Photodisintegration of $^4$He into $p + t$

The two-body photodisintegration of $^4\text{He}$ into a proton and a triton has been studied using the CEBAF Large-Acceptance Spectrometer (CLAS) at the Thomas Jefferson National Accelerator Facility. Real photons produced with the Hall-B bremsstrahlung-tagging system in the energy range from 0.35 to 1.55 GeV were incident on a liquid $^4\text{He}$ target. This is the first measurement of the photodisintegration of $^4\text{He}$ above 0.4 GeV. The differential cross sections for the $\gamma^4\text{He} \rightarrow pt$ reaction were measured as a function of photon-beam energy and proton-scattering angle and are compared with the latest model calculations by J.-M. Laget. At 0.6–1.2 GeV, our data are in good agreement only with the calculations that include three-body mechanisms, thus confirming their importance. These results reinforce the conclusion of our previous study of the three-body breakup of $^3\text{He}$ that demonstrated the great importance of three-body mechanisms in the energy region 0.5–0.8 GeV.

DOI: 10.1103/PhysRevC.80.044603 PACS number(s): 13.40.–f, 13.60.Rj, 13.88.+e, 14.20.Jn

I. INTRODUCTION

One of the difficult challenges of nuclear physics is to understand the nature of the strong many-body interaction among the nucleons in the nucleus. In particular, understanding the contribution and manifestations of three-body forces is an important ingredient of the theoretical calculations that attempt to describe the reaction mechanisms. Photonuclear reactions are induced by a well-known probe and are especially sensitive to meson-exchange currents and isobar degrees of freedom.

The two-body photodisintegration of $^4\text{He}$ into a proton and a triton has been studied over the years in the low- and intermediate-energy regions, up to 0.4 GeV, where the one- and two-body mechanisms dominate the reaction [1–5]. The higher photon-energy region used in this experiment allows us to access larger momentum transfers, where the three-body mechanisms, mostly through higher-mass-meson double scattering, are expected to make a larger contribution.

In this analysis, the differential cross sections for the $\gamma^4\text{He} \rightarrow pt$ reaction were measured as a function of photon energy from 0.35 to 1.55 GeV, and over a wide range of the proton-scattering angle in the center-of-mass frame, as shown in Fig. 1. These measurements are complementary to the three-body breakup of $^3\text{He}$ for the study of three-body reaction mechanisms [6]. The results are compared with the latest model predictions of J.-M. Laget [7], where three-body mechanisms for this channel are included in the calculations.

II. MODEL PREDICTIONS

A calculation has been performed by J.-M. Laget [7] that includes three types of reaction mechanisms for this channel. Figures 2–4 show the diagrams for one-, two-, and three-body reaction mechanisms, respectively. The one-body mechanisms include the proton and triton (three-nucleon) exchange diagrams in which a proton or a triton knockout is assumed. The proton-exchange diagram is dominant when the proton is emitted at forward angles. The two-body mechanisms included in this calculation are the two-nucleon meson exchange (including the pion and the $\rho$ meson) and nucleon-nucleon final-state interactions. The diagrams due to the antisymmetry of the two active nucleons are also included in the two-body mechanisms. The three-body mechanisms include the meson double-scattering amplitudes. As shown in the bottom panels of Fig. 4, diagrams that correspond to the antisymmetry of the two nucleons in the pair that absorbs the pion are also included in the model.

The two- and three-body diagrams included in this model were found to be dominant in the study of two- and three-body disintegration of $^3\text{He}$. The relevance of this description is investigated here in a different environment, the $^4\text{He}$ nucleus, having markedly different $n$-body density and wave function.

Results of the model calculations are compared with previous world data in Fig. 5, in which the cross sections are plotted as functions of the incident photon energy for three values of the proton angle with the incident photon-beam direction, $\theta_p = 60^\circ$, $\theta_p = 90^\circ$, and $\theta_p = 120^\circ$. The comparison with Laget’s model [7] reveals that three-body mechanisms must be taken into account to describe the data.

This model has been extended to higher energies according to Ref. [8] and improved using (i) the full relativistic expression for the nucleon currents, (ii) a high-energy diffractive $NN$ scattering amplitude, and (iii) the latest ground-state wave function [9] that has been generated from the Argonne AV18 $NN$ potential [10] and the Urbana UIX three-nucleon force [11].
A thorough investigation of three-body mechanisms was performed earlier in the analysis of the reaction $\gamma \ ^3\text{He} \rightarrow \ ppn$ from the CLAS g3a data, which revealed that three-body mechanisms are most prominent in the energy range from 0.5 to 0.8 GeV [6]. Three-body mechanisms also have been studied in the two-body photodisintegration of $^3\text{He}$ [12]. The results presented here are the first to include the $\gamma \ ^4\text{He} \rightarrow \ pt$ reaction at energies higher than 0.4 GeV.

III. EXPERIMENT AND DATA ANALYSIS

A. Experimental apparatus

The $\gamma \ ^4\text{He} \rightarrow \ pt$ reaction was measured during the g3a experiment in December 1999 with the CEBAF Large-Acceptance Spectrometer (CLAS) [13] at Thomas Jefferson National Accelerator Facility (Jefferson Lab), shown in Fig. 6. CLAS is a large-acceptance spectrometer used to detect multiparticle final states. Six superconducting coils generate a toroidal magnetic field around the target with azimuthal symmetry about the beam axis. The coils divide CLAS into six sectors, each functioning as an independent magnetic spectrometer. Each sector is instrumented with three regions of drift chambers (DCs), R1–R3, to determine charged-particle trajectories [14], scintillator counters (SCs) for time-of-flight measurements [15], and, in the forward region, gas-filled threshold Cherenkov counters (CCs) for electron/pion separation up to 2.5 GeV [16], and electromagnetic calorimeters (ECs) to identify and measure the energy...
of electrons and high-energy neutral particles, as well as to provide electron/pion separation above 2.5 GeV [17]. In the g3a experiment, real photons produced with the Jefferson Lab Hall-B bremsstrahlung-tagging system [18] in the energy range from 0.35 to 1.55 GeV were incident on an 18-cm-thick liquid $^4$He target.

The photon beam was produced via bremsstrahlung from the primary electron beam operating at 1.645 GeV. Electrons were incident on the thin radiator of the Hall-B photon tagger [18]. Tagged photons were produced with 20–95% of the energy of the primary electron beam. About $10^9$ triggers were collected at the production current of 10 nA. The magnetic field of the CLAS toroidal magnet was set to 1920 A, half of its maximum value, to optimize the momentum resolution and the efficiency for positively charged particles. A trigger was used with a required coincidence between hits in the tagger, the start counter (ST), and the time-of-flight (TOF) paddles.

### B. Event selection

To associate the reaction of interest with the triggering tagged photon, the coincidence time between the tagger and CLAS was required to be within 1 ns. A cut was applied to the time difference $\Delta t$ between the CLAS start time at the interaction point recorded by the start counter (ST) and the tagger. The central peak in Fig. 7 corresponds to the tagger hits that are in time coincidence with CLAS within the 2-ns-wide beam bucket. In the g3a run period, only about 2% of the events contained more than one tagged photon.

The particles were identified by determining their charge, momentum, and velocity. Charge and momentum were obtained from the drift-chamber tracking information and the velocity from the time of flight and path length to the TOF detectors. Figure 8 shows the reconstructed mass distribution of positively charged particles. The events of interest were those with two and only two positively charged particles detected in coincidence. A triton candidate was required to...
FIG. 8. (Color online) Hadron mass calculated from the TOF and tracking information. The solid histogram shows the mass distribution for all the positively charged hadrons, the dashed histogram is the selected sample of protons and tritons that are detected in coincidence, and the shaded histogram shows the same distribution after applying all the kinematic cuts to remove the background (see Sec. III C for details).

have a positive charge and a reconstructed mass squared \( m^2 \) between 6.5 and 11.0 \((\text{GeV}/c^2)^2\). A proton candidate was required to have a positive charge and a reconstructed mass squared between 0.4 and 1.4 \((\text{GeV}/c^2)^2\). To ensure that the events of interest are produced within the \(^4\text{He} \) target volume, a cut was applied to the \( z \) component of the interaction vertex along the beam line.

Energy-loss corrections were applied to the selected particles because they lose a non-negligible part of their energy in the target material and start counter before they reach the drift chambers. The effect of the energy-loss corrections after applying all of the kinematic cuts on the final sample of \( pt \) data is shown in Fig. 9. The importance of these corrections can be demonstrated by comparing the missing-mass squared of either the detected proton or the detected triton before and after applying these corrections. As expected, the amount of energy loss for a particle depends on the mass of that particle; therefore, these corrections have a larger effect on the measurement of the triton than of the proton. Table I summarizes the result of fitting Gaussians on the final sample of \( pt \) events (see Sec. III C).

To eliminate any possible background, two-body kinematics were used to select a clean sample of \( pt \) events (see Sec. III C).

C. Background corrections

To select cleanly the \( \gamma^4\text{He} \rightarrow pt \) channel, two-body kinematics were used. The two-body final-state kinematics for real events requires that the missing energy, missing momentum, and missing-mass squared for \( pt \) events be zero. Also, the opening angle between the three-vectors of the detected proton and triton \( \theta_{pt} \) should be close to \( 180^\circ \) in the center-of-mass frame. Our initial sample of events contains two and only two charged particles. Four-vector conservation for the reaction \( \gamma^4\text{He} \rightarrow pt \), as specified in Eq. (1), leads to the determination of three kinematic variables; the missing energy \( E_X \), the missing momentum \( P_X = \sqrt{P_X(x)^2 + P_X(y)^2 + P_X(z)^2} \), and the missing-mass squared \( M_X^2 = E_X^2 - P_X^2 \):

\[
\begin{pmatrix}
E_y \\
0 \\
0 \\
E_y
\end{pmatrix}
+ \begin{pmatrix}
M_{4\text{He}} \\
0 \\
0 \\
0
\end{pmatrix}
= \begin{pmatrix}
\sqrt{m_p^2 + p_p^2} \\
\sqrt{m_p^2 + p_p^2} \\
0 \\
0
\end{pmatrix}
+ \begin{pmatrix}

FIG. 10. (Color online) $pt$ two-body final-state kinematics require the missing energy (upper left), missing-mass squared (upper right), and missing momentum (lower left) to be zero, and the $pt$ opening angle in the center-of-mass frame (lower right) to be 180°. The peaks correspond to the real $pt$ events from the two-body breakup of $^4\text{He}$. The shaded areas correspond to the nearly background-free sample of $pt$ events after the kinematic cuts described in this section were applied. The upper left panel shows the cut applied to the missing energy for $pt$ events; the other three panels show the derived event distributions.

The value of each of these cuts is optimized such that the maximum number of “good” $pt$ events is retained. Using these cuts, the background in the spectra of the previously described kinematic variables is mostly removed, as can be seen for the shaded areas of Fig. 10. The sample of events used after these cuts is therefore essentially background-free. This also can be confirmed by calculating the missing-mass squared of either the detected proton or the detected triton. These distributions are shown before and after the above cuts in Fig. 12, and

where $E_{\gamma}$ is the incident photon energy, $M_{t^4\text{He}}$ is the mass of the target nucleus, $m_p$ and $m_t$ are the masses of the proton and triton, respectively, and $p_p$ and $p_t$ are the measured three-momenta of the proton and triton, respectively. These kinematic variables are plotted in Fig. 10. For the real two-body breakup events into $pt$, we then have $E_\gamma = 0$ GeV, $P_X = 0$ GeV/c, $M_X^2 = 0$ (GeV/c)^2, and $\theta_{pt} = 180^\circ$. Indeed, in Fig. 10, we see clear peaks showing the real two-body $pt$ breakup events. However, some background can be seen in the selected events. These events (mostly due to the $pt\pi^0$ channel) can be removed by applying additional kinematic cuts as follows:

(i) The first cut is applied to the difference between the measured scattering angle of the proton in the c.m. frame (from the measured three-momentum vector of the proton) and the calculated one from the conservation of the four-momenta in the $^4\text{He} \rightarrow pt$ reaction (by measuring only the triton momentum). This difference is plotted in the upper-left side of Fig. 11. The clear peak around zero corresponds to the real events from the two-body breakup of $^4\text{He}$ into a proton and triton. The events for which this angular difference is outside of the range $[-0.15, 0.15]$ were removed from the data.

(ii) The second cut is applied to the difference between the momenta of the proton and the triton in the c.m. frame. For the real $pt$ events, this difference shows a peak around zero with a tail that could be due to the $pt\pi^0$ events, as shown in the upper-right panel of Fig. 11. The applied cut requires this difference to be between $-0.15$ and $0.15$ GeV/c.

(iii) The third cut requires the proton and triton three-momenta to be in the same plane, i.e., the difference between the azimuthal angles for the proton and the triton in the c.m. frame is selected to be $165^\circ < \Phi_{c.m.}^p < 195^\circ$. This distribution is shown in the lower-left panel of Fig. 11. A prominent peak around $180^\circ$ is clearly seen.

(iv) The fourth cut is applied to the sum of the cosines of the proton and triton scattering angles in the c.m. frame, shown in the lower-right panel of Fig. 11. This cut retains only those events with $-0.15 < \cos \theta_{p,c.m.}^t + \cos \theta_{c.m.}^t < 0.15$.

(v) Finally, the fifth cut requires the $pt$ missing energy to be $-0.1 < E(X) < 0.1$ GeV, shown in the upper left panel of Fig. 10.
PHOTODISINTEGRATION OF $^4$He INTO $p + t$

**FIG. 12.** (Color online) Calculated values for the missing-mass squared for the detected proton (left) and the detected triton (right), before (solid histogram) and after (shaded histogram) applying the kinematic cuts. The background is completely removed by the kinematic cuts (see Sec. III C for details).

They show that the background has been completely removed. The clean sample of protons and tritons that are detected in coincidence is also shown within the shaded areas of Fig. 8.

Table II summarizes the final cuts used to identify the $p t$ events as described in this section.

### D. Detector efficiency and acceptance

The raw $p t$ yields are obtained as a function of the photon beam energy $E_\gamma$ and the proton polar angle in the center-of-mass frame $\theta_{p,m}^c$. The yields are corrected for the detector acceptance using a Monte Carlo simulation of phase-space-distributed $p t$ events within the entire $4\pi$ solid angle. The photon energy was generated randomly with a uniform distribution from 0.35 to 1.55 GeV. The standard GEANT-based CLAS simulation package [19] was used to simulate the detector response. The simulated events were processed with the same event-reconstruction software that was used to reconstruct the real data. Figure 13 shows the reconstructed mass distributions for the simulated events with one proton and one triton after applying all the cuts.

The acceptance is defined as the ratio of the number of reconstructed events to the number of generated events. Owing to the geometry and the structure of CLAS, there are regions of solid angle that are not covered by the detector. Furthermore, the inefficiencies in the various components of the detector affect its acceptance and consequently the event reconstruction in CLAS. The acceptance correction factors are shown as functions of proton-scattering angle $\theta_{p,m}^c$ and photon energy $E_\gamma$ for each kinematic bin in Fig. 14. These correction factors are used to convert the raw yields into unnormalized cross sections. Data points with poor acceptance ($<0.4$) at smaller angles are not included in the final data set.

### IV. RESULTS

#### A. Cross sections

The differential cross sections are obtained from the expression

$$\frac{d\sigma}{d\Omega} = \frac{N}{\eta_a N_\gamma N_T \Delta\Omega},$$

where $N$ is the number of measured events in a given energy and angular bin of solid angle $\Delta\Omega = 2\pi \Delta\theta_{c.m.}$. The CLAS acceptance is given by $\eta_a$; $N_\gamma$ is the number of photons within...
the given energy range incident on the target; and $N_T$ is the number of target nuclei per unit area.

The number of target nuclei per unit area $N_T$ is determined from

$$N_T = \frac{\rho l N_A}{A} \approx 3.0066 \times 10^{-10} \text{ nb}^{-1},$$

where $l = 16.0 \text{ cm}$ is the target length, $\rho = 0.1249 \text{ g/cm}^3$ is the density of liquid $^4\text{He}$, $A = 4.0026 \text{ g/mole}$ is its atomic weight, and $N_A = 6.022 \times 10^{23}$ atoms/mole is Avogadro’s number.

The photon yield $N_\gamma$ was obtained from the tagger hits using the GFLUX analysis package [20]. This number is corrected for the data-acquisition dead time. The angle-integrated cross section as a function of photon energy is shown in Fig. 15 in linear and logarithmic scales. The logarithmic plot was fitted with an $A e^{-B E_\gamma}$ functional form with $A = 1.35 \mu\text{b}$, and $B = 7.8 \text{ GeV}^{-1}$. It is remarkable that the total cross section follows an exponential fall-off so closely, over the entire energy range from 0.4 to $\sim 1.0 \text{ GeV}$, flattening somewhat only above this energy, where forward angles dominate.

The measured differential cross sections are shown in Figs. 16 and 17 as functions of photon energy and proton-scattering angles, respectively. These plots show that the peak of the angular distributions shifts slightly toward smaller angles with increasing photon energy.

### B. Systematic uncertainties

Table III summarizes the systematic uncertainties. The uncertainty in the photon-flux determination, including the tagger-efficiency evaluation, is taken from the g3a analysis of Niccolai et al. [6]. The value of the target density given in the literature was used; its uncertainty is no larger than 2%. The uncertainties due to the fiducial cuts are estimated and have been found to be negligible.

The systematic uncertainty due to the CLAS acceptance was obtained by comparing the cross sections measured by each pair of the CLAS sectors independently (i.e., the data from sectors 1 and 4, 2 and 5, and 3 and 6 were combined). The mean deviation between the three sets of cross sections is considered to be an estimate of the systematic uncertainty for the CLAS acceptance.

To estimate the systematic uncertainty due to applying the kinematic cuts, two sets of altered cuts, loose and tight, were used and compared with the nominal cuts. The rms of the distribution of the differences between the cross sections obtained with loose, tight, and the nominal cuts is considered to be a measure of the systematic uncertainty due to these cuts.

The CLAS acceptance and kinematic cuts contribute the largest part of the systematic uncertainty. The individual systematic uncertainties are summed in quadrature to less

PHOTODISINTEGRATION OF $^4$He INTO $p + t$

PHYSICAL REVIEW C 80, 044603 (2009)

FIG. 15. (Color online) Total angle-integrated cross section as a function of $E_\gamma$ in linear (top) and logarithmic (bottom) scales. Error bars indicate statistical uncertainties. The logarithmic plot was fitted with an $Ae^{-bE_\gamma}$ functional form with $A = 1.35$ µb, and $b = 7.8$ GeV$^{-1}$.

than 15%. The statistical uncertainties for the results usually dominate the systematic uncertainties.

V. DISCUSSION AND SUMMARY

Our bin-averaged cross sections are compared in Figs. 18 and 19 with the latest model calculations by J.-M. Laget [8]. Figure 18 shows the cross sections as a function of proton-scattering angle in the c.m. frame for four energy bins, centered at 0.6, 0.8, 1.0, and 1.2 GeV. Each energy bin is 100-MeV wide.

In general, for all photon-energy bins, our data are in qualitative agreement only with the calculations that include three-body mechanisms, confirming the importance of the contribution of three-body mechanisms at these energies. At 0.6 and 0.8 GeV, our data are higher than the calculations between $60^\circ$ and $100^\circ$ and between $60^\circ$ and $80^\circ$, respectively. Our data are consistent with the three-body calculations at large angles for all photon-energy bins. However, at the higher of these energies, and at small proton angles, there are discrepancies between the data and the results of the calculations. This disagreement at the most forward angles at higher energies might result from either of two factors:

(i) Off-mass-shell effects might become significant when the energy increases. Although the elementary electromagnetic operator (the coupling of the photon to the nucleon) used in this model is the fully relativistic version of the coupling of the photon to an
on-mass-shell nucleon, the actual photon energy that enters the amplitude is not the same as the photon energy when the target proton is at rest. The difference between the two energies increases with the photon energy. This is a well identified problem that still has no definite solution.

(ii) The previous drawback is less severe for the three-body amplitude that dominates at large angles. Here, the momentum transfer is shared between the three nucleons and one probes mainly the low-momentum components of the $^4$He wave function. Also, the amplitude depends mainly on the elementary processes, where the nucleons are mostly on-shell.

The cross sections are shown in Fig. 19 as a function of photon energy for three angular bins centered at 60°, 90°, and 120°. Each angular bin is 10° wide. Comparison with Fig. 5 shows that the trend of the data and calculations are very similar. However, there is a clear difference between the relative strength of the two- and three-body contributions with respect to the one-body contribution shown in the two plots. This is because the earlier version of the Laget model [7] used the AV14 potential [21]. This version included fewer high-momentum components than the newer version, which uses AV18 [10]. Comparison shows that in general our data stand above all the curves, especially at 90° and 120°, but qualitatively are in good agreement with the calculations.

Figure 19 also shows some of the earlier experimental data from the Saclay group [2] and the MIT group [4], compared with the results of this experiment. There is a very limited overlap in the photon-energy range between our data and the older data from Saclay. The range of the overlap is from 423 to 430 MeV for 60°, and from 357 to 369 for 90°, and there is no overlap at all between our data and older data from MIT. The comparison shows a continuous trend with increasing photon energy for the previous data to lie below our data in the overlap region. The CLAS acceptance evaluation and the photon flux normalization were checked and found reliable within the quoted uncertainties based on cross section measurements of other processes. In particular, for this experiment the cross sections of the three-body photodisintegration of $^3$He [6] have been measured.
In summary, we have measured the differential cross sections for the $\gamma^4\text{He} \rightarrow p+t$ reaction in the energy range from 0.35 to 1.55 GeV, for proton center-of-mass scattering angles between 40° and 140°. It is important to emphasize that the interpretation of these data is model dependent. We have compared them with the results of the only available theoretical calculation at these energies [8]. The comparison between our data and the Laget model indicates a significant contribution of the three-body mechanisms, especially in the energy region of 0.6–0.8 GeV, at large momentum transfer. At this kinematics, the model calculation is less uncertain, since it depends on the low-momentum components of the $^4\text{He}$ wave function and elementary processes where the nucleons are mostly on-shell. Our conclusion about the importance of three-body mechanisms to the reaction amplitude is in agreement with the results of our previous study for $^3\text{He}$ [6]. These data are important for understanding the reaction mechanisms and for developing models of this process for photon energies above 0.4 GeV, and even more important for understanding and appreciating the importance, in the relevant range of energy and wavelength, of strong many-body forces in nuclei.

ACKNOWLEDGMENTS

We would like to acknowledge the outstanding efforts of the staff of the Accelerator and the Physics Divisions at Jefferson Lab that made this experiment possible. This work was supported by the US Department of Energy under Grant No. DE-FG02-95ER40901, the National Science Foundation, the Italian Istituto Nazionale di Fisica Nucleare, the French Centre National de la Recherche Scientifique, the French Commissariat à l’Énergie Atomique, the Korean Science and Engineering Foundation, and the UK Science and Technology Facilities Council (STFC). The Southeastern Universities Research Association (SURA) operated the Thomas Jefferson National Accelerator Facility for the US Department of Energy under Contract No. DE-AC05-84ER40150.
