#### ABSTRACT

Mixing in a micro-scale coaxial turbulent **jet** mixer for the fabrication of nanoparticles for drug delivery was experimentally characterized. Rapid mixing due to turbulence offers improved control of nanoparticle production over conventional bulk nanoprecipitation methods.

Mixing time was determined based on photographs of mixing of an acidic solution and a basic solution in the device, with phenolphtalein used as an indicator of the extent of mixing. The average Reynolds number and velocity ratio were varied. The velocity ratio varied between **0.1** and **10.** The Reynolds number varied between 200 and **1800.** Mixing times on the order of 1 to **50** ms were measured in the device. The mixing time was found to be proportional to average velocity to the **-3/2** power. The data showed some agreement with predicted mixing time based on the EDD model for turbulent micromixing in the jetting regime.

## **1. Introduction**

Nanoparticles have shown promise as a vehicle for delivering drugs to target cells within the body. In comparison to bulk nanoprecipitation methods, microfluidic devices for nanoparticle fabrication have demonstrated a good ability to control physiochemical properties of therapeutic nanoparticles, which strongly affect their *in vivo* fate.<sup>1,2</sup>

**A** significant hurdle in the further clinical acceptance of nanoparticles for medical applications is the development of consistent, high-throughput devices for nanoparticle fabrication.<sup>3</sup> This study focuses on the mixing of two fluids in a novel coaxial turbulent jet mixer for the production of nanoparticles, which allows high throughput and control of the product's physicochemical properties. We characterize the mixing time in the device as a function of the net Reynolds number and the velocity ratio of the input flows.

## **1.1 Nanoparticles** in **Medicine**

Nanoparticles are well-suited to medical applications because they are on the same scale as the biological processes typically disrupted by disease.<sup>4</sup> In particular, nanoparticles have much to offer in the areas of drug delivery and imaging. Loaded liposomes and polymeric nanoparticles have been used to deliver drugs to specific types of cells,<sup>5</sup> while metallic nanoparticles, especially iron oxide nanoparticles, have been developed for use as contrast agents for magnetic resonance imaging  $(MRI)^6$ .

One key advantage of nanoparticles is that they can be engineered to target specific cells. This is important both for drug delivery and imaging applications. Many drugs, especially cancer-fighting drugs, are toxic to healthy cells and diseased cells alike, so the maximum dosage is limited **by** the need to minimize side effects such as the necrosis of healthy cells. <sup>7</sup>**A** method of drug delivery that specifically targets diseased cells practically circumvents that limit. Targeting is also useful for imaging, where the ability to visually distinguish between healthy and diseased tissue is advantageous for diagnostic **6** purposes.

Physicochemical properties of nanoparticles determine their ability to target diseased cells. The enhanced permeability and retention (EPR) effect describes cancerous tissue's tendency to allow greater permeation of large molecules from the bloodstream, and to retain these molecules for a longer time, relative to healthy tissue. Cancer cells can thus be passively targeted based on nanoparticles' size.<sup>5</sup> Cells can also be actively targeted using surface modifications that enhance binding to or uptake **by** specific kinds of cells.3

The size of nanoparticles in such applications partially determines their effectiveness. The size of iron oxide nanoparticles used as MRI contrast agents governs the speed of uptake **by** organs, so the nanoparticles' size is engineered to suit the imaging of specific organs and structures.<sup>6</sup> Size also contributes to the fate of nanoparticles used for targeted drug delivery.<sup>5</sup> Consequently, good control of the size and size distribution of nanoparticles is required of nanoparticle production processes.

## **1.2 Methods for Fabrication of Nanoparticles**

**A** wide range of processes are used for the fabrication of nanoparticles. Two-step methods first emulsify and then form nanoparticles from the emulsion. Emulsification may be carried out **by** a variety of methods and technologies, such as droplet extrusion or the use of a colloidal mill. Nanoparticles can then be formed from the emulsified droplets by such methods as evaporation of solvent and polymerization of the nanoparticle.<sup>8</sup>

**A** simpler, less energy-intensive method for forming nanoparticles is nanoprecipitation, which adds a polymer in its non-solvent to the polymer's solvent, causing polymer nanoparticles to precipitate out in a simple and repeatable way.' This process may be done in bulk, but microfluidic devices offer greater control over the mixing process and the resulting particles.<sup>3</sup> Microfluidic mixing devices using flow focusing<sup>1</sup> and impinging jets<sup>10,11</sup> have been proposed and studied.

## **1.3 The Coaxial Jet Mixer**

The coaxial jet mixing device under consideration here is shown below in Figure 1. Its geometry is simple: two flows enter the device through coaxial tubes, and mixing occurs at the termination of the inner tube. The behavior of the device depends on the velocities of the flows into the device. The mixer may function as an axially symmetric **3** dimensional flow-focusing device, where a focused inner flow is mixed with the outer flow **by** diffusion. Alternatively, if the velocities are high enough, turbulence may induce rapid mixing. Rapid mixing is desirable in such devices because it accelerates throughput,

allows the fabrication of more complicated composite nanoparticles, and reduces the need for nanoparticle storage.<sup>12</sup>

**Figure 1: Schematic illustration of the coaxial jet mixer, showing two distinct flow regimes: (a) turbulent flow and (b) eddy flow. Mixing occurs after the inner flow** is **injected into the coaxial outer flow.**

**Mixing** time depends on the fluid properties and input flow velocities, but the way in which the mixing time may scale with input parameters is difficult to determine analytically. Baldyga and Bourne demonstrate a computational approach to a similar problem.<sup>13</sup> This project examines experimental data on mixing time in the device for a range of velocity ratios and Reynolds numbers, in order to characterize mixing in the device.

# **2. Predicting mixing time**

Mixing is the process of homogenizing the distribution of one material in another. As mixing occurs, the length scale of inhomogeneities shrinks.<sup>13</sup> Depending on the Reynolds number and flow rate ratio, mixing may occur due to turbulence or due to flow focusing. To determine which effect dominates, it is useful to compare the expected mixing time for each of these regimes.

## **2.1 Problem Summary**

The flow in the device is depicted in Figure 2.

**Figure 2: Flow through the coaxial jet mixer.**

In the case examined here, the two fluids have approximately the same density  $\rho$  and kinematic viscosity *v.* The kinematic viscosity of the water-ethanol mixture used in the experiments (see Section 3.1) was assumed to be  $2.589 \times 10^{-6} \frac{\text{m}^2}{\text{s}}$ , based on the work of Khattab et al.<sup>14</sup> The device geometry is described by  $D$ , the diameter of the outer tube,

and  $d_i$  and  $d_o$ , the inner diameter and outer diameter, respectively, of the inner tube. The device's length is much greater than its diameter or any observed mixing length, except in some cases when the flow is not turbulent. The two input velocities  $U_i$  and  $U_o$  may be fully defined by setting the dimensionless velocity ratio  $R_u$  and average-velocity Reynolds number *Reave* where

$$
R_u = \frac{U_i}{U_o} \tag{1}
$$

and

$$
Re_{ave} = \frac{u_{ave}D}{\nu} \tag{2}
$$

Here  $u_{ave}$  is the average velocity over a cross-section of the device:

$$
u_{ave} = \frac{(D^2 - d_o^2)U_o + d_i^2 U_i}{D^2}
$$
 (3)

## **2.2 Mixing due to flow focusing**

Flow focusing is expected to be the dominant mixing phenomenon when the velocity ratio and Reynolds number are small. Extending the correlation for mixing time in a twodimensional flow focusing device given **by** Kamik et al.,' we find a correlation for the mixing time due to flow focusing in a cylindrical flow focusing device:

$$
\tau_{mix} \sim \frac{d_f^2}{4D},\tag{4}
$$

where  $d_f$  is the focused diameter of the inner flow, and  $D$  is the mass diffusivity.

The focused diameter of the inner flow is

$$
d_f = d_i \sqrt{\frac{u_i}{u_{ave}}} \tag{5}
$$

from the conservation of mass.

### **2.3 Turbulent Mixing**

Description of mixing is complicated **by** the fact that length scales on different orders of magnitude contribute to the problem.<sup>15</sup> The engulfment, deformation, diffusion (EDD) turbulent micromixing model considers mixing to be a process in which unmixed fluid is entrained into turbulent vortices, the vortices stir the fluid at their characteristic frequency, creating a layered structure, and, once the layers are small enough, molecular diffusion finishes the mixing process.<sup>13</sup> The characteristic time for this process is given as

$$
\tau_{\omega} \approx 12 \left(\frac{v}{\langle \varepsilon \rangle}\right)^{\frac{1}{2}} \tag{6}
$$

where  $\langle \varepsilon \rangle$  is the average turbulent kinetic energy dissipation rate. The energy dissipation rate in the core of a pipe flow can be estimated as

$$
\epsilon_c = 0.0668 \frac{\bar{u}^3}{Re^{1/4} D}
$$
 (7)

where  $\bar{u}$  is the average velocity in the axial direction.<sup>16</sup> The Reynolds number used in this analysis is the average-velocity Reynolds number *Reave.*

## **3. Testing mixing time predictions**

### **3.1 Experimental procedure**

The experimental device was a coaxial jet mixer shown previously in Figure **1.** The inner flow was injected through a 23-Gauge needle into the coaxial outer flow through 1/8"-diameter tubing. The inner diameter and outer diameter of the needle were 0.6414 mm and **0.337** mm, respectively. Three syringe pumps drove the inner and outer flows at a set inner and outer velocity. For each velocity ratio, which ranged from  $\frac{U_i}{U_p} = 0.1$  to 10, tests were carried out at an outer velocity varying from **100** to **1000** mm/s.

The mixing of an acidic outer flow with a basic inner flow was tracked using the **pH** indicator phenolphthalein, which is purple in basic solutions and becomes transparent in neutral or acidic solutions. The inner flow solution contained **by** volume **10% IN** NaOH, **23.3%** phenolphthalein solution, and **66.7%** ethanol. The phenolphthalein solution contained **1%** phenolphthalein (mass per volume) in water. The outer flow solution contained **by** volume **10% HCl, 23.3%** water and **66.7%** ethanol.

As mixing occurred during testing, the **HC1** neutralized the NaOH, and the color of the fluid indicated the degree of mixing: an unmixed jet appeared purple, and as mixing enabled a change in **pH,** the color weakened until the jet became indistinguishable in color from the surrounding fluid.

The mixing in the device was photographed several times for each combination of velocities. **A** right angle prism mirror placed next to the device, shown in Figure **3** enabled photographs to capture a view from above the device and a view from the side of the device simultaneously.

Figure **3: Photograph of experimental setup. Flow is driven by three syringe pumps. The** device is **boxed in red. The right-angle prism mirror is located just below the device.**

These photographs support the assumption that the density of the two flows is almost the same: the vertical drift of the mixing flow is very small, indicating negligible buoyant forces and thus a negligible difference in the densities of the two flows.

## **3.2** Image Analysis

**A** characteristic mixing length was determined from photos of the device taken under different flow conditions (velocity ratio and average velocity were varied systematically). Since the phenolphthalein appears fuchsia, the complementary green channel of the RGB images was analyzed in ImageJ to extract a mixing length for each photo, as shown in Figure 4.

**Figure 4: Method for determining mixing time. The mixing length is shown superimposed on the original image (top). This mixing length** is **the length at which the gray value of the RGB green channel is 90% of its maximum value** *h,* **both relative to the initial value (bottom). The selected distance** is **chosen somewhere after the flow is visibly fully mixed, but before any major change in the glare in the photographs.**

**The intensity profile** of the green color channel of the image was found along the centerline of the jet, and the mixing length *L* was **defined as the length at which** the difference between it and the beginning of the jet was **90%** of the intensity difference between the completely mixed flow far downstream and the beginning of the jet.

No mixing time was estimated for the tests for which the flow was still unmixed at the rightmost edge of the image.

### **3.3 Determining Mixing Time**

From the mixing lengths, determined in as described above, mixing times were estimated using the following equation:

$$
\tau_{mix} = \frac{L}{u_{ave}}.\tag{8}
$$

The use of  $(8)$  assumes that the particles being mixed travel at  $u_{ave}$  as their average velocity throughout the mixing process. This is not strictly true: though the particles' speed far downstream is  $u_{ave}$ , they enter the device at the inner flow velocity  $U_i$ . If  $U_i$ and  $u_{\alpha\nu}$  are not equal, any one particle's time-average velocity will not be  $u_{\alpha\nu}$ . However, this assumption allows us to make simplified statements about the scaling of the mixing in the devices.

## **4. Results and Discussion**

The mixing time was plotted and compared to the predictions of the **EDD** model described above.

## **4.1 Mixing Time**

The mixing times are plotted as a function of *Reave* for each velocity ratio in Figure *5.*

Figure **5:** Mixing time data, plotted versus average-velocity Reynolds number *Reave.* Mixing times are averaged over multiple photographs. Error bars indicate one standard deviation. Absence of error bars indicates that the error bar is within the symbol size.

Mixing is clearly expedited as the Reynolds number increases, but the scaling is not obvious from the data presented in Figure *5.*

The mixing time was non-dimensionalized by dividing it by  $\tau_{\omega}$ , given in (6). This dimensionless mixing time is plotted versus *Reave* in Figure **6.**

**Figure 6: Mixing time, non-dimensionalized using**  $\tau_w$ **. Error bars indicate one standard deviation. Absence of error bars indicates that the error bar is within the symbol size.**

For velocity ratios  $R_u > 1$ , the data have more nearly collapsed onto the line  $\frac{\tau_{mix}}{\tau_{\omega}} = 1$ , especially at *Reave* above about **800.** For these higher Reynolds numbers and flow rate ratios, the measured mixing time is within 40% of the predicted value. For  $R_u \leq 1$ , there is considerably more scatter. The flow in this region may be better described **by** another model that accounts for the vortices generated at the end of the inner tube.

## **4.3 Future Work**

The low-Reynolds number, low-velocity ratio flows, which are believed to be dominated **by** flow focusing, can not be analyzed because mixing was not complete before the end of the image. Additional experiments, designed to capture a longer distance, would allow investigation of the flow-focusing regime, which was not possible with the data collected in this project. The effect of the assumption in Equation **(8),** which was used to calculate mixing time, needs to be looked into.

Further investigation into mixing theory could shed light on the nature of the mixing at velocity ratios less than **1.**

# **5. Conclusion**

Mixing in the coaxial jet mixer was characterized based on experimentally determined mixing times. In the jetting regime, these mixing times were approximately consistent with those predicted **by** the **EDD** model.
