Abstract: The deposition of amyloid-like fibrils, composed primarily of the 99-residue protein β_2-microglobulin (β_2m), is one of the characteristic symptoms of dialysis-related amyloidosis. Fibrils formed in vitro at low pH and low salt concentration share many properties with the disease related fibrils and have been extensively studied by a number of biochemical and biophysical methods. These fibrils contain a significant β-sheet core and have a complex cryoEM electron density profile. Here, we investigate the intrasheet arrangement of the fibrils by means of $^{15}N-^{13}C$ MAS NMR correlation spectroscopy. We utilize a fibril sample grown from a 50:50 mixture of $^{15}N,^{12}C$- and $^{14}N,^{13}C$-labeled β_2m monomers, the latter prepared using 2-^{13}C glycerol as the carbon source. Together with the use of ZF-TEDOR mixing, this sample allowed us to observe intermolecular $^{15}N-^{13}C$ backbone-to-backbone contacts with excellent resolution and good sensitivity. The results are consistent with a parallel, in-register arrangement of the protein subunits in the fibrils and suggest that a significant structural reorganization occurs from the native to the fibril state.

β_2-Microglobulin (β_2m) is a 99-residue protein that forms amyloid fibril deposits associated with dialysis-related amyloidosis (DRA).[1] Under acidic conditions (pH = 2.5) and low salt concentration, the protein can also form amyloid fibrils *in vitro* through a nucleation-dependent mechanism.[2,3] These fibrils are long, straight, and unbranched in appearance (Figure S1) and share many properties with the fibrils isolated from tissues of DRA patients, including the same characteristic amide I′ band in FTIR spectra.[4] It has been shown that the fibrils themselves, and not the prefibrillar oligomeric species formed in the lag phase of assembly, can disrupt model membranes and are toxic to cells.[5] While an atomic structural model for these fibrils is not yet available, structural details emerged first through methods like limited proteolysis,[6,7] hydrogen exchange,[8,9] and more recently by magic angle spinning (MAS) NMR,[10] electron paramagnetic resonance (EPR),[11] and cryo-electron microscopy (cryoEM).[12] In particular, analysis of the chemical shifts of 64 assigned residues of β_2m fibrils has shown that the protein contains a rigid fibril core with substantially more β-sheet character than the native protein.[10] CryoEM maps revealed a complex picture of the fibrils, where non-native globular β_2m monomers pack in "dimer-of-dimers" building blocks that associate asymmetrically into crescent-shaped units.[12] In addition, site-directed EPR spin labeling suggested that the major building block consists of six β_2m polypeptide chains, arranged in a parallel, in-register manner.[11]

In the experiments described here, we investigate the tertiary structure of β_2m amyloid fibrils with $^{15}N-^{13}C$ MAS NMR correlation spectroscopy. MAS NMR has been successfully used to obtain information about the inter- and intramolecular interactions that form the β-sheet core of amyloid fibrils, including Aβ(1−40),[13] a 22-residue fragment of β_2m,[14] Het-s(218−289),[15] and curli amyloid.[16] Various sample preparation techniques and experiments have been employed to achieve that end, including methods that rely on the incorporation of single labels[17,18] or proton-mediated transfer.[19] Here, we use ZF-TEDOR (z-filtered transferred echo double resonance) mixing[20,21] to obtain intermolecular $^{15}N-^{13}C$ correlations that establish that the protein subunits in long, straight β_2m fibrils formed at pH 2.5 are arranged as parallel, in-register β-sheets.

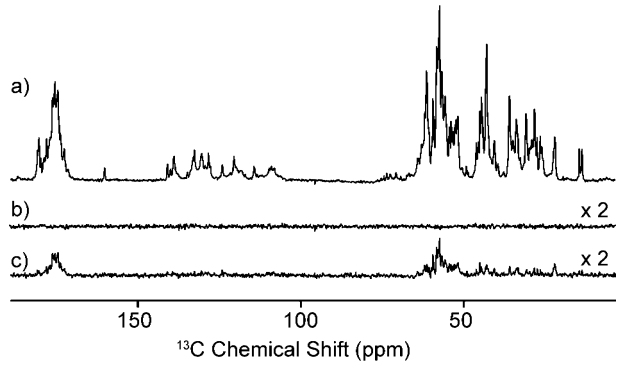

Figure 1. (a) ^{13}C CP spectrum of mixed 2-β_2m fibrils, 512 scans; (b) ZF-TEDOR spectrum obtained with $\tau_{mix} = 1.76$ ms, 512 scans;, (c) ZF-TEDOR with $\tau_{mix} = 18$ ms, 5120 scans.

Our experiments utilize fibrils formed from a 50:50 mixture of $^{15}N,^{12}C$- and $^{14}N,^{13}C$- labeled β_2m monomers, the latter half being prepared using [2-^{13}C]-glycerol as the carbon source. This sample, referred to as "mixed 2-β_2m", offers improved resolution in the ^{13}C dimension[22−24] (Figure 1a) as well as potential gains in experimental transfer efficiency due to the significantly reduced number of directly bonded ^{13}C atoms.[25] The absence of ^{13}C *J*-couplings and the elimination of strong (intramolecular) dipolar $^{15}N-^{13}C$ couplings as a result of the mixed nature of the sample improve the efficiency of ZF-TEDOR.[20,26,27]

In a 100% uniformly $^{15}N,^{13}C$ labeled β_2m sample, the experimental one-bond $^{15}N-^{13}C$ transfer efficiency after 1.76 ms of ZF-TEDOR mixing is typically ∼20% of the ^{13}C CP signal. In the mixed 2-β_2m sample, after such a short mixing time, no significant buildup of ^{13}C polarization is observed, as shown in Figure 1b. This is due to the absence of ^{13}C nuclei in the $^{15}N,^{12}C$-labeled monomers, which were prepared using ^{13}C-depleted glucose (99.9% purity) to eliminate contributions from natural abundance. In particular, signals from one-bond $^{15}N-^{13}C$ interactions are not detected. On the other hand, longer ZF-TEDOR mixing times lead to the buildup of ^{13}C intensity, which reaches a maximum at 18 ms (Figure 1c and Figure S2) and is consistent with $^{15}N-^{13}C$

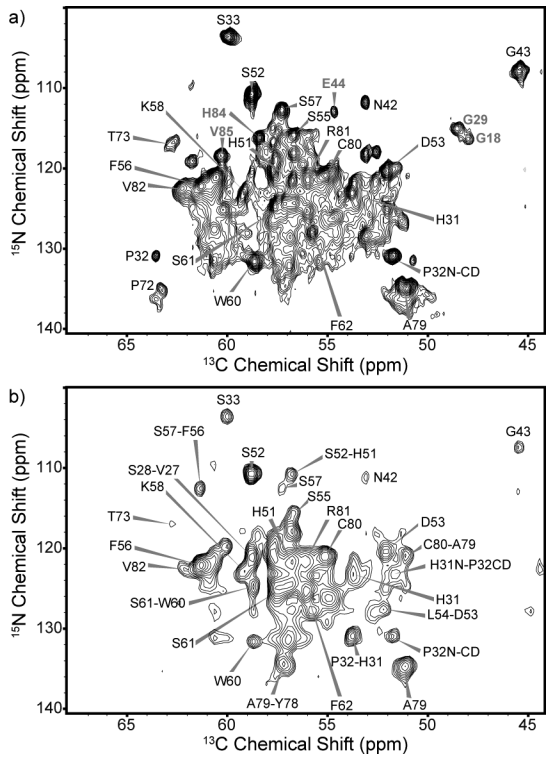

Figure 2. Comparison of the ^{15}N−^{13}Cα region of correlation spectra obtained with ZF-TEDOR mixing for two differently labeled β_2m fibril samples. (a) 2-β_2m, τ_{mix} = 1.6 ms, 12 mg of sample, 2 days of experimental time. Labels correspond to intramolecular N_i−$C\alpha_i$ transfer, unless otherwise noted, while labels in gray denote cross-peaks that appear only in the 2-β_2m spectrum. (b) Mixed 2-β_2m, τ_{mix} = 16 ms, 16 mg of sample, 9 days of experimental time. Labels correspond to intermolecular N_i−$C\alpha_i$ or N_i−$C\alpha_{i-1}$ transfer, unless otherwise noted.

distances of ∼5.0−5.5 Å. The maximum bulk transfer efficiency for the Cα region is ∼3%, which is better than the experimental transfer efficiencies observed for uniformly ^{13}C labeled samples (<1% for similar distances).[20]

In order to obtain site-specific information regarding the origin of the ^{15}N−^{13}C intermolecular contacts in mixed 2-β_2m, we recorded a 2D ZF-TEDOR experiment with τ_{mix} = 16 ms (Figure S3). This spectrum presents excellent resolution (^{13}C line widths ∼50 Hz) and sufficient sensitivity after a long acquisition period, which was facilitated by the robustness of the TEDOR sequence. Overall, the positions of the observed cross-peaks in this mixed 2-β_2m spectrum correspond exactly with the positions of cross-peaks in one-bond (Figure 2a) or two-bond TEDOR spectra (data not shown) of a β_2m fibril sample prepared from 100% ^{15}N, 2-^{13}C glycerol labeled material (2-β_2m). The majority of the cross-peaks in the mixed 2-β_2m sample could be readily assigned based on known chemical shifts of long, straight β_2m fibrils,[10] and they correspond exclusively to *intermolecular* N_i−$C\alpha_i$, N_i−$C\alpha_{i-1}$, N_i−CO_i, or N_i−CO_{i-1} transfer (Figures 2b and S3). In particular, the following residues giving rise to intermolecular contacts in the mixed 2-β_2m sample were assigned: H31−S33, N42, G43, R45, I46, V49, H51−F62, P72, T73, and Y78−V82. While P32, S33, G43, F56, S57, K58, and F62 are part of well-ordered loops in the fibrils, the remainder of the residues represent all of the currently assigned fibril β-strands.

Some cross-peaks in Figure 2b (mixed 2-β_2m) do not presently have assignments. Conversely, not all of the strong cross-peaks shown in Figure 2a (2-β_2m) appear in the mixed 2-β_2m spectrum. This includes G18, G29, E44, H84, and V85 (shown in gray in Figure 2a) among others. This is most likely due to differences in local dynamics and relaxation whose effects are exacerbated at long mixing times, resulting in large variations in the cross-peak intensities.[30]

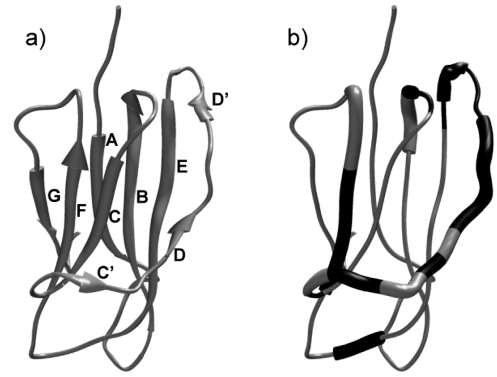

Figure 3. (a) Crystal structure of native monomeric β_2m (PDB ID: 1DUZ)[28] showing the antiparallel β-sheet arrangement of the strands (labeled A to G). (b) Residues that form β-strands in fibrillar β_2m painted onto the native fold. β-Strands in the fibrils[10] are shown as thick tubes, and the residues giving rise to assigned intermolecular N_i−$C\alpha_i$ cross-peaks are shown in black. The structures were prepared using the Chimera software.[29]

The data presented above suggest that long, straight β_2m fibrils grown at pH 2.5 and low salt concentration form parallel, in-register β-sheets. In such a case the average distances for intermolecular N_i−$C\alpha_i$ and N_i−$C\alpha_{i-1}$ contacts are ∼5 and ∼5.5 Å respectively (Figure S4), which is consistent with the bulk ZF-TEDOR buildup (Figure S2). In order to accommodate such an arrangement, substantial reorganization of the native antiparallel β-sheet structure[31−33] is required, indicating that the structure of the monomers within the fibrils must be highly non-native. Figure 3 highlights two clear pieces of evidence for the non-native structure of β_2m within fibrils: first, residues involved in loops/turns in native β_2m (Figure 3a) reorganize to form ordered β-strands in the fibrils (Figures 3b and S5), and second, while all β-strands form antiparallel β-sheet contacts with residues distant in sequence in native β_2m, β-strands in the fibrils are parallel and in register.

The parallel arrangement of the β-strands in β_2m fibrils was predicted initially by FTIR experiments[34,35] and is in agreement with data obtained by site-directed spin labeling and EPR.[11] The results described here verify and expand upon the latter, which indicates that spin labels attached to cysteine-substituted residues S33, S55, S61, and T73 among others give EPR spectra indicative of immobile, parallel, and in-register stacked spin labels (Figure S5). Stacks of six β_2m monomers arranged in that manner are then required to fulfill the electron density maps obtained by cryoEM.[12] The site-specific information regarding the intermolecular arrangement of β_2m fibrils presented here provides an important step toward a full molecular model of the fibrils. Additional experiments, particularly aimed at determining the quaternary fold of the fibrils, are in progress and should shed light on how this tertiary fibril arrangement fits into such a complex cryoEM electron density profile.
