# Quantifying and Stratifying the Spatial Patterns of Residential Clusters: A Socioeconomic and Geographic Comparisons of Metropolitan Areas 

by

Myoung-Gu Kang

Submitted to the Department of Urban Studies and Planning on May 17, 2001 in Partial Fulfillment of the Requirements for the Degree of Master in City Planning

#### Abstract

What activities are located where and why? This is a fundamental question in urban studies, which should be answered before planning. In urban economics, fine mathematical models have been developed and have provided an internally consistent economic framework for answering these questions. However, as cities grow and get larger, the spatial structure of cities has changed and become increasingly complicated. The emergence of sub-centers and socioeconomically distinct clusters within the metropolitan areas weaken the assumptions on which the urban economic models are based. Also, there are increasing needs of the people and space interaction models at the micro level, or neighborhood level. This thesis revisits this fundamental issue in a different way. In particular, it investigates the spatial patterns of residents within the metropolitan areas at the census blockgroup level, using Database Management Systems (DBMS) with Structured Query Language (SQL), Geographic Information Systems (GIS), and statistical methods including factor analysis and cluster analysis.

What socioeconomic factors make one type of neighborhood different from another within the metropolitan areas? This thesis finds four common socioeconomic factors; baseline factor, children factor, income factor, and age factor. Baseline factor shows that the major generic whites are, roughly speaking, more likely to be citizens, to speak only English at home, to drive to work, not to be poor, to own homes, and to live in the lower population density areas. These above variables move synchronously, so we can reduce them into one factor which we have abbreviated as the 'baseline factor'. Using the same factor analysis, we developed the four such socioeconomic factors above.

Then, I investigate where they are located? In all four metropolitan areas there are wedges of clustered neighborhoods with similar socioeconomic characteristics around the urban center. Each section contrasts with each other, for example, rich versus poor, or white versus non-white. Younger people formed their own wedges, too. Second, the downtown and subcenters, where the jobs are located, are more likely occupied by non-whites or low income individuals. So, they also appear along the circumferential highway corridor where the subcenters are located.

In addition to the common pattern over all metropolitan areas, each metropolitan area also has its own peculiar characteristics. In the Boston Metropolitan Area, the delineation of socioeconomically different neighborhoods coincides with town boundaries. That is, the characteristics of neighborhoods are discrete rather than continuous over the space. In the Chicago Metropolitan Area, the percentage of citizens is another key factor differentiating neighborhoods, and, hence, noncitizens occupy a separate cluster. The unique geography of the San Francisco Metropolitan Area creates two stark types of neighborhoods; affluent neighborhoods at the west of the bay along the ocean, and poor neighborhoods at the east of the bay, especially at the entering points of the bridges to the downtown. In Dallas Metropolitan Areas, the geographic contrast between rich and poor neighborhoods are clearer, i.e., the northern area is wealthier while the southern area is poorer.

In this thesis, I find the key socioeconomic factors characterizing the neighborhoods and the spatial pattern of residents. Also, I developed a different methodology to look at this issue. This study gives us a foundation for micro level urban simulation modeling by providing a systematic method of quantifying neighborhood characteristics in ways that can be incorporated into economic models. Furthermore, we can analyze the urban structure of diverse land uses over space and time simultaneously. This can make participatory planning far easier by supplying a clear picture of a city's profile, stimulating communications, and facilitating understanding among residents.

Thesis Supervisor: Joseph Ferreira, Jr.
Title: Professor of Urban Planning and Operations Research

## ACKNOWLEDGMENTS

I deeply appreciate my thesis advisor, Professor Joseph Ferreira, Jr., for his invaluable guidance throughout the study.

I am also greatly indebted to Anne Kinsella Thompson, Mizuki Kawabata, Michael Shiffer, Qing Shen, Phillip Thompson, Thomas Grayson, and the entire Planing Support Systems Group (PSS) for helping me develop the ideas and providing a heartwarming atmosphere.

I want to say thanks to my friends and faculty in DUSP for helping me shape my ideas and providing emotional support.

Especially, I would like to thank my wife, Mihyun Kim, and my son, Minqu Simon Kang as well as my parents for their love and understanding.

## 1

## INTRODUCTION

We must understand cities as much as possible before planning. Urban economics sheds light on the urban spatial structure and gives us a better understanding about how cities work. Now, thanks to today's high technology and computation capacity - including Geographic Information Systems (GIS), Statistics, and Database Management Systems (DBMS) - and rich datasets like the U.S. Census, we can approach our cities with attention to spatial detail beyond that of traditional abstract and spatially aggregated urban economic models. This bottom-up way of research is essential to develop a micro level urban simulation model for participatory planning. It will help practitioners and residents understand their cities and planning, and hence will enrich the communication between them.

I hypothesize that there are socioeconomically distinct neighborhoods within metropolitan areas: similar neighborhoods generally tend to agglomerate geographically with locational preferences, and unlike the traditional urban economic models suggest, they are less likely to be located in circumferencial
distribution.

As cities have grown, urban economists have developed theories to understand the internal structure of cities. With the urban economic models, we learn about where people live, where firms and retail stores are located, how housing and real estate markets work, how we can improve our cities, etc. The theories have given us a concise and clear picture of the internal structure of cities. The simple and powerful models successfully simplify the entangled interactions between people, and between people and spaces. However, most urban economic models are built based on three critical assumptions: one dimensional space, smooth transition over distance, and a predefined city center point.

### 1.1 Three Issues in Urban Economics with Space

Urban economic models generally, Implicitly or explicitly, assume that space is a "line" and hence, interpret a "circular" city on two dimensional space. That is, the models only allow circular distribution, like a circle or donut, but don't allow "holes" or "wedges". However, we can easily find the "holes" and "wedges" in metropolitan areas. It is hard to explain the non-circular patterns with the traditional linear city models even though the models illustrate the overall structure of cities well with density and land value declining with destance from
the 'center.' (Figure 1.1)

Figure 1.1 Linear city and two dimensional space

Furthermore, subcenters within metropolitan areas stand out these days, so understanding the role of the subcenters is becoming important for planning and transportation. Controlling these subcenters relates to whether urban growth is sprawl or sound development. We observed the fact that the sizes of cities have grown bigger and more people and industries tend to live away from the traditional city center. In many cases, however, the urban fringes have developed independently. Therefore, new developments are not consistent with other land usages, either new or old. Urban economists take the traditional view
and try to explain it with linear city models. The two dimensional distance issues arise here again. In Figure 1.2, point $D$ on the linear city cannot easily be intepreted as point G or even H or J. If we have more subcenters, like today's metropolitan areas, these issues become complicated.

Figure 1.2 Distance issue of linear city with a subcenter

Secondly, we assume that the transition over distance is smooth. For example, as the distance increases, rent goes down smoothly, population density goes down smoothly, and so on. In Figure 1.3, we can see the overall trend of the smoothly decreasing population density away from CBD. However, the flattening slope and the emergence of subcenters requires a different approach beyond
traditional urban economics. Again, the subcenters become more important to explain the internal structure of cities.

Figure 1.3 Population Density by Blockgroup in Boston Metropolitan Area

Source: U.S. Bureau of the Census, 1990 Census of Population and Housing, Summary Tape File 3

Thirdly, we have traditionally treated the center of a city as a fixed point. The assumption is closely related to the level of geographic aggregation. Considering the city of Boston merely as a point would definitely be a reasonable proxy when
we do a national level of study, or beyond. However, for example, when we do research on the residential distribution within the Boston metropolitan area, the city of Boson is too big to be a point, or even an entity. Maps in the following chapters illustrate this point.

Urban economics has done an effective job in shedding light on the internal urban sturucture. Today's high technology and computation capacity - GIS, Statistics, and DBMS - and rich dataset like the U.S. Census, allow us to go further, beyond the current limit of urban economics. Therefore, I take a bottomup approach to examine the spatial patterns of residential clusters utilizing modern technology.

### 1.2 Methodology

In this thesis, I am trying to measure the residential pattern of cities as it is on two dimensional space. First of all, I will classify the neighborhoods ${ }^{1}$ by their
${ }^{1}$ In this thesis, I will use Census blockgroup as a unit of analysis, and call it neighborhood. Census blockgroup has quite good characteristics to be a homogeneous community and is the most detailed and richest data set I can use. (See Appendix for more detail information about Census Blockgroup)
socioeconomic characteristics. What are the effective factors which make them different from each other? How many different clusters do the metropolitan areas have? The combination of factor analysis and cluster analysis is a good tool to answer these questions. Secondly, I pose the following questions: Where are they located? Are similar neighborhoods located closely to each other? I will use GIS and draw maps of the residential distribution patterns for each metropolitan areas. All of the above procedures require intensive use of DBMS.

Conventionally, multiple linear regression analysis is used most frequently in quantitative modeling. However, the attendant problems of nonlinearities and interactions, multicollinearity, functional heterogeneity, and heteroscedasticity can severely degrade the accuracy of the estimates.

Some of these problems can be reduced by stratifying or clustering the data into more homogeneous subgoups, each of which is treated as separate independent data base for the purpose of regression modeling. The cluster analysis can be modified to accomplish such data base segmentations.

We can use factor analysis to adjust the variable interactions. The basic idea of factor analysis is finding few principal latent factors to explain complicated phenomena. This statistical method has been widely used in fields where factors cannot be manipulated, such as psychology.

In this research, I first do the factor analysis to extract the few principal latent factors out of the eighteen socioeconomic characteristics of residents, which differentiate the neighborhoods within metropolitan areas. I next perform a cluster analysis to stratify the neighborhoods into fewer groups of the socioeconomically similar neighborhoods with the factors extracted from factor analysis. Third, I input the result of statistical analysis into GIS, and draw a map of spatial patterns of residential clusters in order to answer whether or not similar neighborhoods are located near one another.

### 1.3 Study Areas and Data

In this cross-sectional analysis, I look into four metropolitan areas and compare their characteristics: Boston, Chicago, San Francisco, and Dallas. Each of these areas are selected to represent the four subregions of the Unites States: Northeast, Midwest, West, and South. I use 1990 Census STF 3A by the U.S. Census Bureau, Census Transportation Planning Package (CTPP) by Bureau of Transportation Statistics, and digital maps by Environmental Systems Research Institute, Inc. (ESRI).

I select eighteen socioeconomic variables from the Census to identify the characteristics of each neighborhood, including population density, racial
composition (percent white), percent of children, percent of old, percent of students in secondary school or under, percent of citizenship, household size, language used at home, percent of bachelor's degree or higher, primary transportation mode to work, travel time to work, unemployment rate, labor force participation rate, household income, income per capita, source of income (percent of workers receiving wage and salary), percent of residents under the absolute poverty level, and home ownership rate.

Table 1.1 Brief Summary of the Four Metropolitan Areas

|  | Number of <br> Blockgoups | Area of <br> Land $\left(\mathrm{Km}^{2}\right)$ | Total <br> Population | Income per <br> Capita |
| :---: | :---: | :---: | :---: | :---: |
| Boston, MA * | 3,419 | $6,564.9$ | $3,867,738$ | 18,690 |
| Chicago, IL | 6,222 | $11,363.4$ | $7,326,291$ | 16,736 |
| San Francisco, CA | 4,679 | $18,749.3$ | $6,230,376$ | 19,664 |
| Dallas, TX | 3,510 | $17,968.1$ | $3,884,004$ | 15,904 |

$\dagger$ The Census blockgroups having no population, no household, and no workers have been excluded. (See Appendix for more detail information.)

* The error of 1990 Census STF3A of Boston has been fixed.

## e 1.2 Variables of Socioeconomic Characteristics of Residents

| Variable Name | Variable Definition | Related Census Table | Relat Census |

## QUANTIFYING and STRATIFYING RESIDENTIAL CLUSTERS in BOSTON METROPOLITAN AREA

There are 3.9 million people in the Boston Metropolitan Area as of $1990^{1}$. The average population density is 589 persons per square kilometer (1,525 persons per square mile). The white population is 3.4 million, which is 88 percent of total population. That is, roughly speaking, nine out of ten people in the Boston Metropolitan Area are white. This is higher than the United States average of 80 percent. 22 percent of the population is under 18 years old, which is less than the United States average of 26 percent. 13 percent of the population is 65 years and over. The adults having bachelor's degree or higher degree out of people aged 25 years and over is 31 percent, which is far greater than the U.S. average of 20 percent.

[^0]Table 2.1 Comparison of U.S. and the Four Metropolitan Areas

|  | U.S. ${ }^{*}$ | Boston | Chicago | San Francisco | Dallas |

* Source: U.S. Bureau of the Census, 1990 Census of Population and Housing, Summary Tape File 1. The study areas are based on the selected blockgroups which come from U.S. Bureau of the Census, 1990 Census of Population and Housing, Summary Tape File 3
** January 1991 CPI; North Eastern Urban, Chicago CMSA Urban, San Francisco CMSA Urban,
and South Urban for all Items. Base period 1982-84 = 100
${ }^{* * *}$ Here, $I$ calculate a radius as a simple measure of geographic size. $V$ is the angle of available wedge, i.e., Area $=\left[(V / 360)^{*} p^{*} R^{2}\right]$. So, $R=\left[(360 / V)^{*}(\text { Area } / p)\right]^{1 / 2}$.

The median household income of the Boston Metropolitan Area was much higher than the U.S. average. The nominal median household income of Boston is 42,000 dollars, which is 40 percent higher than that of U.S. Even though I adjust the nominal income with the Consumer Price Index (CPI), Boston households earn 34 percent more than the U.S. average. The percent of people who are under absolute poverty threshold was 8.4 percent, which is also far less than the United States average of 13.1 percent. The percent of people having bachelor's degree or a higher degree is much higher than the U.S average, and about one out of three adults 25 years or older living in the Boston Metropolitan Area, had college or higher level of education.

### 2.1 What Latent Factors Differentiate Neighborhoods?

Factor analysis is a statistical approach that can be used to analyze interrelationships among a large number of variables and to explain these variables in terms of their common underlying dimensions (factors). Factor analysis is a way of condensing the information contained in a number of original variables into a smaller set of dimensions (factors) with a minimum loss of information.

Factor analysis is especially useful in social science, where there are no obvious fundamental variables as in physical science, and also no way of performing laboratory experiments to keep selected variables constant. Thus, we can start with what may be a rather arbitrary selection of characteristics and reduce them to a formally fundamental set of factors. This concept is based on the principles of parsimony. Or, in many cases, we interprete the newly sorted variables as a fundamental underlying, or latent, forces dictating the observable social phenomena.

For example, one can summarize the correlation between two variables in a scatterplot. A regression line can then be fitted that represents the "best" summary of the linear relationship between the variables. If we could define a
variable that would approximate the regression line in such a plot, then that variable would capture most of the "essence" of the two items. Subjects' single scores on that new factor, represented by the regression line, could then be used in future data analyses to represent that essence of the two items. In a sense we have reduced the two variables to one factor. Note that the new factor is actually a linear combination of the two variables.

The example described above, combining two correlated variables into one factor, illustrates the basic idea of factor analysis, or of principal components analysis. If we extend the two-variable example to multiple variables, then the computations become more involved, but the basic principle of expressing two or more variables by a single factor remains the same.

After we have found the line on which the variance is maximal, there remains some variability around this line. In principal components analysis, after the first factor has been extracted, that is, after the first line has been drawn through the data, we continue and define another line that maximizes the remaining variability, and so on. In this manner, consecutive factors are extracted. Because each consecutive factor is defined to maximize the variability that is not captured by the preceding factor, consecutive factors are independent of each other. Put another way, consecutive factors are uncorrelated or orthogonal to each other.

Note that as we extract consecutive factors, they account for less and less
variability. The decision of when to stop extracting factors basically depends on when there is only very little "random" variability left. The nature of this decision is arbitrary; however, various guidelines have been developed. First, we can retain only factors with eigenvalues greater than 1. In essence this is like saying that, unless a factor extracts at least as much as the equivalent of one original variable, we drop it. This criterion was proposed by Kaiser (1960), and is probably the one most widely used. Second, A graphical method is the scree test first proposed by Cattell (1966). We can plot the eigenvalues in ascending order in a simple line plot. Cattell suggests to find the place where the smooth decrease of eigenvalues appears to level off to the right of the plot. To the right of this point, presumably, one finds only "factorial scree" -- "scree" is the geological term referring to the debris which collects on the lower part of a rocky slope. Both criteria have been studied in detail (Browne, 1968; Cattell \& Jaspers, 1967; Hakstian, Rogers, \& Cattell, 1982; Linn, 1968; Tucker, Koopman \& Linn, 1969). Using this general technique, the first method (Kaiser criterion) sometimes retains too many factors, while the second technique (scree test) sometimes retains too few; however, both do quite well under normal conditions, that is, when there are relatively few factors and many cases. In practice, an additional important aspect is the extent to which a solution is interpretable.

The extraction of principal components amounts to a variance maximizing (varimax) rotation of the original variable space. We could rotate the axes in any
direction without changing the relative locations of the points to each other; however, the actual coordinates of the points, that is, the factor loadings would of course change. For example, in a scatterplot we can think of the regression line as the original X axis, rotated so that it approximates the regression line. This type of rotation is called variance maximizing because the criterion for (goal of) the rotation is to maximize the variance (variability) of the "new" variable (factor), while minimizing the variance around the new variable

Using the above set of factor analysis, I standardize the description of neighborhoods, which in turn should allow for comparisons between different neighborhoods on a common basis. We can see if the fundamental factors are the same for each neighborhood. In addition, we can calculate factors which are independent, and can be used as basic variables for another model, such as cluster analysis and multiple regression analysis.

In the Boston Metropolitan Area, four principal components of the 18 variables explain 71.4 percent of total variation. In other words, we reduced the variables by 22.2 percent ( 18 to 4 ), but they can still explain 71.4 percent of variations across all blockgroups. As we shall see, examination of the four principal components suggests that they focus on baseline, children, income, and age in order of importance.

## Figure 2.1 Scree Plot (Boston)

Table 2.2 Percent of variance explained by factors (Boston)

|  | Initial Eigenvalues |  |  | Rotation Sums of Squared Loadings |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Comp. | Total | \% of Var. | Cumul. \% | Total | \% of Var. | Cumul. \% |
| 1 | 5.871 | 32.618 | 32.618 | 4.681 | 26.006 | 26.006 |
| 2 | 3.486 | 19.364 | 51.982 | 3.216 | 17.868 | 43.874 |

| 4 | 1.293 | 7.184 | 71.408 | 2.314 | 12.855 | 71.408 |

* Extraction Method: Principal Component Analysis.

If all the original variables were perfectly independent ideally, the eigen values of each variables would be one and each variable would explain 5.5 percent of the total variation. We would then need all of the variables to explain the differences among neighborhoods. In actuality, however, many observable characteristics are correlated with each other. A single cause can make them move synchronously, or they move to the same direction by chance. Because they vary simultaneously, we can reduce the number of variables according to principles of parsimony.

In Table 2.3, each coefficient in each cell in the component matrix represent the load, in both magnitude and direction. The square of each coefficient shows the percent of loading of each variables on the extracted principal components, i.e., 0.731 means Component 1 is loaded by 53.4 percent of the variation of the population density (POP_DEN). The negative sign indicates a negative relationship between the original variables and the component. That is, neighborhoods having higher scores of Component 1 are less dense areas.

In addition, the composition of components shows the relationship among original variables. For example, we can say that white people tend to live in lower density neighborhoods because a higher score of Component 1 arise in blockgroups with lower density (POP_DEN -0.731) and higher percentage of white people (WH_PCT 0.779) at the same time.

* Extraction Method: Principal Component Analysis. Rotation Method: Varimax with Kaiser Normalization. Rotation converged in 6 iterations.
** The shaded cells represent main loads to each component. They are the largest load out of each row and not less than 0.6 , i.e. at least 36 percent of the variation of each variable $\left(0.6^{2}=\right.$ $0.36)$.
**** The shaded variables (leftmost column) tend to evenly spread across the components instead of focusing on a specific component.

The most important factor of the Boston Metropolitan Area is Component 1, called 'Baseline Factor'. In Boston, this Baseline Factor consists of the seven variables out of eighteen variables. ${ }^{2}$ The variables move at the same time, i.e., higher score of Baseline Factor means; higher percent of white, lower population density, higher percent of citizenship, higher percent of english speaking households at home, higher percent of driving to work, lower percent of the absolutely poor population, and higher percent of home ownership in the neighborhood. The compositions of principal components are a little different from each Metropolitan Areas, as you will see in the following chaper.

By itself, this factor explains 26 percent of the total variation among neighborhoods across all 18 variables. High value of this factor apply to neighborhoods of not poor white citizens speaking only English at home, owning a home, living in low density area, and driving to work. Low values arise in neighborhoods of poor non-white foreigners speaking a language other than English at home, not owning a home, living in high density area, and not driving to work.

[^1]The Children Factor is the second most important factor in the Boston Metropolitan Area. Component 2 shows a similar patterns of variation in the percent of children, the percent of students attending secondary school or below, and the percent of households having three and more members. So, Component 2 represents children and family characteristics which are independent from other factors (geometrically perpendicular). It explains 18 percent of overall variation. For example, if a neighborhood has a higher children factor, it tends to have more kids, more students, and more household members.

Third, education and income vary among neighborhoods independently from other socioeconomic variables. The coefficients suggests, if more people have bachelor's or higher degree, the people in the neighborhood tend to have higher household income and personal income per capita. As you notice, both higher education and income go in same direction, i.e., higher educated people have higher income. It explains 15 percent of the total variations.

The last important delineating factor of the Boston Metropolitan Area is what we call 'age' consisting of percentage of old population and percentage of labor force participation. The Component 4 is bigger if a neighborhood has less old population, more workers, and more people whose income source is wage or salary. It explains 13 percent.

In total, all the above four principal factors explain 71.6 percent of variations
among neighborhood characteristics in the Boston Metropolitan Area in 1990.

Interestingly, the average travel time to work and unemployment rate are not important component of our socioeconomic factors. Both of them are dispersed in many components, so they don't form independent components. This means that the variation of both of them among neighborhoods are not significantly different compared to other socioeconomic variables. The correlation coefficients between average travel time to work (or unemployment rate) and other variables are also smaller that other coefficients. In other words, the covariance between average travel time and percentage of people driving to work, for example, is weaker than the covariance between percentage of whites and percentage of people driving to work.

### 2.3 Stratification of Neighborhoods

In order to classify the neighborhoods, I use cluster analysis based on the four independent factors extracted by the factor analysis in the previous section. Cluster analysis is a multivariate analysis technique that seeks to organize information about cases or variables so that relatively homogeneous groups, or "clusters," can be formed. The clusters should be internally homogenous and externally heterogeneous. In other words, members in a cluster are similar to one another in the same group, and members are not like members of other groups.

The joining or tree clustering method uses the dissimilarities or distances between objects when forming the clusters. These distances can be based on a single dimension or multiple dimensions. For example, if we were to cluster fast foods, we could take into account the number of calories they contain, their price, subjective ratings of taste, etc. The most straightforward way of computing distances between objects in a multi-dimensional space is to compute Euclidean distances. If we had a two- or three-dimensional space this measure is the actual geometric distance between objects in the space (i.e., as if measured with a ruler). We can use actual real distances, or some other derived measure of distance that is more meaningful to the researcher.

In this thesis I use Ward's method. This method uses an analysis of variance
approach to evaluate the distances between clusters. In short, this method attempts to minimize the Sum of Squares (SS) of any two (hypothetical) clusters that can be formed at each step. (Ward, 1963). In general, this method is regarded as very efficient.

Cluster analysis presents the problem of how many clusters to keep. Yet, no widely accepted statistical method to determine the number of clusters has developed. However, we can use $\mathrm{R}^{2}$ to decide a reasonal number of groups. For example, we can classify all neighborhoods into two groups, then we can measure $R^{2}$ taking the variance between the groups (explaned portion by the clustering) divided by the total variance among all neighborhoods. We can again calculate $\mathrm{R}^{2}$ with three groups, and so on. $\mathrm{R}^{2}$ would be 0 (zero) with no classification because there is no explanation. If we use the same number of groups as many as the number of neighborhoods, $\mathrm{R}^{2}$. would eventually be one because we treat each blockgroup as each particular group.

As we use more number of groups, $R^{2}$ increases, but the increment of $R^{2}$, generally speaking, decreases. So, there is a trade-off: number of groups vs. explanation power. In other words, we need to decide the smaller number of groups with a minimum loss of explanation power. In this thesis, I decided number of clusters when $R^{2}$ is between 0.7 and 0.8 , which means the classification explain 70 or 80 percent of the total variation.

Table 2.4 Types of Neighborhoods (Boston)

| Type | Factor | Minimum | Maximum | Mean | Std. Deviation |
| :---: | :---: | :---: | :---: | :---: | :---: |

* The shaded cells are selected by author to highlight the characteristics of each cluster.

In the Boston Metropolitan Area, I find there are four distinct types of neighborhoods. Type A is a typical white neighborhood having a slightly higher score of the Baseline factor. That is, major whites in Boston are generally citizens living in lower density neighborhoods and driving to their workplaces. This type of neighborhoods look like the typical suburban neighborhoods of the Boston Metropolitan Area. 55 percent of the neighborhoods are in this category.

Another group of neighborhoods (Type B) has a non-white younger labor force whose family size is small. 15.4 percent of neighborhoods are in this category. The third type of residents are non-white with many children (13.3 percent). The last unique type of neighborhoods are highly educated people whose income is high.

### 2.4 Where are the Clusters?

The socioeconomic clustering reveals the locational preferences of residents on the map. First of all, as indicated, socioeconomically similar neighborhoods are geographically close to each other. (Figure 2.2) That is, they tend to agglomerate.

Typical white citizens (type A) live in surburban area of the Boston Metropolitan Area. This type of neighborhood comes the majority of the Boston Metropolitan Area; 55 percent of neighborhoods. These are the generic neighborhoods in Boston. Generally, young workers tend to have less children and live near the city, including nothern Boston, Cambridge, Somerville, and the western area along the Interstate Highway 90 which has many jobs. Non-whites with many children live in downtown Boston, Lowell, Lawrence, or subcenters around Interstate Highway 495. Highly educated people earning higher income mainly
live in the western suburban area of Boston.

Interestingly, the edges of the neighborhood agglomeration match the town boundaries. Considering the fact that the city/town governments have the authority to decide the school quality, property tax rate, zoning, etc., the relationship between neighborhood characteristics and municipal government would be another topic for further research.

Non-whites with many children live in the downtowns of cities, but their average time to work is not less than that of other areas. In a simple monocentric city model of urban economics, downtown residents should have more benefit of transportation than suburban residents. It is another possible topic that should be examined in terms of location choice in the future. ${ }^{3}$

## 3

## CHICAGO, SAN FRANCISCO and DALLAS ${ }^{1}$

In this chapter, three more metropolitan areas are examined; Chicago (IL CMSA), San Francisco - Oakland - San Jose (CA CMSA), and Dallas - Fort Worth (TX CMSA). What are the factors which delineate the neighborhoods in each metropolitan areas? Are the factors similar across the metropolitan areas? What are the common factors? How about the geographical distribution of each metropolitan area? Do they show identical preferences or different preferences across the metropolitan areas? I use the same methodology and basic criteria to look at these metropolitan areas as applied in the Boston Metropolitan Area.

[^3]
### 3.1 Chicago Metropolitan Area

Chicago has about twice bigger land and population ( $11,363 \mathrm{~km}^{2}$ and 7.3 million population) than Boston has ( $6,565 \mathrm{~km}^{2}$ and 3.9 million population). The average population density is 644.7 persons per square kilometer, quite similar population density to that of Boston Metropolitan Area (589 persons per square kilometer). The percent of whites is 70.9 percent, which is less than the U.S. average (80.3 percent). The household income ( 38,501 dollars) and income per capita (16,736 dollars) are greater than those of the the United States average ( 30,056 dollars and 14,420 dollars, respectively).

Using the same methodology as I did on the Boston Metropolitan Area, I identified five key factors in Chicago Metropolitan Area: Baseline factor, children factor, income factor, age factor, and citizenship. Roughly speaking, we have a similar set of underlying factors in the Chicago Metropolitan Area as in the Boston Metropolitan Area, except the percent of the English speaking citizens.

Like the Boston Metropolitan Area, baseline factor is the most important factor of the Chicago Metropolitan Area. This component consists of; population density (), percent of white (+), driving to work (+), unemployment rate (-), percent of
absolutely poor people (-), and home ownership (+). That is, a higher score of this factor means; lower population density, higher percent of white, more driving to work, lower unemployment rate, lower percent of absolutely poor residents, and more home owners.

Second, children and household size relates to the location of residents in Chicago Metropolitan Area even though simple correlation coefficients show that the correlations between the percent of children and the other variables are not large.

The third important factor is education and income. These two variables move the same way, i.e., highly educated people generally get higher income. The fourth factor is the percent of younger labor force.

The fifth factor is percentage of non-citizen population. It is unique in the Chicago Metropolitan Area. As you will see, Dallas has the same non-citizen factor.

Table 3.1 Rotated Component Matrix (Chicago)

|  | Component 1 Baseline Factor (22.3 \%)** | Component 2 <br> Children Factor <br> (17.6 \%) | Component 3 Income Factor (16.0 \%) | Component 4 <br> Age Factor <br> (12.5 \%) | Component 5 Citizen Factor (12.0 \%) |

| POV_PCT | -0.737 | 0.247 | -0.364 | -0.272 | -0.013 |
| OWN_PCT | 0.738 | 0.204 | 0.366 | -0.053 | 0.226 |

* Extraction Method: Principal Component Analysis. Rotation Method: Varimax with Kaiser Normalization. Rotation converged in 8 iterations.
** Variance Explained by the component.
*** The shaded cells represent main loads to each component. They are the largest load out of each row and not less than 0.6 , i.e. at least 36 percent of the variation of each variable $\left(0.6^{2}=\right.$ 0.36 ).
**** The shaded variable (leftmost column) tends to evenly spread across the components instead of focusing on a specific component.

With these five factors, I do cluster analysis on Chicago Metropolitan Area. I find that threre are five clusters in Chicago Metropolitan Area: generic white neighborhoods as background (Type A), the young high-income neighborhoods with less children (Type B), non-white poor citizens' neighborhood (Type C), highly educated high-income neighborhoods (Type D), and non-citizen neighborhoods with many children (Type E).

In the Chicago Metropolitan Area, highly educated high income people formed their neighborhoods and are located at the northern part and around the West near the intersections of major highways.

Young labors with less children tend to agglomerate at the Nothern part along the lake side or at the suburban area.

Even though the land is physically much flatter than Boston Metropolitan Area, we see clear "wedges" at least in the inside of the inner interstate highway. Beyond the inner interstate highway, we see some mixture pattern of neighborhoods instead of continuous and homogeneous circumferential pattern which is almost always assumed in the traditional urban economic model. Therefore, social factors affect people's choice of residential location at least as much as economic factors do. Furthermore, the combined effects - not a single effect - are necessary for us to understand the land use correctly, which is not easily captured in the multivariate regression analysis.

As you will see again, the socioeconomically similar neighborhoods generally tend to be located close to similar neighborhoods in the Chicago Metropolitan Area.

Notice that each factor alone is not enough to tell the characteristics of the types of neighborhoods. As you see in the cluster anlaysis, for example, a 'combination' of the percent of children and other variables define a neighborhood's characteristics. There are a group of neighborhoods in which noncitizens speaking a language other than English at home with more children live. These type of neighborhoods appear at the Northwest and Southwest wedges from downtown Chicago. They also appear along the circumferential highway corridor.

## Table 3.2 Types of Neighborhoods (Chicago)

| Type | Factor | Minimum | Maximum | Mean | Std. Deviation |

|  | Citizen Factor | -4.637 | 0.810 | -1.386 | 1.129 |

[^4]
-50-

### 3.2 San Francisco Metropolitan Area

San Francisco has a land area three times larger $\left(18,749 \mathrm{~km}^{2}\right)$ than Boston ( $6,565 \mathrm{~km}^{2}$ ), but about one and a half times more population ( 6.2 millions) than Boston ( 3.9 millions). The average population density, therefore, is 332 persons per square kilometer, i.e., about a half of Boston Metropolitan Area (589 persons per square kilometer). The average percent of white people is 69.5 percent, which is less than the U.S. average, 80.3 percent. The household income (44,119 dollars) and income per capita (19,663 dollars) are greater than those of the the United States average (30,056 dollars and 14,420 dollars, respectively).

Using the same factor analysis approach as for Boston and Chicago, I identify five key factors in the San Francisco metropolitan area which can be interpreted, in order of importance, as primarily related to income, children, baseline, age, and the average travel time to work. Four of these are the same factors as the above metropolitan areas, and one factor is new which is average travel time to work.

Table 3.3 Rotated Component Matrix (San Francisco)

* Extraction Method: Principal Component Analysis. Rotation Method: Varimax with Kaiser Normalization. Rotation converged in 8 iterations.
** Variance Explained by the component.
*** The shaded cells represent main loads to each component. They are the largest load out of each row and not less than 0.6 , i.e. at least 36 percent of the variation of each variable $\left(0.6^{2}=\right.$ 0.36 ).
**** The shaded variable (leftmost column) tends to evenly spread across the components instead of focusing on a specific component.

The most important factor of the San Francisco Metropolitan Area is the income component. This component consists of; percent of highly educated people (+), median household income (+), income per capita (+), and percent of absolutely poor people (-). Higher score of this factor means; higher percent of highly educated people, higher median household income, higher income per capita, and lower percent of absolutely poor people. This component alone explain the 21 percent of total variations among neighborhoods in San Fracisco Metropolitan Area.

Second, children and household size is another distinct factor amongh neighborhoods in San Francisco Metropolitan Area. Simple correlation coefficients show very little correlation between the percent of children and the other variables. However, this factor alone explains 19 percent of the total.

The third important factor is baseline. The fourth factor is the percentage of younger labor force. Finally, the average travel time to work is a unique factor in the San Francisco.

Cluster analysis shows that there are five clusters in San Francisco Metropolitan Area: High income neighborhood, young labor force with no children, low income people spending more time to get to work, white citizens, and non-white people. As you see on the map, the neighborhoods in a same group generally tend to
agglomerate. The high income residents or young workers live at the left side of the bay along the ocean. Non-white people or poor residents live at the right side of the bay along the water. Beyond them, we can find wealthy neighborhood again, then relatively low income people appear next.

In the San Francisco Metropolitan Area, generic white neighborhoods (Type A) tend to be located in low density suburban area. Yuppies (Type B), who are young labor force with no children, appear at the Northwestern and Southwestern of downtown and left bottom side of inner bay.

Interestingly, the entering points at the East side of the bay, of the bridges to downtown, are occupied by low income neighborhoods. This could be examined in a later study. It could have been a very far fringe of the San Francisco Metropolitan Area created by the geography, "water body". The affluent residents expanded outward along the ocean side. The bridge suddenly created a new land near downtown, then low income people went there because of the access. The rich people can go a liitle further than them, then reside at the East of the bay.

We can observe the long commuting low income neighborhood clusters (Type E) at the right side of the bay in San Fracisco Metropolitan Area. These group of neighborhoods are low income people, however, spend more time to get to workplace than other groups. They tend to be located either on the outskirt of the
metropolitan area or on the right side of the bay along the interstate highway corridors.

[^5]Generally speaking, the young workers and low income people tend to live closer to the highway corridor than other residents do. The residential location of San Francisco Metropolitan Area seems more likey a mixture of the parrallel development by the sea and the circumferencial development from the downtown thanks to the bridges.

- 57 -

### 3.3 Dallas Metropolitan Area

Dallas has about three times larger land area $\left(17,968 \mathrm{~km}^{2}\right)$ than Boston $(6,565$ $\mathrm{km}^{2}$ ), but the same number of population (3.9 million) as Boston ( 3.9 million). The average population density, hence, is 216 persons per square kilometers, i.e., approximately one third of Boston Metropolitan Area (589 persons per square kilometer). The average percent of whites is 75.3 percent, which is a little bit less than the U.S. average, 80.3 percent. The percent of eldery people (65 years and over) was 8 percent, far less than U.S. average, (12.6 percent). The percent of labor force was 73 percent higher than the U.S. average ( 65.3 percent). The median household income (35,926 dollars) and income per capita (15,904 dollars) are greater than those of the the United States average ( 30,056 dollars and 14,420 dollars, respectively).

As shown in Table 3.5, I find five key factors in Dallas metropolitan area: Children, baseline, income, age, and citizenship in order of importance. These variables are consistent with other metropolitan areas.

## Table 3.5 Rotated Component Matrix (Dallas)

|  | Component 1 <br> Baseline Factor <br> $(16.1 \%)^{* *}$ | Component 2 <br> Children Factor | Component 3 <br> Income Factor | Component 4 <br> Age Factor | Component 5 |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Citizen Factor |  |  |  |  |  |

* Extraction Method: Principal Component Analysis. Rotation Method: Varimax with Kaiser Normalization. Rotation converged in 6 iterations.
** Variance Explained by the component.
*** The shaded cells represent main loads to each component. They are the largest load out of each row and not less than 0.6 , i.e. at least 36 percent of the variation of each variable $\left(0.6^{2}=\right.$ $0.36)$.
**** The shaded variables (leftmost column) tend to evenly spread across the components instead of focusing on a specific component.

The most important factor of the Dalllas Metropolitan Area is the children and household size component. Again, simple correlation coefficients show there is no correlation between the percent of children and the other variables. Nevertheless, this component alone explain the 19 percent of total variation.

The second is the baseline factor. This component consists of; percent driving to work (+), unemployment rate (-), and percent absolutely poor people (-).This component alone explain the 16 percent of total variation among neighborhoods in the Dallas Metropolitan Area.

The third important factor is education and income. In the Dallas Metropolitan Area, there is a group of white citizen neighborhoods which are located in low density suburban area. The fourth factor is the percent of younger labor force. Finally, the percent citizens explains 13 percent of the variation in Dallas Metropolitan Area.

Through Cluster analysis, we can find five clusters in Dallas Metropolitan Area: general whites, non-citizens with children, young labor force with no children, high income residents, non-white citizens. As you see on the map, neighborhoods in the same group generally tend to agglomerate. The high income residents are found at the northern part of Dallas and non-white citizens live in the southern part of Dalls. The non-citizens seems to be filling the gap
between them. Young workers without children tend to appreciate the access to the major transportation network; they live closer to major roads.

## 4

## Conclusion

In this thesis, I try to capture the socioeconomic topography of residents in metropolitan areas. As cities are evolving, the inner structures of metropolitan area are becoming more complex, different from the past, and creating new urban life. The booming emergence of subcenters, for example, changes people's lifestyle and also changes the people's location choice. Now, therefore, we need to look at the spatial structure of cities in more detailed, and review the theoretical models in order to capture the changing real world more correctly.

In addition, the dramatically increasing computation capacity - including GIS, Statistics, and Database Management Systems (DMBS) - and the available ample data set - including the U.S. Census information - make a more detailed examination of spatial pattern. Therefore, we can take a step forward beyond the existing urban models.

I adopt the factor analysis and the cluster analysis with four metropolitan areas including Boston, MA (Northeast), Chicago, IL (Midwest), San Francisco, CA (West), and Dallas, TX (South) out of each region. The factor analysis and the
cluster analysis are sensitive to the initial data set. I use the 1990 Census blockgroup as a basic unit of my analysis because it is the finest exhaustive data set I have access to.

### 4.1 Summary of the Four Metropolitan Areas

This research finds four common factors that account for above 70 percent of the variation in socioeconomic characteristics of local neighborhoods and that generate a spatial pattern with significant clustering: Baseline factor, children factor, income factor, and age factor. Average whites of the metropolitan areas live virtually any place which is not specialized yet by a certain type of residents. Non-whites, however, show the tendency of agglomeration. Number of children and large household size vary among neighborhoods and are generally not correlated with other variables. They are, however, related to location. The peculiar factor of San Francisco metropolitan area is the average travel time to work. In Chicago and Dallas, citizenship is an additional factor.

The variation of neighborhoods by income group clearly emerge. Generally, there are high-income neighborhoods in each metropolitan areas, which agglomerate at a preferable geographic location, not in downtown. Low income neighborhoods generally are near to downtown or job locations with high density. Incidentally,
neighborhoods with larger number of low income households tend to have relatively more children than other neighborhoods.

Young workers, especially those with no children, tend to live basically near to their jobs in two ways. They tend to live physically near the employment and to the places where they can easily access transportation corridors. So, they are found near downtown or along the highways.

In addition, all the locational patterns do not follow the circumferential pattern in these four metropolitan areas. Near the downtown areas, up to about 15 miles away from center, we see vivid wedges of socio-economically different neighborhood clusters.

Travel time to work is not a factor differentiating residential clusters, except San Francisco. Interestingly, the downtown residents' travel time is not shorter than surburban residents' travel time. We might guess that walking to job or using public transportation to job may takes longer than driving in terms of time. In other words, poor people generally spend more time to commute even though they live in downtown.

-66-

By examining the geographical locations of the neighborhoods using GIS, we can see the same neighborhoods tend to be located together geographically as of 1990. Whether people choose their place close to the socioeconomically same group could be another longitudinal research topic. If it proves true, we can predict people's residential choice based on the existing residential neighborhood characteristics.

This alternative methodology is good for at least explanatory research for finding the key latent factors delineating neighborhoods in terms of socioeconomic characteristics. Then, we can stratify the neighborhoods based on the factors using cluster analysis. This methodology reduces the risk of the assumptions of the conventional regression analysis. We can also use the result of this analysis as an input to a further research including, for example, multivariate regression analysis.

### 4.2 Future Study

This kind of detailed research is critical for participatory planning as a consensus building process. Residents who are willing to participate in the planning need to know what the plans are, what the effect of the plans are, and so forth. The
existing urban models are terse but too complicated and generalized for common residents to understand their community and plan. Furthermore, it is hard to answer the neighborhood level question.

For example, different neighborhoods requre different planning policy. A lot of non-white people live in the sothern part of the city of Chicago, and they spend more time to get their jobs than the rest metropolitan area, even though they live close to the Central Business District (CBD). Enhancing the inner-city transportation system could be more relevant in this area.

With panel data - time series as well as cross-sectional data - we can develop urban space-time simulation model for forecasting the future of the city: demographic pattern, land use, and so forth. The model also increases our capability of planning by exploring spatial patterns and correlationed factors that may suggest useful spatial dimension to begin modeling in theoretical models of urban spatial structure.

This model can be integrated with the Build-out scenarios and/or with the conventional economic models. We can then forecast the city through the time line, for one year, 3-5 years, and the full (eternal) equilibrium. Then, we can see the longitudinal pattern as well as cross sectional pattern at the same time.

Figure 4.2 Examples of people and land use change

(1) One type of residency (or land use) expands to outward (A -> B -> C).
(2) One type of residency (or land use) expands to outward and moves to West (A -> B $\rightarrow$ C).
(3) One type of residency (or land use) moves to East keeping similar size (A -> B -> C).

Then, we can develop a space-time simulation model for planning; being able to work with the established economic models and helping people participate in the planning. New technology, in turn, make such simulation model possible.

## APPENDIX A. GEOGRAPHIC AREAS REFERENCE ${ }^{1}$

## Block Group (BG)

U.S. Census Bureau guidelines specify an ideal size for a BG of 400 housing units, with a minimum of 250 , and a maximum of 550 housing units. The guidelines further required that BG boundaries follow clearly visible features, such as roads, rivers, and railroads.

#### Abstract

A BG is a combination of census blocks ${ }^{2}$ that is the finest grained subdivision of a census tract or block numbering area (BNA). (A county or its statistically equivalent entity contains either census tracts or BNAs; it can not contain both.)

[^7]A BG consists of all census blocks whose numbers begin with the same digit in a given census tract or BNA; for example, BG 3 includes all census blocks numbered in the 300 s . The BG is the smallest geographic entity for which the decennial census tabulates and publishes sample data. It has now largely replaced the earlier enumeration district (ED) as a small-area geographic unit for purposes of data presentation.

## Metropolitan Area (MA) ${ }^{3}$

The MA standards specify the step-by-step definition process by which the concept of a densely settled core area plus its suburbs becomes realized as individual MSAs, CMSAs, PMSAs, and NECMAs. Qualification of an MSA requires the presence of a city of 50,000 or more inhabitants, or a Census Bureau-defined UA (of at least 50,000 inhabitants) and a total population of at least 100,000 (75,000 in New England). The county or counties including the largest city in the core area of population become central counties of the MSA; so
extent, age, type, and density of urban and rural development.
${ }^{3}$ The collective term used for Federal metropolitan areas has varied over time, beginning with standard metropolitan area (SMA) in 1950, changing to standard metropolitan statistical area (SMSA) in 1959, to metropolitan statistical area (MSA) in 1983, and to metropolitan area (MA) in 1990.
does any adjacent county that has at least 50 percent of its population in the UA ${ }^{4}$ surrounding the largest city. (In New England where all land is allocated to be in one or another town, the basic geographic unit for defining MSAs is the city or town rather than the county.)

Additional outlying counties are included in the MSA if they meet specified requirements of commuting to the central counties as well as other requirements of metropolitan character. The minimum level of commuting to central counties required to make a county eligible for consideration as an outlying county is 15 percent. In general, the lower the percentage of a county's resident workers commuting to the central counties, the more demanding the other requirements of metropolitan character the county must meet in order to qualify for inclusion. The measures of metropolitan character specified in the standards include required levels for the county's (1) population density; (2) percentage of population that is classified as urban; (3) percentage growth in population between the previous two decennial censuses; and (4) percentage of, or absolute number of, inhabitants within the UA that qualifies the MSA. Qualification of outlying cities and towns in New England is based on commuting and population density.

[^8]An area that meets the requirements for recognition as an MSA and also has a population of one million or more may be recognized as a CMSA if (1) separate component areas can be identified within the entire area by their meeting population and commuting criteria specified in the standards, and (2) local opinion indicates there is support for the component areas. If recognized, the component areas are designated PMSAs (and the entire area becomes a CMSA). If no PMSAs are recognized, the entire area is designated an MSA. (PMSAs, like the CMSAs that contain them, are composed of counties outside New England and cities and towns within New England.)

The collective term used for Federal metropolitan areas has varied over time, beginning with standard metropolitan area (SMA) in 1950, changing to standard metropolitan statistical area (SMSA) in 1959, to metropolitan statistical area (MSA) in 1983, and to metropolitan area (MA) in 1990.

[^0]:    ${ }^{1}$ Throughout this thesis, all the numbers are as of 1990 according to the 1990 Census Summary Tape File 3A if there is no other remark.

[^1]:    ${ }^{2}$ The composition of each factor may subtly vary across metropolitan areas, but I use the same name for similar factor.

[^2]:    ${ }^{3}$ Note that the geographic unit of this analysis is a Census blockgroup, especially when you see maps in this paper. Each blockgroup can be assumed equivalent for the purpose of this thesis in terms of population or socioeconomic characteristics. However, the bigger shading on the map may not represent more people or more importance because the physical sizes of blockgroups vary. The blockgroups in the suburban area are generally larger.

[^3]:    ${ }^{1}$ Refer to Appendix for all the detailed statistics.

[^4]:    * The shaded cells are selected by author to highlight the characteristics of each cluster.

[^5]:    * The shaded cells are selected by author to highlight the characteristics of each cluster.

[^6]:    * The shaded cells are selected by author to highlight the characteristics of each cluster.

[^7]:    ${ }^{1}$ Source: U.S. Department of Commerce. 1994. Geographic Areas Reference Manual. http://www.census.gov/geo/www/garm.html
    ${ }^{2}$ Census blocks, the smallest geographic area for which the Bureau of the Census collects and tabulates decennial census data, are formed by streets, roads, railroads, streams and other bodies of water, other visible physical and cultural features, and the legal boundaries shown on Census Bureau maps.

    Although most people intuitively think of census blocks as being rectangular or square, of about the same size, and occurring at regular intervals, as in many cities of the United States, census block configurations actually are quite different. Patterns, sizes, and shapes of census blocks vary within and between areas. Factors that influence the overall configuration of census blocks include topography, the size and spacing of water features, the land survey system, and the

[^8]:    ${ }^{4}$ Urbanized Areas (UAs): A UA is a continuously built-up area with a population of 50,000 or more. It comprises one or more places-central place(s)-and the adjacent densely settled surrounding area-urban fringe-consisting of other places and nonplace territory.
