A Single-Phase Photovoltaic Inverter Topology with a Series-Connected Energy Buffer

Brandon J. Pierquet, Member, IEEE, and David J. Perreault, Senior Member, IEEE

Abstract—Module integrated converters (MICs) have been under rapid development for single-phase grid-tied photovoltaic applications. The capacitive energy storage implementation for the double-line-frequency power variation represents a differentiating factor among existing designs. This paper introduces a new topology that places the energy storage block in a series-connected path with the line interface block. This design provides independent control over the capacitor voltage, soft-switching for all semiconductor devices, and full four-quadrant operation with the grid. The proposed approach is analyzed and experimentally demonstrated.

I. INTRODUCTION

Grid-tied inverters for photovoltaic systems represent a rapidly developing area. Module-integrated converters (MICs), sometimes known as microinverters, are designed to interface a single, low-voltage (25–40 V, typically) panel to the AC grid [1]–[5]. Such converters provide a number of benefits: ease of installation, system redundancy, and increased energy capture in partially shaded conditions [6].

MICs typically target single-phase electrical systems [7] (e.g. at 240 V), and are typically restricted to unity power factor operation [8]. Therefore, the converter must deliver average power plus a time-varying power component at twice the line frequency, while drawing a constant power from the PV module. Fig. 1 illustrates the power transfer versus time for the grid and the PV module, with the shaded area between the curves indicating the temporal energy storage required for the inverter. To model this transfer of energy through the converter, a generalized three port system can be used. The constant power source of the PV and the sinusoidal power load of the grid are illustrated in Fig. 2, and can be written as

\[ P_{PV} = P_{avg}, \]
\[ P_{Line} = -P_{avg}(1 - \cos(2\omega t)), \]

when no reactive power is transferred. The energy storage buffer must absorb and deliver the difference in power between these two ports, specifically

\[ P_{Buf} = -P_{avg}\cos(2\omega t), \]

Inverters investigated in the past (see literature reviews [4], [5]) can be classified by the location and operation of the energy storage buffer within the converter. Most single-stage topologies, such as flyback and ac-link converters, place capacitance in parallel with the PV panel [9], [10]. This is an effective low-complexity implementation, but to avoid interfering with the maximum peak-power tracking (MPPT) efficiency, substantial energy storage is required to limit the voltage ripple low across the panel. A second common method involves two complete cascaded conversion stages, providing energy storage at an intermediate dc bus. This arrangement can be implemented with less energy storage than the previous method, as a larger voltage fluctuation on the intermediate bus can be tolerated without impacting MPPT operation. The removal of the energy storage from the input also improves the transient response for peak-power tracking, as the PV module voltage can be controlled with a much higher bandwidth.

One drawback common to both of the energy storage methods described above involves the typical use of electrolytic capacitors for the dc energy storage. Electrolytic capacitors are traditionally selected due to their high energy density, but suffer from the stigma of long-term failure rates. As MICs are typically mounted on the frame or backsheet of the PV module assembly, the high temperatures can accelerate aging process for many of the internal components. To address this, focus is placed on improving in converter efficiency (i.e. reduction in thermal output) and transitioning to the use of higher-reliability capacitors. Recent developments in converter topologies have included “third-port” systems [11],
providing active control of the energy storage stage, independent of the input and output voltages. This reduces the required energy storage, and provides the opportunity for less energy-dense film capacitors to be used.

The power converter presented in this paper implements a new type of third-port topology, where the energy storage (buffer) block is placed “in series” with the line voltage interface. The topology achieves high efficiencies with its continuous constant-power operation, zero-voltage switching (ZVS) capability for all devices, and reduces the volt-seconds applied to the high-frequency transformer.

II. PROPOSED SOLUTION

The block diagram and schematic in Fig. 3 illustrate the four functional blocks of the converter: the high-frequency resonant inverter, transformation stage, energy buffer, and cycloconverter. Each is connected electrically in series, with a common high-frequency resonant current linking them together.

At first glance, this series-connected configuration would seem to impose a heavy conduction-loss penalty. However, scaling up device sizes appropriately can reduce this impact, and the switching losses associated with large MOSFET devices can be greatly reduced through soft-switching techniques [13]. Additionally, the resistive channel structure allows current to flow both directions through the device, allowing for bidirectional power flow in each block of the converter. This is in contrast with devices such as IGBTs, SCRs, and diodes allow current flow in a single direction and impose a fixed on-state voltage drop. Additionally, the figure-of-merit for MOSFETs has improved steadily since their introduction, particularly with the recent charge-compensation principles. This has allowed high-voltage silicon MOSFETs to surpass the “silicon limit” [14]–[16] and become viable for voltage ranges once relegated to low-frequency IGBTs. Additionally, the emergence of wide-bandgap FET-based device structures, implemented in SiC and GaN, have the potential to meet these same voltage levels while dramatically reducing the on-state resistance and undesirable device parasitics [17], [18]. This historical semiconductor device progress, combined with these and other anticipated future developments, are a motivating factor in the elimination of p-n junction devices in the topology. This work shows that this approach provides high efficiency with presently-available devices, and is anticipated to scale with the improvements in device technology. Even with the departure from traditional converter design, the well-known methods and algorithms for MPPT [19], grid synchronization [20], and islanding detection [21] can continue to be used.

To place the series-buffer topology in context, a comparative listing of both commercial and academic work is presented in Table I, and the efficiency . At the expense of slightly higher complexity, the proposed converter provides a number of additional capabilities while achieving an unoptimized efficiency that matches presently available designs.

III. TOPOLOGY OPERATION AND ANALYSIS

At a very high level, the converter operation is closely related to the ac-link family of topologies. Here, the switching waveforms of all three series-connected blocks are responsible for generating the intermediate high-frequency current waveform. This can be seen in Fig. 4, where each active switching block is replaced with a square-wave voltage source. The applied voltage of all three blocks results in a high-frequency series current which links each block together.

Fig. 5. Equivalent circuits representing the (a) primary and (b) secondary sides, decoupled by approximating the output of the transformation stage as a current source.

The buffer is composed of one such block, where the energy storage voltage is represented as unipolar, while the line-interfaced cycloconverter is composed of two such blocks, in a common-source layout (each providing operation under opposite voltage polarities).

The modulation of power through the simple circuit in Fig. 6 is accomplished by controlling the switching of the voltage waveform \( v(t) \) relative to the series resonant current \( i(t) \). This is shown in Fig. 7 where the resonant current and switching-voltage waveform is illustrated with the variables \( \delta \) and \( \theta \), corresponding to duty-cycle and phase-shift parameters, respectively. The average power delivery over a switching cycle can the be expressed as a function of these components through

\[
\langle P \rangle = \frac{1}{T} \int_0^T i(t)v(t)dt = \frac{VI}{\pi} \cos(\theta) \sin(\delta/2),
\]

where \( \delta \) and \( \theta \) are expressed in radians. This same result can also be reached by representing the voltage and current waveforms as phasor quantities (at the switching frequency).

B. Resonant Current Magnitude

In addition to the switching parameters, the resonant-current magnitude in (4) remains as an additional method for modulating the power transfer through the converter. For each block, a lower bound exists on the required magnitude of current needed to achieve a desired power transfer. As the terminal voltages \( V \) and resonant current magnitude \( I \) of the canonical circuit in Fig. 6 vary slowly over a line-cycle, the defined power-flow requirements in (1)–(3) result in the minimum

Fig. 6. The constituent sub-circuit of the buffer and cycloconverter blocks from Fig. 5b.
current profiles shown in Fig. 8. For this case, the buffer-block voltage is assumed to be constant, such that the peak current requirements of \( I_B \) and \( I_C \) are equal.

Operating with the minimum resonant current may be desirable to limit conduction losses, however the selection of current magnitude directly impacts the resulting converter control parameters. When operating with a fixed duty-cycle, and implementing simple phase-shift control, the required phase-angle for each block can be derived from (4), such that

\[
\theta_C(t) = \pm \cos^{-1}\left( \frac{\pi I_C \sin(\omega t)}{I_r(t)} \right),
\]

\[
\theta_B(t) = \pm \cos^{-1}\left( \frac{\pi I_B \cos(2\omega t)}{I_r(t)} \right),
\]

where \( \theta_C \) and \( \theta_B \) are the phase angle parameters for the cycloconverter and buffer blocks respectively, \( I_C \) and \( I_B \) are the corresponding peak current requirements, and \( I_r(t) \) is the resonant current amplitude. Each phase expression is symmetric and contains two valid solutions, allowing a choice based on an external constraint or preference (e.g. ZVS).

The phase solutions when operating with minimum-current are dependent on the waveform segments in Fig. 8. The block with the largest current requirement maintains a constant phase, whereas the remaining will vary. With the buffer and cycloconverter having the same peak current requirements as before, then

\[
\theta_C(t) = \begin{cases} 
\pm \cos^{-1}\left( \frac{\pi \sin(\omega t)}{\cos(2\omega t)} \right), & \text{if } \omega t \in \left[ 0, \frac{\pi}{6} \right] \\
\pm \cos^{-1}(1), & \text{if } \omega t \in \left( \frac{\pi}{6}, \frac{\pi}{2} \right]
\end{cases}
\]

\[
\theta_B(t) = \begin{cases} 
\pm \cos^{-1}\left( \frac{-1}{\sin(\omega t)} \right), & \text{if } \omega t \in \left[ 0, \frac{\pi}{6} \right] \\
\pm \cos^{-1}\left( \frac{\pi \cos(2\omega t)}{\sin(\omega t)} \right), & \text{if } \omega t \in \left( \frac{\pi}{6}, \frac{\pi}{2} \right]
\end{cases}
\]

and

\[
\theta_C(t) = \pm \cos^{-1}(\sin(\omega t))
\]

\[
\theta_B(t) = \pm \cos^{-1}(\cos(2\omega t)),
\]

which contain the same symmetry as those for the minimum-current mode. The resulting control angles of (7)–(10) are plotted over a half-line cycle in Fig. 9, with only the ZVS solutions shown.

C. Transformation and Inverter Design

With an understanding of the behavior of the secondary-side of the converter, the primary-side circuit in Fig. 5a can be considered with the objective of obtaining an inverter and transformation stage combination capable of synthesizing the required resonant current, as defined in the preceding section. The transformation stage is designed to provide an impedance appropriate for the primary side driving circuit, in this case it is desired to present a positive reactance at the switching frequency for the bridge converter to achieve the desired ZVS conditions. Additionally, the magnitude of the impedance must be managed such that the inverter is capable of operating over the full required voltage and power range.

The varying control and behavior of the secondary half of the converter results in a dynamic load over a line cycle. Using phasors, the secondary-side circuit can be approximated as a
The buffer-block and cycloconverter in (a) can be approximated as the complex load impedance in (b).

The lower reactive impedance for the minimum current envelope can be understood by the length of time the blocks’ phase deviate from alignment with the resonant current ($0$ or $\pi$). Minimum-current operation always maintains one block in phase with the current, maximizing the power factor of the resonant tank, while the constant-current method results in higher reactance.

In the transformation block, the negative reactance of the secondary side is offset by selecting the components of the series-resonant tank to compensate. The resulting impedance change, as shown in Fig. 12, where the minimal required positive compensating reactance is provided. In this case, the peak magnitude remains the same, however its overall shape has changed.

To drive this compensated load, the inverter is operated as a phase-shift full-bridge, where its applied voltage is defined in phasor form as

$$\bar{V} = 2\frac{V}{\pi} \sin(\delta/4)e^{i\theta},$$

where $\delta$ represents the duty-cycle, and $\theta$ is the phase of the voltage relative to the resonant current waveform. With control of this driving voltage, and the flexibility in selecting the transformer turns ratio and the resonant tank component values, a transformation stage and inverter can be created which is capable of synthesizing the required resonant current.

### D. Control Parameter Solutions

With the control parameters for each block defined, the interdependency between them can be investigated by considering the operation of all blocks together. To simplify the analysis, the equivalent circuit in Fig. 13 illustrates the converter in phasor form, with the voltages normalized to allow the transformation stage to be lumped into a single series element $z_T=R+jX_T$, implicitly dependent on the switching frequency ($f_{sw}$). The series current can then be defined in terms of the circuit voltages and tank impedance, such that

$$\bar{I} = \frac{1}{Z_T e^{i\theta_Z}} (V_A e^{j\theta_A} + V_B e^{j\theta_B} + V_C e^{j\theta_C}),$$

and the power delivery for a given voltage source, $k$, is expressed as

$$P_k = \frac{1}{2} \text{Re} \left\{ \bar{V}_k \bar{I}^* \right\} = \frac{1}{2} \text{Re} \left\{ V_k e^{j\theta_k} \left( V_A e^{-j\theta_A} + V_B e^{-j\theta_B} + V_C e^{-j\theta_C} \right) \right\}.$$

For a single block, this power-transfer equation requires seven parameters: the switching frequency, and the magnitude and phase for the three voltage sources. This list can be reduced by choosing to define one phase as the reference, eliminating it...
Impedance seen by the Inverter and Transformation Stage - Const Current

IV. HARDWARE IMPLEMENTATION

To illustrate the performance and functionality of the series-connected buffer topology, as described in this paper, a prototype platform has been designed for interfacing a 72-cell photovoltaic module, to a single-phase 240 V mains. The operating requirements for the converter are outlined in Table II, and an annotated photograph of the converter can be seen in Fig. 14. The converter’s primary power-stage topology follows directly the circuit shown in Fig. 3, with the components listed in Table III. Additional support circuitry, such as the required gate-drive, isolation, and control hardware can be found in [25].

The resonant inductor value and transformer turns ratio were selected such as to meet the highest power transfer requirement at the lowest input voltage, while also providing enough inductive energy for ZVS transitions at light loads. The resonant inductance of the circuit includes both the discrete inductor and the leakage inductance of the transformer, totaling 6.73 µH. The resonant capacitance was selected such that its reactance was less than that of the inductor at the minimum operating frequency range of 100 kHz. This results in a value of 0.6 µF, and places the resonant frequency at 79 kHz.

A. Experimental Operation

The operation and performance of the converter is measured in two different configurations. First, the converter is operated in dc-dc mode, stepped over a set of discrete operating points as an unknown. Additionally, having implemented phase-shift modulation for the buffer and cycloconverter, in combination with their measurable terminal voltages, results in known voltage magnitudes for \( V_B \) and \( V_C \). This leaves the switching frequency \( f_{sw} \), phases \( \theta_B \) and \( \theta_C \), and the effective driving voltage of the full-bridge, \( V_A \). The single-phase power flow requirements for the converter, given in (1)–(3), provide two independent constraints, and the remaining two are imposed by selecting an appropriate value for the switching frequency \( f_{sw} \) and full-bridge pulse-width \( \delta_A \) (for control of \( V_A \)). To solve for \( \theta_B \) and \( \theta_C \), one can take advantage of the inherently constrained domain of the phase variables to perform a direct search. Implementing a iterative solver is also effective, but often complicated by the existence of multiple solutions.

With a solution method in place for finding the unknown phase angles, it is repeated for additional combinations of the free variables \( f_{sw} \) and \( \delta_A \). This can also be accomplished by creating a map of the solutions, or an optimization algorithm can be implemented to converge toward a desirable result, such as minimizing loss. This process is again repeated for changing operating conditions, expanding the required solution space across power level (\( P_{avg} \)), input voltage (\( V_{PV} \)), and line voltage (\( V_{line} \)).
approximating an ac output. Second, the converter is operated in stand-alone dc-ac mode. In both configurations the converter is fed with constant-voltage at its input, and pre-populated lookup tables are used by the converter for the hardware control parameters.

The oscilloscope waveform captures in Fig. 15 are used to illustrate the switching-level operation of the converter at three points in the line cycle: (a) zero degrees, 0 V; (b) 30 degrees, 170 V; (c) 90 degrees, 340 V. Waveform color key: (1) blue: current, (2) red: full-bridge, (3) green: buffer-block, (4) purple: cycloconverter. Channels 1 and 2 are referenced to the top marker, while channels 3 and 4 are referenced to the bottom marker.

In dc-dc operation, the converter’s efficiency over a line cycle was measured for five average-power levels, at an input voltage of 32 V. These results, shown in Fig. 16, demonstrate efficiencies above 91% for all conditions, with peaks above 98%. These are power stage efficiencies, and the inclusion of the gate drive and auxiliary power accounts for an additional loss of 1-1.8%. This was also performed at two additional input voltages [25], resulting in an approximate CEC efficiency [24] of 95.5%.

The converter was also operated in full dc-ac mode, into a block and cycloconverter are each absorbing 50 W from the source, with voltage waveforms switching complimentary to each other. At a line phase of 90 degrees (340 V), shown in Fig. 15c, the buffer and source are each providing 100 W to the cycloconverter, which is providing 200 W out.

In dc-dc operation, the converter’s efficiency over a line cycle was measured for five average-power levels, at an input voltage of 32 V. These results, shown in Fig. 16, demonstrate efficiencies above 91% for all conditions, with peaks above 98%. These are power stage efficiencies, and the inclusion of the gate drive and auxiliary power accounts for an additional loss of 1-1.8%. The converter was also operated in full dc-ac mode, into a
be operated synchronously to prevent short-circuit conditions at zero-crossings, where the opposing half-bridge circuits can cause current ripple. This unintended operation also illustrates the discrepancy in the converter's efficiency, as demonstrated.

This dc-ac operation results in a 95.3% efficiency, including all gate and auxiliary power. The voltage and current waveform measurements for the dc input and ac output of the converter are shown in Fig. 17. The ideal waveforms would have a constant input voltage and input current with a sinusoidal output current in-phase with the output voltage, however, the measured results deviate slightly from this. The largest contributor to the discrepancy comes from the uncompensated delay associated with voltage measurement, and more significantly, the time duration required to update the converter operating parameters; a total delay of 1 ms. This update latency primarily manifests itself as an unintended phase-shift in the output current relative to the line voltage (reactive power transfer), ultimately reflecting back as input-power ripple (seen as current ripple). This unintended operation also illustrates the well-behaved nature of the cycloconverter near the line zero-crossings, where the opposing half-bridge circuits can be operated synchronously to prevent short-circuit conditions when the voltage polarity may be uncertain [9].
