yield  $C_L = 1/2 (C_{11} + C_{12} + 2C_{44})$ ,  $C_S = 1/2 (C_{11} - C_{12})$ , and  $C_{44}$ . Then  $C_{11} = C_L + (C_S - C_{44})$  and  $C_{12} = C_L - C_S - C_{44}$ . The path length in the [110]-direction was 6.217 mm.

The measurements were made at 20 MHz with coaxially plated X-cut and AC-cut quartz transducers. At this frequency the echo train was modulated by guided-wave modes. However, no particular difficulties occurred if early echoes were used. The  $C_{ij}$  are considered to be accurate to 0.5% and the  $\partial C_{ij}/\partial P$  accurate to 5%.

The results of the single crystal measurements are tabulated in Table IV.3 and calculated aggregate properties in Table IV.4. No bounds for the aggregate property derivatives are implied. However, because of the very small anisotropy of velocities in single crystal garnet, the averages are determined fairly well. The raw frequency versus pressure

## Garnet

data were fitted by a least squares linear relation. The derivative of the "effective elastic constant" [Thurston, 1965] was obtained either by computing the elastic constant  $C_{ij}$  at different pressures and finding the slope, or by differentiating the expression

$$C_{ij} = 4 \rho l^2 f^2 \quad (\text{Eqn. IV.1})$$

where  $\rho$  = density

$l$  = path length

$f$  = reciprocal round trip travel time

with respect to pressure and evaluating it at  $P = 0$ . No distinction between adiabatic and isothermal bulk modulus was made in calculating  $\partial C_{ij} / \partial P$  since the difference does not effect the result within the stated 5% accuracy.

## Garnet

### C. Comparison with other garnets.

#### 1. Ultrasonic measurements on natural garnets.

Tabulated in Table IV.5 are the elastic constants of the present study, garnets 1 and 2 of Verma [1960], the almandine-pyrope of Soga [1967], and the grossularite of Ryzhova et al. [1966]. The immediate conclusion to be drawn from the first four garnets in the upper half of the table is that all four of the natural garnets are very similar in their room condition elastic behavior. All variations are within 2%. Grossularite is an exception as calcium-rich compounds tend to be [Simmons, 1964].

The comparison of the pressure derivative values of the present garnet with Soga's almandine-pyrope is shown in the bottom half of Table IV.5. My value of the bulk modulus pressure derivative is  $\partial K/\partial P = 5.0$  compared to Soga's  $\partial K/\partial P = 5.4$ , an 8% difference. Such a difference is not particularly significant considering the compositional and possible quality difference between the samples. The derivatives of the shear moduli  $C_S$  and  $C_{44}$  are about 1.5. No shear instabilities are indicated.

## Garnet

## 2. Isothermal compression measurements on pyrope-almandine garnets.

The bulk modulus of four garnets in the pyrope-almandine series, including the end members, were recently determined from isothermal X-ray measurements up to pressures of 300 kb by Takahashi and Liu [1970]. The end-member pyrope and almandine samples were laboratory synthesized. A natural pyrope isolated from a Roberts Victor Mine eclogite and Soga's [1967] natural almandine were the other two garnet samples. The microprobe analysis for the natural pyrope is given in Table IV.2.

The volume compression  $V/V_0$  versus pressure data were least-squares fit to a third order Birch-Murnaghan equation where the zero pressure isothermal bulk modulus  $K_0$  and its pressure derivative  $K'_0 = (\partial K/\partial P)_{P=0}$  were the variable parameters. Takahashi and Liu fitted their data once by allowing both  $K_0$  and  $K'_0$  to be adjustable and then fitted their data again by fixing  $K'_0 = 5.45$  (Soga's ultrasonic value) and only allowing  $K_0$  to be adjustable. The two parameter fit yielded values of  $K_0$  10 to 15% higher than  $K_0$  obtained with  $K'_0$  fixed at 5.45. Because the latter analysis yielded a  $K_0$  value for Soga's almandine within 1% of the ultrasonic value, Takahashi and Liu considered the  $K'_0 = 5.45$  fit to be most reliable for all four garnets. The results are tabulated in Table IV.6.

## Garnet

## 3. Ultrasonic measurements on synthetic garnets.

Tabulated in Table IV.7 are the elastic constants of the present spessartite-almandine along with several synthetic or rare-earth garnets. A large range of densities ( $4.24 < \rho < 7.10 \text{ g/cm}^3$ ) and mean atomic weights ( $24 < \bar{M} < 51$ ) is represented. The four synthetic garnets YIG, YGaG, EuIG, and GdGaG have values of  $\rho/\bar{M}$  close to 0.14. YAG has  $\rho/\bar{M} = 0.153$ , while grossularite has  $\rho/\bar{M} = 0.161$  and spessartite-almandine has  $\rho/\bar{M} = 0.17$ . Since both YIG and GdGaG have exactly the same  $\rho/\bar{M} = 0.14$  but different values of the seismic parameter  $\phi = K/\rho$ , they cannot both satisfy the seismic equation of state [D.L. Anderson, 1967].

One might wonder about the effect of electronic structure (both orbital and spin) on the elastic properties. Several of the synthetic garnets are ferrimagnetic (indicated in Table IV.7) and show magnetostriction. The elastic constants might show a change in value upon application of a magnetic field below saturation. This change in elastic constants is known as the  $\Delta E$ -effect and is due to interaction of the elastic field with the magnetic domain structure [see, for example, Bozorth, 1951]. Thus the tabulated constants may not represent purely elastic behavior. Of the magnetic garnets tabulated, the EuIG and YIG measurements were made in a demagnetized state [Bateman, 1966]. No mention of the magnetic state was made in the GdGaG paper [Graham and Chang, 1970].

## Garnet

The pressure derivative values for YIG were calculated from the complete set of third-order elastic constants given by Eastman [1966]. The YIG sample was magnetically saturated to eliminate magnetostrictive effects under pressure. The value of  $(\partial K/\partial P)_{\text{YIG}} = 4.6$  is 10% lower than for spessartite-almandine, but is in the usual range for oxides and silicates.

Besides magnetic effects the different electronic structures may be responsible for deviations from general relations between elastic properties and cell volume. Thus trivalent yttrium, iron, gadolinium, and gallium have valence electronic configurations  $4p^6$ ,  $3d^5$ ,  $4f^7$ , and  $3d^{10}$ , respectively.

## Garnet

## 4. Crystal chemical considerations.

In some sense the parameter  $\rho/\bar{M}$  does normalize wide variations in the individual parameters  $\rho$  and  $\bar{M}$ . When the normalization is expected to be reliably true within a particular structural family (namely, the garnets) will be investigated in this section. The parameter  $\rho/\bar{M}$  within a structural family is inversely proportional to the unit cell volume. Tables of effective ionic radii may be used to indicate the relative sizes of the ions occupying the different sites in the crystal structure. The site radii for the natural and synthetic garnets of Tables IV.5, IV.6, and IV.7 are shown in Table IV.8. In addition, site radii are shown for garnet-transformed  $\text{MgSiO}_3$  and garnet-transformed bronzite. As indicated in the introduction, garnet- $\text{MgSiO}_3$  has the structural formula  $\text{Mg}_3^{\text{VIII}}(\text{Mg},\text{Si})^{\text{VI}}\text{Si}_3^{\text{IV}}\text{O}_{12}$ . Garnet-transformed aluminous pyroxenes will also contain some  $\text{Al}^{3+}$  in the VI-coordinated site. The radius of the ion occupying this B or octahedral site for these transformed garnets is taken to be the formula number average of the individual ions. Thus the B-site radius in garnet- $\text{MgSiO}_3$  is the simple average of the radii of  $\text{Mg}^{2+}$  and  $\text{Si}^{4+}$  appropriate to 6-fold coordination. All the effective ionic radii are taken from Shannon and Prewitt [1969] and are based on  $r(\text{VI}\text{O}^{2-}) = 1.40 \text{ \AA}$ . The radius for 8-coordinated  $\text{Fe}^{2+}$  is estimated by assuming that the ratios  $r(\text{VIII}\text{Fe}^{2+})/r(\text{VI}\text{Fe}^{2+})$  and  $r(\text{VIII}\text{Mn}^{2+})/r(\text{VI}\text{Mn}^{2+})$  are equal.

## Garnet

The natural and synthetic garnets separate into two groups on the basis of different reciprocal volumes per ion. (Recall that the reciprocal volume per ion is proportional to  $\rho/\bar{M}$ .) The difference is due to the much smaller size of the  $\text{Si}^{4+}$  ion in the C-site and to the somewhat smaller size of the  $\text{Mg}^{2+}$ ,  $\text{Mn}^{2+}$ , or  $\text{Fe}^{2+}$  ions in the A-site compared to the transition or rare earth ions. Within each group there occurs a misfit. The  $\text{Ca}^{2+}$  occupying the A-site in grossularite is notably larger than in any of the other natural garnets. And the  $\text{Al}^{3+}$  occupying the C-site in YAG is notably smaller than in any of the other synthetic garnets. These ionic size differences also mean values of  $\rho/\bar{M}$  distinctly different from other members of the group. For the purpose of the present discussion, no particular attempt will be made to fit these two garnets into their respective groups except to note that when the relative ratios of the ions in the different sites change appreciably, the resulting relative distortions in the coordination polyhedra may lead to elastic anomalies not predicted from a universal equation of state [see also D.L. Anderson, 1969]. It turns out that YAG fits in nicely with the other synthetic garnets when an inverse  $\phi$  versus  $\bar{M}$  relationship is considered.

## Garnet

5. Seismic  $\Phi$  - density - mean atomic weight relations.

Universal equations of state such as O.L. Anderson's and Nafe's [1965] relation [also O.L. Anderson, 1966] and D.L. Anderson's [1967] seismic equation of state relate the mean volume per ion pair  $2\bar{M}/\rho$  (or its reciprocal) to the bulk modulus  $K$  (or the seismic parameter  $\Phi = K/\rho$ ). In terms of  $\Phi$  the two equations may be expressed as follows:

$$\text{D.L. Anderson} \quad \Phi = A_1 (\rho/\bar{M})^n \quad (\text{Eqn. IV.2})$$

$$\text{O.L. Anderson} \quad \Phi = (A_2/\bar{M}) (\rho/\bar{M})^{K'_O - 1} \quad (\text{Eqn. IV.3})$$

where  $A_1, A_2, n = \text{constants}$

$\Phi = \text{seismic parameter}$

$\rho = \text{density}$

$\bar{M} = \text{mean atomic weight}$

$K'_O = (\partial K/\partial P)_{P=0}$

The exponent  $n$  in D.L. Anderson's equation is close to 3 as determined by fitting the equation to "31 selected minerals and rocks." When  $n = 3$  the equation implies  $K'_O = 4$ . O.L. Anderson's equation then becomes identical to D.L. Anderson's equation for  $K'_O = 4$  and compounds of equal mean atomic weight  $\bar{M}$ . Except for these special conditions the two relations predict different behavior. In particular, for all the natural garnets where  $\rho/\bar{M}$  is essentially constant, Eqn. IV.2 predicts equal values of  $\Phi$  whereas Eqn. IV.3 predicts  $\Phi$  to be inversely proportional to  $\bar{M}$ . The inverse proportionality of

## Garnet

$\phi$  and  $\bar{M}$  in garnets from Eqn. IV.3 was pointed out by Takahashi and Liu [1970] and was satisfied by their isothermal compression data for the pyrope-almandine series. If all the garnet data including the synthetic garnets are plotted according to  $\phi$  versus  $1/\bar{M}$ , the garnets again separate into two groups (Fig. IV.3). Within each group (except grossularite) the data follow the  $\phi$  versus  $1/\bar{M}$  proportionality fairly well. Note that within the two groups  $\rho/\bar{M}$  is being treated as a constant. For the synthetic garnets  $\rho/\bar{M}$  varies up to 10%. If the variations in  $\rho/\bar{M}$  are taken into account by either Eqn. IV.2 or IV.3, the fit to the data becomes considerably poorer. In Fig. IV.3 all the data points (except grossularite) are within 5% of the fitted lines. Most points are within 2%. Two conclusions are indicated by the plotted data in terms of the crystal chemical discussion of the previous section.

- a. Within the isostructural garnet family neither D.L. Anderson's relation (Eqn. IV.2) nor O.L. Anderson's relation (Eqn. IV.3) fit all the data. The different A:B:C site-radii influence  $\phi$  in a way not predicted from a cell volume dependence.
- b. However, the plausible condition is that if garnets have equal values of  $\rho/\bar{M}$  and have ions of equal radii in the individual coordination sites, then they satisfy the inverse proportionality between  $\phi$  and  $\bar{M}$  derived from O.L. Anderson's relation (Eqn. IV.3).

## Garnet

6. Garnet-MgSiO<sub>3</sub>.

If a density increase of 10% over pyroxene-MgSiO<sub>3</sub> is assumed, the density of garnet-MgSiO<sub>3</sub> is 3.52 g/cm<sup>3</sup>, the mean atomic weight is 20.08, and  $\rho/\bar{M} = 0.175$ . Compare these values to pyrope, Mg<sub>3</sub>Al<sub>2</sub>Si<sub>3</sub>O<sub>12</sub>. The density of pyrope is 3.56 g/cm<sup>3</sup>, the mean atomic weight is 20.16, and  $\rho/\bar{M} = 0.177$ . Not only is the cell volume for garnet-MgSiO<sub>3</sub> the same as for pyrope and the other natural garnets, but also the radii of the cations in the three sites are the same (see Table IV.8). Recall that the B-site radius of garnet-MgSiO<sub>3</sub> is the average of the Mg<sup>2+</sup> and Si<sup>4+</sup> radii when both are in 6-fold coordination. That the effective radii of the three cation sites are nearly the same for pyrope and garnet-MgSiO<sub>3</sub> is consistent with their nearly equal values for  $\rho/\bar{M}$ .

So the elastic properties of pyrope and garnet-MgSiO<sub>3</sub> will probably be the same (shown also in Table IV.8). Though the discussion has so far concentrated on  $\Phi$ , the justification for also estimating values for  $V_p$  (compressional wave velocity) and  $V_s$  (shear wave velocity) comes from noting in Table IV.5 that the ratio  $V_p/V_s$  for the ultrasonically measured natural garnets is fairly constant.

Since the single crystal elastic constants of orthopyroxene-bronzite have been determined [Kumazawa, 1969], the estimated values for a garnet-transformed bronzite have also been tabulated in Table IV.8. Note that iron substitution

## Garnet

into garnet-transformed pyroxenes does not affect the cell volume or individual coordination site radii just as it does not in the pyrope-almandine series. Hence the elastic parameters may be determined from the inverse  $\Phi$  versus  $\bar{M}$  proportionality.

## Garnet

## D. Garnet's role in the mantle.

The relative proportion of mantle compounds in the garnet structure is not well-determined at present. Ringwood's estimate of 14 weight percent of pyrope-rich garnet in the 150 to 250 km region of the upper mantle was mentioned in the introduction to this chapter. For greater depths high pressure phase studies show different transformation possibilities. Though emphasis has been placed in this chapter on estimating the elastic properties of  $\text{MgSiO}_3$  transformed into the garnet structure, this transformation has not been observed directly but rather is inferred from Ringwood's studies [reviewed in Ringwood, 1970] on  $\text{MgSiO}_3$ :10%  $\text{Al}_2\text{O}_3$ ,  $\text{MnSiO}_3$ ,  $\text{CaGeO}_3$ , and  $\text{CdGeO}_3$ . Direct transformation of  $\text{MgSiO}_3$  into the garnet structure must occur at pressures greater than 200 kb. By such pressures competing modes of transformation are:

The presence of  $\text{Al}_2\text{O}_3$  as aluminous pyroxene alters the situation since the aluminous pyroxenes transform into the garnet structure at lower pressures.

## Garnet

Does the seismic data provide evidence for the pyroxene  $\rightarrow$  garnet transformation occurring in the earth's mantle? First, some laboratory data must be considered.  $\text{MgSiO}_3$  forming a garnet solid solution with pyrope is indicated by the sharp increase in lattice parameter of garnet crystallized from  $\text{MgSiO}_3:10\% \text{Al}_2\text{O}_3$  glass at 100 kb (see Fig. IV.4 after Ringwood, 1967). The magnitude of the velocity change over the pyroxene  $\rightarrow$  garnet transformation may be obtained from the single crystal elastic constants of bronzite [Kumazawa, 1969] and the estimated values for the velocities of bronzite transformed into the garnet structure shown in Table IV.8. The Hill averages for the single crystal bronzite are compared with the estimated garnet-bronzite values

Pyroxene- bronzite	$V_p = 7.84 \text{ km/sec}$	$V_s = 4.74 \text{ km/sec}$
Garnet- bronzite	$V_p = 9.32 \text{ km/sec}$	$V_s = 5.22 \text{ km/sec}$

The value of  $\Phi$  changes from  $31.5 \text{ km}^2/\text{sec}^2$  to  $50.5 \text{ km}^2/\text{sec}^2$  (estimated) over the pyroxene  $\rightarrow$  garnet transition in bronzite.

## Garnet

A density increase of 10% is thus matched by an increase of 20% in  $V_p$  and an increase of 10% in  $V_s$ . A 20% increase in  $V_p$  accompanying a 10% increase in density was found by Mizutani et al. [1970] for the olivine  $\rightarrow$  spinel transition in  $Fe_2SiO_4$ .

Ringwood in 1967 placed the pyroxene  $\rightarrow$  garnet transformation at a depth of 350 km after correcting the 900 °C conditions of Fig. IV.4 to 1500 °C (the 2500 °C temperature on p. 260 of his paper must be a misprint). He stated that "some seismologists now suspect that the rapid increase of seismic velocity marking the beginning of the transition zone occurs around 17 or 18°, or a depth of about 350 km." Since that time compressional wave discontinuities have been found by looking for reflectors. Whitcomb and D.L. Anderson [1970] found a P'P' reflector at 280 km but none at 440 km. Simpson et al. [1971] separated the 360 km discontinuity into ones at 280 km and 440 km. It seems reasonable then to associate the 280 km discontinuity with Ringwood's aluminous pyroxene to garnet transformation, as Whitcomb and D.L. Anderson have done.

The magnitude of the velocity discontinuity is dependent upon the amount of the pyroxene component in the upper mantle. Ringwood's [1970, p. 140] estimate for pyrolite is about

## Garnet

25 weight percent orthopyroxene. The resulting seismic discontinuities would be about 0.4 km/sec for  $V_p$  and 0.1 km/sec for  $V_s$ . Thus there is little chance for resolving the discontinuity from shear velocity profiles and only a slight chance from compressional velocity profiles. Perhaps the argument so far used may be reversed so that the magnitude of the discontinuity becomes a broad band estimator of the pyroxene component.

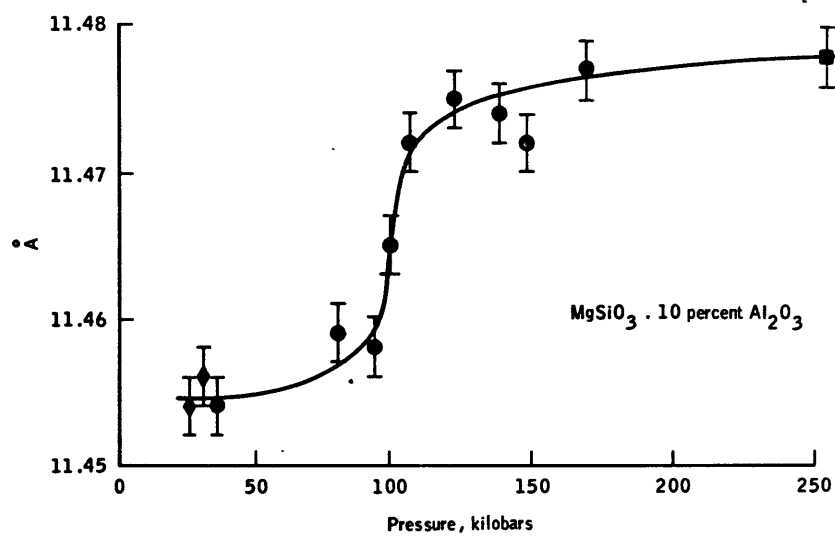

Fig. IV.4

## Summary

### V. Summary.

The elasticity of high-pressure mantle phases may be characterized by measurements on crystal chemically similar compounds. Analogue compounds available as single crystals yield the most reliable elastic constant data.

#### A. Spinel.

The  $C_S = 1/2 (C_{11} - C_{12})$  shear modulus pressure derivative of pleonaste is slightly negative. Though the pressure derivative of  $C_S$  in  $MgO:2.6Al_2O_3$  is positive, it is small in magnitude. Small shear moduli pressure derivatives are characteristic of the spinel structure. The weak shear modes imply a low kinetic barrier to phase transformations and diffusion. The decrease in  $C_S$  with iron substitution due to Jahn-Teller relaxation indicates that for iron-rich spinels an electronic instability is superposed on the structural weakness.

Pleonaste and hercynite belong to the  $MgAl_2O_4 - FeAl_2O_4$  series. The series is a particularly good analogue to the  $Mg_2SiO_4 - Fe_2SiO_4$  series in the spinel phase. The molar volumes, densities, and mean atomic weights are exactly similar for  $(Mg_{1-x}Fe_x)Al_2O_4$  and  $(Mg_{1-z}Fe_z)_2SiO_4$  when  $z = x/2$ . Lines for compressional velocity  $V_p$  and shear velocity  $V_s$  as a function of mean atomic weight are determined by the new pleonaste and hercynite elastic constant data. Application

## Summary

of the data to the question of iron content change in the transition zone leads to inconclusive results. An increase in iron content is indicated by the  $V_p$  data while no increase is indicated by the  $V_s$  data.

### B. Rutile.

Germanium dioxide and germanates are good crystal chemical analogues to silica and silicates. The bulk modulus pressure derivative  $\partial K/\partial P$  of rutile-structure  $\text{GeO}_2$  is about 6.2, a value higher than most other oxides and silicates. Since rutile- $\text{TiO}_2$  has a value of  $\partial K/\partial P$  equal to 6.8, it is likely that  $\partial K/\partial P$  for stishovite is between 6 and 7. Both rutile- $\text{GeO}_2$  and  $\text{TiO}_2$  are elastically anisotropic and both display a weak  $C_S$ -mode.

The seismic parameter  $\phi$  of stishovite is not well-determined at present. The use of  $\phi(\text{stishovite})$  in a molar averaging scheme to deduce the FeO and  $\text{SiO}_2$  content of the lower mantle contains inconsistencies. There is no strong evidence for enrichment of either component in the lower mantle.

### C. Garnet.

Ultrasonic and static compression elastic constant data exist for both natural garnets and synthetic garnets. Within each group of garnets the unit cell volumes are nearly the

## Summary

same and the ions occupying the different coordination sites have similar sizes. Then within each group the seismic parameter  $\phi$  is inversely proportional to the mean atomic weight  $\bar{M}$ .

The elastic velocities of garnet-transformed  $\text{MgSiO}_3$  may be estimated from the inverse proportionality between  $\phi$  and  $\bar{M}$ . The velocity change over the pyroxene  $\rightarrow$  garnet transformation is estimated to be 20% for compressional velocity  $V_p$  and 10% for shear velocity  $V_s$ .

## Procedure

### Appendix A: Experimental procedure.

In this appendix I describe my experimental procedure. The documentation may be useful to someone in the future making similar measurements or for any evaluation of my results. At present some differences between ultrasonic laboratories seem to exist on values for the pressure derivatives of elastic constants. The values are sensitive to experimental procedure. A section is devoted to discussing ambiguities that occurred in the pulse-echo-overlap method of measurement.

#### A. X-ray orientation and polishing.

The crystals were cut and oriented by a standard Laue back-reflection X-ray method in the MIT Crystal Physics Laboratory. A crystal was mounted on a goniometer aligned with the X-ray beam. A Polaroid camera (Type 57 film) was between the sample and the beam. After exposure the angular distances (both horizontal and vertical) between the center of the beam and a point of symmetry on the film were determined by overlaying a Greninger chart on the film [see, for example, Cullity, 1956]. The Greninger chart is a graphical display of the coordinate transformation between the back-scattered X-rays and the flat film plane. Fig. A.1 is an example of an oriented {100}-face with the Greninger chart shown for scale. The goniometer was adjusted over several

## Procedure

exposures until the center of the beam and the desired symmetry axis nearly coincided. Since the Geringer chart translated angles into distances on the film, the goniometer could be adjusted until orientation within  $1/2^\circ$  was assured. The goniometer was then taken off the X-ray track and slid into a track perpendicular to a diamond saw blade whose thickness was about 0.020". Two parallel cuts were made and the alignment of the blade was checked by placing the crystal on the end of a machined rod with double-stick tape and taking a final Laue picture.

Extremely small samples could be accurately oriented. For example, I oriented and cut a pair of {100}-faces and a pair of {110}-faces on an  $\text{FeAl}_2\text{O}_4$  crystal  $4 \times 4 \times 10$  mm (Fig. II.2, Chapter II).

Accurate ultrasonic measurements required sample faces to be optically polished flat and parallel to  $10^{-4}$  in/in. I could not do a good enough job with simple holding jigs and hence had it commercially done by the A.D. Jones Optical Works in Burlington, Mass. They charged \$150 per pair of faces.

## Procedure

### B. Transducers and bonding.

Coaxially plated one-quarter inch X-cut and AC-cut quartz transducers generated compressional and shear waves, respectively. They were purchased from the Valpey-Fisher Corp., Holliston, Mass. with resonant frequencies of 10 or 20 MHz ( $\pm 1\%$ ) and with third-overtone polish. The shear wave polarization ( $\pm 1^\circ$ ) was marked by a flat to which the particle motion was perpendicular.

A 50/50 mixture (by volume) of <sup>h</sup>phthalic anhydride and glycerin was used as the bonding material for pressure runs and an epoxy (Tra-bond 2101, Tra-Con, Inc., Medford, Mass.) was used for shear wave temperature runs. Methylene chloride was the epoxy stripping agent. A few small drops of the phthalic anhydride and glycerin mixture were heated on the sample under an infrared lamp until it flowed quite readily. It was spread thinly and uniformly over the sample face with copper wire before the transducer was "wrung" on with a Q-tip. The phthalic anhydride and glycerin mixture was not dissolved by the pressure fluid of petroleum ether so that both shear and compressional waves could be transmitted. An epoxy bond was cured for at least 2 hours at 80 °C and it remained hard to 100 °C whereas a thermosetting bond became too soft to maintain a good shear signal.

## Procedure

The crystal sample with transducer was then placed in a cylindrical holder with a spring-loaded pin making electrical contact with the center spot of the coaxial transducer (Fig. A.2). The entire assembly was grounded and placed directly into either the pressure vessel or oven.

## Procedure

### C. Ultrasonic equipment.

The elastic constants were determined by measuring the velocity of plane compressional or shear waves in specific propagation directions. Since sample lengths were 5 to 10 mm and velocities were 5 to 10 mm/ $\mu$ sec (1 mm/ $\mu$ sec = 1 km/sec), round trip travel times were 1 to 4  $\mu$ sec. I measured these travel times by the pulse-echo-overlap method developed by Papadakis [1964, 1967]. The particular modification in our laboratory enabled the simultaneous measurement of travel time and attenuation [Chung et al., 1969], but attenuation was not a part of my study.

I only briefly describe the principles of the technique since it is covered in detail by Papadakis and Chung et al. A block diagram of the equipment, as I used it, is shown in Fig. A.3. An rf-pulse whose rf-frequency was tuned to the resonance or overtone of the transducer was applied to the transducer. The same transducer was used also for receiving successive echoes which have travelled the length of the specimen and back. A typical echo-train is shown in Fig. A.4a. A rough idea of the travel time in the sample was obtained by using the oscilloscope's calibrated time base and noting the distance between successive echoes on the screen grid. The actual measurement was made by intensifying any two echoes

## Procedure

and sweeping the X-axis of the oscilloscope at just the reciprocal of the travel time between the echoes. Only the intensified echoes were displayed on the oscilloscope face. The X-axis sweep rate was controlled by a sinusoidal frequency generator. Thus when the triggering frequency was the reciprocal of the travel time, successive sweeps of the electron beam presented a stable image of the two echoes with their rf-cycles in synchronization (Fig. A.4b). The frequency was read directly on a digital counter and was the raw datum of the experiment.

All my measurements were made with  $f_0 = 1/T$  (where  $T$  is the travel time) between 100 kHz and 1 MHz. Rf-pulses from the Arenberg pulsed oscillator had a repetition rate  $f_0/100$  and were in synchronism with all the echoes. Using a division factor of 100 in the single crystals kept only one pulse train in the crystal at a time, i.e., all the echoes from the input pulse died away before the next pulse occurred. The synchronism between the main pulse and echoes was necessary for a stable display of the individual echoes when the oscilloscope was swept at the reciprocal of the travel time.

## Procedure

### D. Ambiguities in the measurements.

While making my measurements, I found ambiguities which could limit the accuracy of the frequency determination as a function of pressure or temperature. These ambiguities were especially significant for the short path length and high-velocity crystals with which I worked. I discuss the following difficulties, several of which are related: (1) Guided-wave modes (2) Cyclic mismatches (3) Changes of transducer resonance with pressure or temperature (4) Incomplete damping of one echo before the next (5) Trigger delay between channels in dual channel operation (6) Shear wave polarization mis-orientation.

#### 1. Guided-wave modes.

In my samples one pair of parallel faces nearly always had another pair perpendicular to them (see Figs. II.1, II.2, III.3, and IV.2 for sample shapes). Thus, besides the reflection at the end of the wave path, there existed multiple side-wall reflections. When the side-wall reflections were in phase, a guided-wave mode resonance occurred. The resonance appeared as a modulation on the envelope of the wave train (Fig. A.5). Without the effect the echoes should have decayed exponentially. The nodal minima and build up again in amplitude indicated that energy was being fed in by the

## Procedure

"free oscillations" which were of longer period than the time between successive echoes. Also side-wall reflections could lead to spurious echoes in the oscilloscope display.

The guided-wave modes could affect measurements in two ways if a pair of echoes near a node was chosen. First, phasing effects near a node might alter the proper cyclic match [Papadakis, 1969; also discussed in the next section D.2]. Second, the strong phasing near a node was a function of pressure and temperature and hence might lead to incorrect coefficients for the elastic constants.

The solution of the problem was to stay away from nodal points and to work preferably with the first and second or second and third echoes. Another help was to use the slightly higher frequency of 30 MHz rather than 20 MHz so that less beam energy was diffracted to the parallel side-walls. A careful study of the effects of phasing near nodal points on the pressure and temperature derivatives of the elastic constants would be useful.

### 2. Cyclic mismatch.

A big error (2 to 5%) in the travel time determination occurs if the overlapping of two echoes is off by one or more cycles. It is not reliable to merely match the "leading edge" of the pulse nor to match peak half-cycle with peak half-cycle. The maximum peaks of two adjacent echoes are

## Procedure

often displaced one cycle apart because part of the energy of each cycle of the first echo is delayed by the transducer upon reflection at that interface, and makes its appearance in a subsequent cycle of the second echo [Papadakis, 1969].

Papadakis [1967, 1969] described two methods of determining the proper cyclic matching in the pulse-echo-overlap technique. The first method is based on the McSkimin criterion and the second is based on a video-pulse-matching method. These methods will be discussed in turn.

### a. McSkimin criterion.

The basis of the McSkimin criterion or method [McSkimin, 1962] is to measure the travel time both at the resonant frequency of the transducer and at a frequency 10% lower for different cyclic matches. The travel time  $T$  is given by

$$T = p\delta - \frac{p\gamma}{360 f} + \frac{n}{f} \quad (\text{Eqn. A.1})$$

where  $\delta$  = true round trip travel time

$p$  = number of round trips between echoes used

$\gamma$  = phase angle upon reflection at the specimen-transducer interface

$f$  = rf frequency

$n$  = number of cycles of mismatch.

## Procedure

Then denote the measurements at resonance by the subscript R and denote the measurements at  $0.9 f_R$  by the subscript L.

$$\Delta T = \frac{1}{f_L} \left( n - \frac{p\gamma_L}{360} \right) - \frac{1}{f_R} \left( n - \frac{p\gamma_R}{360} \right) \quad (\text{Eqn. A.2})$$

$$\text{where } \Delta T \equiv T_L - T_R .$$

For a thin bond  $\gamma_R \ll \gamma_L$  [see calculations by McSkimin, 1961, Table I, p. 15]. Then

$$\Delta T \approx \left( 0.111 n - \frac{p\gamma_L}{324} \right) \frac{1}{f_R} . \quad (\text{Eqn. A.3})$$

Eqn. A.3 is the basic equation to be interpreted for the condition  $n = 0$ , i.e., no cyclic mismatch. Putting  $n = 0$  in Eqn. A.3 yields  $\Delta T(n=0) < 0$ . So a necessary condition for proper cyclic matching is that  $\Delta T < 0$ . But note that for any  $n < 0$ ,  $\Delta T < 0$ . Therefore, the condition  $\Delta T < 0$  is not a sufficient condition for proper cyclic matching. Also note from Eqn. A.3 that for some  $n \geq 1$ ,  $\Delta T$  will be greater than zero. Then consider the following theorem.

For adjacent echoes in high density ( $\rho > 3 \text{ g/cm}^3$ ) - high elasticity ( $V_p > 7 \text{ km/sec}$ ,  $V_s > 4 \text{ km/sec}$ ) crystals,  $\Delta T > 0$  whenever  $n \geq 1$ . Thus the proper cyclic match occurs at the last negative  $\Delta T$  just before it turns positive, i.e., at the smallest negative  $\Delta T$  in magnitude.

## Procedure

Call the result of the theorem the "crossover condition."  
It is illustrated by an example for a shear mode in garnet  
(Fig. A.6 and Table A.1).

The assumptions of adjacent echoes, high density, and high elasticity are important. For example, the crossover condition is not always true for fused quartz [Papadakis, 1967]. Also examination of Eqn. A.3 shows that for some  $p > 1$  (several round trips between echoes),  $\Delta T < 0$  for  $n = 1$ .

The justification for the crossover condition is now given. The assumption of a high density - high elasticity crystal is immediately translated into a high value for the acoustic impedance  $Z = \rho V$  where  $\rho$  is the density and  $V$  is the compressional or shear velocity. The assumption of adjacent echoes sets  $p = 1$  in Eqn. A.3. Then in order for  $\Delta T$  to be greater than zero for  $n = 1$ ,  $\gamma_L$  must be less than  $36^\circ$ . To satisfy  $\gamma_L < 36^\circ$  for X-cut quartz transducers, the impedance  $Z$  should be greater than about 20 [McSkimin and Andreatch, 1962, Fig. 11, p.614]. For Y-cut quartz transducers,  $Z$  should be greater than about 10 [McSkimin and Andreatch, 1962, Fig. 13, p.614]. Then for high density ( $\rho > 3 \text{ g/cm}^3$ ) - high elasticity ( $V_p > 7 \text{ km/sec}$ ,  $V_s > 4 \text{ km/sec}$ ) crystals, the cyclic match condition occurs at the last negative  $\Delta T$  before it turns positive.

## Procedure

### b. Video-pulse-matching method.

Ambiguities still occurred, however, in determining the sign of  $\Delta T$  in the course of an actual experiment. Changing the rf-frequency changed the pulse shape so the match at  $0.9 f_R$  became uncertain. Furthermore, guided-wave effects could introduce spurious  $\Delta T$  measurements. Proper cyclic matching was then determined by Papadakis' [1969] video-pulse-matching method. A video or square pulse rather than an rf-pulse was used for the electrical input to the transducer. In terms of the block diagram (Fig. A.3) a Velonex pulse generator was substituted for the Arenberg pulsed oscillator. The pulse had an amplitude of about 200 V and its width was 0.1  $\mu$ sec. Because of the finite bandwidth of the transducer resonance, its spectrum was broad enough to encompass both the sharp phase fluctuation near a node and the large region of little fluctuation.

The first echo had the trident shape seen also in rock velocity measurements in which a square pulse input is used. The second echo had a portion of energy from each half cycle shifted one cycle because of delay in the transducer. The proper cyclic match was made as in Fig. A.7. The earlier of the two large peaks in the second echo was aligned with the maximum peak in the first echo. When the rf-pulse was substituted back for the square pulse, only a very minor adjustment in the reciprocal travel-time frequency was necessary;

## Procedure

the proper cyclic match had already been effected.

An experiment of possible interest would be to test the effect of a one cycle mismatch on the measured pressure or temperature coefficients. Would the effect be large or small?

### 3. Changes of transducer resonance with pressure or temperature.

The transducer was bonded directly to the sample for both the pressure and temperature runs. As a result the transducer's resonant frequency will change slightly during a run [less than 1% over either 5 kb or 100 °C, McSkimin and Andreatch, 1962].

For the  $n = 0$  condition and symbols as in Eqn. A.1,

$$\frac{\delta_o}{\delta} = \frac{\frac{T_o}{p} + \frac{\gamma_o}{360 f_o}}{\frac{T}{p} + \frac{\gamma}{360 f}} \quad (\text{Eqn. A.4})$$

Variables with a subscript zero refer to values at room conditions and unsubscripted variables refer to values at some pressure or temperature. Since  $\frac{\gamma}{360 f} \ll \frac{T}{p}$ , Eqn. A.4 becomes

Procedure

$$\frac{\delta_o}{\delta} = \frac{T_o}{T} \left[ 1 + \frac{p\gamma_o}{360 f_o T_o} \left( 1 - \frac{\frac{Y}{\gamma_o}}{\frac{f}{f_o} \frac{T}{T_o}} \right) \right] \quad (\text{Eqn. A.5})$$

What error results for not taking into account the change in transducer resonance? That is, what is the magnitude of

$\frac{p\gamma_o}{360 f_o T_o}$  ? For typical values ( $\gamma_o = 10^\circ$ ,  $f_o = 20$  MHz,

$T_o = 1$   $\mu$ sec) , the error in travel time is about 0.5%.

Then the error in the pressure or temperature derivatives of the elastic constants is about 1 to 2%.

#### 4. Incomplete damping of one echo before the next.

The incomplete damping of one echo before the next arrived was quite a problem for a few compressional wave modes (see Fig. A.8 for an example). The input rf-pulse had a width of about 1/2  $\mu$ sec, but returned echoes had a width of about 1  $\mu$ sec. Because of the short path lengths in the crystals, some travel times were 1.1  $\mu$ sec and caused the blending of echoes. In addition side-wall reflections could clutter returned echoes. The presence of a high noise level resulted in phase shifts equivalent to an uncertainty of 0.3% in the velocity. What was unknown was the relative change in these phase shifts as a function of pressure or

## Procedure

temperature. The blending of echoes was probably the major source of error and was a consequence of having small samples. On the basis of cross checks from different modes, the accuracy of pressure and temperature derivatives was about 5 and 10%, respectively.

### 5. Trigger delay between channels in dual channel operation.

Chung et al. [1969] mentioned a dual channel mode of operation in which the oscilloscope sweep was on an alternate mode. The amplitudes of the intensified echoes could then be adjusted individually. I found that dual channel operation could lead to a minor ambiguity. Because the triggering levels of the two channels were not calibrated, a phase lag or lead was introduced.

### 6. Shear wave polarization misorientation.

The shear wave polarization was aligned by eye to within 1 or 2°. A small misorientation meant that a minor amount of energy would be propagated with the velocity of the shear mode 90° to the one desired (assuming nondegenerate shear modes). The second mode was never detected in the echo train.

## Procedure

### 7. Summary of ambiguities.

The main source of error was a high background noise level due to insufficient echo damping. The existence of side-wall reflections contributed to spurious noise. Guided-wave modes caused no problem if echoes away from nodes were chosen. Cyclic mismatches could be avoided either by an analysis of the McSkimin criterion or by video-pulse-matching. The change in transducer resonant frequency as a function of pressure or temperature could be neglected. Single channel operation was preferred. The accuracy of zero pressure, room temperature elastic constants was 0.5%. Pressure and temperature derivatives were 5 and 10%, respectively.

## Procedure

### E. Reduction of raw data.

#### 1. Pressure data.

The reciprocal travel-time frequency  $f = 1/T$  where  $T$  is the travel time was linear with pressure  $P$ . The raw data were represented by a least squares line

$$\frac{f}{f_0} = 1 + b P \quad (\text{Eqn. A.6})$$

where  $b$  = least squares slope

and  $f_0$  = least squares zero pressure frequency.

(Note that the symbol  $f_0$  no longer refers to the rf-frequency as in the previous section.)

The elastic constant  $C_{ij}$  is given by:

$$C_{ij} = \rho \left( 2 \frac{p}{m} l f \right)^2 \quad (\text{Eqn. A.7})$$

where  $\rho$  = density

$l$  = sample path length

$p$  = number of round trips between echoes used

$m$  = integer multiple of reciprocal of travel time;  $m/f$  = travel time between echoes used

$f$  = some multiple  $m$  of  $1/T$

## Procedure

Then

$$\frac{\partial C_{ij}}{\partial P} = (\chi - 2\beta + 2b) C_{ij}^0 \quad (\text{Eqn. A.8})$$

where  $\chi$  = volume compressibility,  $\text{kb}^{-1}$   
 $\beta$  = linear compressibility in propagation direction,  $\text{kb}^{-1}$   
 $b$  = slope of  $\frac{f}{f_0}$  versus  $P$  line,  $\text{kb}^{-1}$   
 $C_{ij}^0$  = elastic constant at zero pressure,  $\text{kb}$  .

## 2. Temperature data.

For temperature runs the elastic constant  $C_{ij}$  is given by:

$$C_{ij}(T) = \rho_0 \left( 2 \frac{P}{m} l_0 f(T) \right)^2 [1 + (2\alpha_1 - \alpha_V)\Delta T] \quad (\text{Eqn. A.9})$$

where  $\alpha_V$  = volume thermal expansion,  $^{\circ}\text{C}^{-1}$   
 $\alpha_1$  = linear thermal expansion in propagation direction,  $^{\circ}\text{C}^{-1}$

A least squares fit for the coefficient  $\partial C_{ij}/\partial T$  was then made on the  $C_{ij}$  as a function of  $T$ .

## Procedure

### F. Pressure system.

Pressure runs were made to 5 kb in a standard liquid-medium (petroleum ether) pressure system (Fig. A.9). A cylindrical hydraulic ram pushed a piston of smaller area into the vessel so that pressure behind the ram was intensified by the ratio of the areas. The top seal was an O-ring and the bottom seal was an O-ring and brass retaining ring assembly.

Pressures were read both on a calibrated Heise gauge and on a digital voltmeter. The digital voltmeter recorded the output of a linear bridge amplifier [Philbrick Researches, Inc., 1966, section III.80] in which the gain was linear with the resistance change in a manganin coil (Fig. A.10). The amplifier was calibrated so that  $1 \text{ mV} = 1 \text{ bar}$ . The pressure in the vessel could be held to  $\pm 2$  bar for periods of thirty minutes. Readings were taken at 500 bar intervals every twenty minutes to allow the vessel to equilibrate to room temperature ( $20^\circ \text{C}$ ).

## Procedure

### G. Temperature system.

A non-inductively wound tubular oven was used to 100 °C for temperature runs. The sample holder was directly inserted into a brass tube in the oven. Mullite was plugged into the ends as an insulator. Temperature could be maintained to  $\pm 0.2$  °C simply by allowing the sample to equilibrate twenty minutes for some fixed current value in the oven windings. The temperature was read on a potentiometer with a copper-constantan thermocouple in contact with the sample. The thermocouple junction was shielded from direct radiation from the windings. The temperature corresponding to a thermocouple voltage was determined from a quadratic fit to standard emf tables:

$$T = -0.2135 + 25.4442 E - 0.4918 E^2 \quad (\text{Eqn. A.10})$$

where  $T$  = temperature in °C

$E$  = copper-constantan thermocouple emf in mV

The formula fitted the tables to within 0.1 °C.

The most difficult problem in making temperature measurements was in maintaining a good bond between the sample and the transducer. Above 100 °C an epoxy bond was not very satisfactory, so this was the upper temperature limit used. The 20 to 100 °C temperature range provided just about the same changes in elastic constants as did the 0 to 5 kb pressure range.

## Procedure

### H. Density determination.

Since an elastic constant  $C_{ij}$  is the product of a density and a velocity squared, accurate density determinations were necessary. Both hydrostatic weighing and X-ray densities were measured. Agreement between the two was within 0.3 to 0.5%. The hydrostatic weighings were made in the MIT Crystal Physics Laboratory with ethylene bromide ( $C_2H_4Br_2$ ) as the immersion fluid. The apparatus was described in Smakula and Sils [1955].

The subscript L refers to echo-overlap readings taken at a carrier frequency 10%  
below resonance R.

T = travel time in sample,  $\mu\text{sec}$

$$\Delta T = T_L - T_R, \mu\text{sec}$$

n = number of cycles of mismatch

The results are plotted in Fig. A.6.

p=1 refers to one round trip in the sample and

p=2 refers to two round trips in the sample.

## Procedure

## Figure Captions

Fig. A.1. Laue back-reflection photograph showing four-fold axis of symmetry in pleonaste. The center of the X-ray beam is indicated by the intersection of the horizontal and vertical line segments connecting the four black spots or fiducial points. The center of symmetry is indicated by the intersection of the line segments connecting Laue spots related by inversion symmetry. When the two points of intersection are one, orientation is perfect. The scale for misorientation is indicated by the Greninger chart.

Fig. A.2. Schematic of assembly for making electrical contact with a coaxially-plated transducer.

Fig. A.3. Block diagram of ultrasonic equipment [after Chung et al., 1969]. (1) Hewlett-Packard model 606B signal generator (2) Hewlett-Packard model 524L electronic counter (3) Airtech model DD-103 decade divider (4) General Radio model 1217-C unit pulse generator (5) Arenberg model PG-650C pulsed oscillator (6) Matec model 5-30 MHz broad band receiver (7) Matec model 2470 attenuation recorder with double delay strobe (8) Tektronix model 546 oscilloscope.

## Procedure

Fig. A.4. (a) Typical pulse-echo train. The picture is for a shear wave polarized in the  $[1\bar{1}0]$ -direction and propagating in the  $[110]$ -direction in garnet. The time base is 10  $\mu\text{sec}/\text{cm}$ . (b) Overlap of two echoes.

Fig. A.5. Guided-wave mode effect appearing as modulation of the echo train envelope. The picture is for a shear wave polarized in the  $[1\bar{1}0]$ -direction and propagating in the  $[110]$ -direction in  $\text{GeO}_2$ . The time base 20  $\mu\text{sec}/\text{cm}$ .

Fig. A.6. Crossover condition for proper cyclic matching. Plotted are the experimentally determined  $\Delta T = T_L - T_R$  versus the number of cycles of mismatch  $n$  for  $p = 1$  and  $p = 2$ . The  $\Delta T$  values are for a shear wave polarized in the  $[001]$ -direction and propagating in the  $[110]$ -direction in garnet. Note that in accord with Eqn. A.3,  $\Delta T$  is smaller for  $p = 2$  than for  $p = 1$ . If the cross plotted at  $n = 1$  had been very slightly negative, application of the smallest-negative- $\Delta T$ -in-magnitude criterion would have lead to a one cycle mismatch. However, for  $p = 1$  (adjacent echoes) in a high acoustic impedance crystal, the distinction is quite clear.

Fig. A.7. Proper cyclic-match overlap for video-pulse-matching method [after Papadakis, 1969, p. 1553].

## Procedure

Fig. A.8. Incomplete damping of one echo before the next arrived. The picture is for a compressional wave propagating in the [100]-direction in pleonaste. The time base is 2  $\mu$ sec/cm.

## Pressure data

### Appendix B: Least squares fits to pressure data.

For any pressure run the individual frequency readings at different pressures were least squares fit to a straight line. The slope of the least squares line  $\frac{f}{f_0} = 1 + bP$  is given in Tables B.1, B.2, and B.3 for the individual pressure runs in pleonaste,  $\text{GeO}_2$ , and spessartite-almandine, respectively. The standard deviation of the slope is also given.

Table B.1

Pleonaste least squares fits to raw pressure data.  $\frac{f}{f_0} = 1 + bP$

Mode	Direction	Polarization	Elastic constant	Path length	Number of data points	$b, Mb^{-1}$	$\sigma_{b_1}, Mb^{-1}$	$\partial C_{ij}/\partial P$
L	[110]	---	$C_L$	6.645	19	0.760	0.008	6.08
L	[110]	---	$C_L$	6.645	9	0.728	0.025	5.86
T	[110]	[1 $\bar{1}$ 0]	$C_S$	6.645	20	-0.084	0.002	0.00
T	[110]	[1 $\bar{1}$ 0]	$C_S$	6.645	19	-0.167	0.013	-0.09
T	[110]	[001]	$C_{44}$	6.645	9	0.153	0.002	0.69
T	[110]	[001]	$C_{44}$	6.645	10	0.194	0.003	0.80
T	[100]	Any	$C_{44}$	4.933	14	0.179	0.012	0.76

$\sigma_b$  = standard deviation of  $b$ ,  $C_L = 1/2 (C_{11} + C_{12} + 2C_{44})$ ,  $C_S = 1/2 (C_{11} - C_{12})$ .

L = longitudinal

T = transverse

## Biographical Note

Birth date and place: 14 September 1946 in Shanghai, China.

Marital status: Married with one child.

## Education:

Grade	School	Location	Years	Degree
K-2	Union Hill	Boulder, Colo.	1951-1954	-----
3	Leal	Urbana, Ill.	1954-1955	-----
4-6	Wiley	Urbana, Ill.	1955-1958	-----
7-9	University High	Urbana, Ill.	1958-1960	-----
10-12	Wisconsin High	Madison, Wisc.	1960-1963	-----
13-16	U. Wisconsin	Madison, Wisc.	1963-1966	B.A.
17-18	Harvard U.	Cambridge, Mass.	1966-1968	A.M.
19-21	MIT	Cambridge, Mass.	1968-1971	Ph.D.

## Summer jobs:

Title	Description	Institution	Location	Year
Physicist	X-ray analyzed glass samples	Corning Glass Works	Corning, New York	1966
Instructor	Taught elementary calculus	Corning Community College	Corning, New York	1967

Teaching assistantships: Physics of the Earth (1970)  
Planetary Physics and Chemistry (1971)

Fellowships: NSF (1966-1968), NDEA (1968-1970)  
Chevron (1970-1971)

Honorary societies: Phi Beta Kappa (1966), Sigma Xi (1969)

## Co-authored publications:

On the calculation of the seismic parameter  $\phi$  at high pressure and high temperatures, J. Geophys. Res., 75, 5113-5120, 1970.
