ABSTRACT

We present the results of a LIGO search for short-duration gravitational waves (GWs) associated with the 2006 March 29 SGR 1900+14 storm. A new search method is used, “stacking” the GW data around the times of individual soft-gamma bursts in the storm to enhance sensitivity for models in which multiple bursts are accompanied by GW emission. We assume that variation in the time difference between burst electromagnetic emission and potential burst GW emission is small relative to the GW signal duration, and we time-align GW excess power time–frequency tilings containing individual burst triggers to their corresponding electromagnetic emissions. We use two GW emission models in our search: a fluence-weighted model and a flat (unweighted) model for the most electromagnetically energetic bursts. We find no evidence of GWs associated with either model. Model-dependent GW strain, isotropic GW emission energy $E_{GW}$, and $\gamma = E_{GW}/E_{EM}$ upper limits are estimated using a variety of assumed waveforms. The stacking method allows us to set the most stringent model-dependent limits on transient GW strain published to date. We find $E_{GW}$ upper limit estimates (at a nominal distance of 10 kpc) of between $2 \times 10^{45}$ erg and $6 \times 10^{50}$ erg depending on the waveform type. These limits are an order of magnitude lower than upper limits published previously for this storm and overlap with the range of electromagnetic energies emitted in soft gamma repeater (SGR) giant flares.

Key words: gamma rays: bursts – gravitational waves – pulsars: individual (SGR 1900+14) – stars: neutron

1. INTRODUCTION

Soft gamma repeaters (SGRs) sporadically emit brief ($\sim 0.1$ s) intense bursts of soft gamma-rays. Three of the five known SGRs have produced rare “giant flare” events with initial bright, short ($\sim 0.2$ s) pulses with peak electromagnetic (EM) luminosities between $10^{42}$ and $10^{47}$ erg s$^{-1}$, placing them among the most EM luminous events in the universe. According to the “magnetar” model SGRs are galactic neutron stars with extreme magnetic fields $\sim 10^{15}$ G (Duncan & Thompson 1992). Bursts may result from the interaction of the star’s magnetic field with its solid crust, leading to crustal deformations and occasional catastrophic cracking (Thompson & Duncan 1995; Schwartz et al. 2005; Horowitz & Kadau 2009) with subsequent excitation of nonradial neutron star $f$-modes (Andersson & Kokkotas 1998; de Freitas Pacheco 1998; Ioka 2001) and the emission of GWs (de Freitas Pacheco 1998; Ioka 2001; Horvath 2005; Owen 2005). For reviews, see Mereghetti (2008) and Woods & Thompson (2004).

Occasionally, SGRs produce many soft gamma bursts in a brief period of time; such intense emissions are referred to as “storms.” We present a search for short-duration GW signals ($\lesssim 0.3$ s) associated with multiple bursts in the 2006 March 29 SGR 1900+14 storm (Israel et al. 2008) using data collected by the Laser Interferometer Gravitational Wave Observatory (LIGO; Abbott et al. 2009b). The storm light curve, obtained from the Burst Alert Telescope (BAT) aboard the Swift satellite (Barthelmy et al. 2005), is shown in Figure 1. It consists of more than 40 bursts in $\sim 30$ s, including common SGR bursts and some intermediate flares with durations $> 0.5$ s. The total fluence for the storm event was estimated by the Konus-Wind team to be $(1−2) \times 10^{-4}$ erg cm$^{-2}$ in the $(20−200)$ keV range (Golenetskii et al. 2006), implying an isotropic EM energy $E_{EM} = (1−2) \times 10^{42}$ erg at a nominal distance to SGR 1900+14 of 10 kpc (source location and distance is discussed in Kaplan et al. 2002). At the time of the storm both of the 4 km LIGO detectors (located at Hanford, WA and Livingston, LA) were taking science quality data.

We attempt to improve sensitivity to multiple weak GW burst signals associated with the storm’s multiple EM bursts by adding together GW signal power over multiple bursts. In doing so we assume particular GW emission models, which we describe in the next section. Figure 2 illustrates the stacking procedure using the four most energetic bursts in the storm.

2. METHODS

The analysis is performed by the Stack-a-flare pipeline (Kalmus et al. 2009), which extends the method used in a recent LIGO search for transient GW associated with individual SGR bursts (Abbott et al. 2008a) and relies on an excess power detection statistic (Anderson et al. 2001). To “stack” $N$ bursts in the storm, we first generate $N$ excess power time–frequency tilings of GW emission and potential burst GW emission. These are two-dimensional matrices in time and frequency produced by combining the two detectors’ data streams so as to provide sensitivity to correlated signals, as described in Kalmus et al. (2007). Each tiling element gives an excess power estimate in the GW detector data stream in a small period of time $\delta t$ and a small range of frequency $\delta f$. The time range of each tiling is chosen to be centered on the time of one of the target EM bursts in the storm. We then align these $N$ tilings along the time dimension so that times of the target EM bursts coincide, and perform a weighted addition.

Stacking significantly improves sensitivity to GW emission under a given model. However, improving detection probability depends upon stacking according to GW emission models that correctly describe nature. The storm light curve motivated two stacking models: a flat-weighted model with an energy cutoff, which includes the 11 most energetic EM bursts with unity weighting factors; and an EM-fluence-weighted model comprised of the 18 most energetic EM bursts. In the flat model, we assume that a fixed amount of GW energy is released in each burst independently of its EM energy, provided the EM energy is above a threshold. The threshold choice is motivated by a clear separation in EM fluence of the 11 most energetic bursts from out of the total of $\sim 40$ bursts in the storm observed by BAT. A histogram of EM fluence of bursts (in terms of BAT counts) illustrating this separation is shown in Kalmus et al. (2009). In the EM-fluence-weighted model, we make the hypothesis that $\gamma = E_{GW}/E_{EM}$ is constant from burst to burst, i.e., $E_{GW}$ is always proportional to $E_{EM}$. Including the 18 most energetic bursts accounts for $95\%$ of the total EM fluence of the more
than 40 bursts in the light curve. Both burst samples include the seven intermediate flares identified in Israel et al. (2008). In the fluence-weighted model, time–frequency excess power tilings are weighted according to burst-integrated BAT counts before stacking. Further details are in Kalmus et al. (2009).

To obtain estimates of the times of EM bursts in the storm, we measure the intersections of the rapid rising edges of each burst with the light curve noise floor measured in a quiescent period of data in the 50 s BAT sequence before the start of the storm (Figure 1). We correct these times for satellite-to-geocenter times-of-flight using the known SGR 1900+14 sky position and Swift ephemeris, which vary from (17.12 to 17.48) ms over the ∼30 s duration of the storm. The stack-a-flare analysis method is robust to relative timing errors smaller than
We divide the GW data into an on-source time region, in which GWs associated with the storm could be expected, and a background region, with statistically similar noise in which we do not expect a GW. This is done after data quality cuts (categories 1 and 2 described in Abbott et al. 2009a) are applied to the GW data, so as to remove, e.g., periods of instrumental or data acquisition problems, or nonstationary noise due to bad weather or other environmental conditions. The on-source region consists of 4 s of stacked data. Each 4 s region comprising the stack is centered on the time of one of the EM bursts included in the GW emission stacking model. Background regions consist of 1000 s of data on either side of the storm. On-source and background segments are analyzed and stacked identically, and the stacked time–frequency tilings are passed through a two-dimensional clustering algorithm resulting in lists of “analysis events.” Each analysis event corresponds to one discrete cluster found by the algorithm and consists of information on the cluster central frequency, central time, bandwidth, and duration (Kalmus et al. 2009). Background analysis events due to fluctuating detector noise are used to estimate the significance of on-source events; significant events, if any, are subject to vetoes (Abbott et al. 2009a).

Using ±2 s regions around bursts in the storm accounts for uncertainties in the EM burst times and a possible systematic delay between GW and EM emission. Although GW emission in SGRs is expected to occur almost simultaneously with the EM burst (Ioka 2001), a common bias in trigger times shared by all bursts in the stacking set of 2 s on-source regions.

As in Abbott et al. (2008a), this search targets neutron star fundamental mode ringdowns (RDs) predicted in Andersson & Kokkotas (1998), de Freitas Pacheco (1998), Ioka (2001), and Andersson (2003) as well as short-duration GW signals of unknown waveform. RDs are targeted because f-modes are the most efficient GW emitters (Andersson & Kokkotas 1998). We assume that given a neutron star, f-mode frequencies and damping timescales would be similar from event to event, and that unknown signals would at least have similar central frequencies and durations from event to event.

As in Abbott et al. (2008a), we thus focus on two distinct regions in the target signal time–frequency parameter space. The first region targets ~100–400 ms duration signals in the (1–3) kHz band, which includes f-mode RD signals predicted in Benhar et al. (2004) for ten realistic neutron star equations of state. We choose a search band of (1–3) kHz for RD searches, with a 250 ms time window which was found to give optimal search sensitivity (Kalmus 2008). The second region targets ~(5–200) ms duration signals in the (100–1000) Hz band. The target durations are set by prompt SGR burst timescales (5–200 ms) and the target frequencies are set by the detector’s sensitive region. We search in two bands: (100–200) Hz (probing the region in which the detectors are most sensitive) and (100–1000) Hz (for full spectral coverage below the RD search band) using a 125 ms time window. In all, we search in three frequency bands and two GW emission models (flat and fluence-weighted). This amounts to a total of six 4 s long stacked on-source regions.

We estimate loudest-event upper limits (Brady et al. 2004) on GW root-sum-squared strain $h_{\text{rss}}$ incident at the detector. We can construct simulations of impinging GW with a given $h_{\text{rss}}$. Following Abbott et al. (2005b)

$$h^2_{\text{rss}} = h^2_{\text{rss}+} + h^2_{\text{rss}×},\quad (1)$$

where, e.g.,

$$h^2_{\text{rss}+} = \int_{-\infty}^{\infty} |h_{+}(t)|^2 \, dt$$

and $h_{+,\times}(t)$ are the two GW polarizations. The relationship between the GW polarizations and the detector response $h(t)$ to an impinging GW from a polar angle and azimuth $(\theta, \phi)$ and with polarization angle $\psi$ is

$$h(t) = F_+ (\theta, \phi, \psi) h_+(t) + F_\times (\theta, \phi, \psi) h_\times(t),\quad (3)$$

where $F_+ (\theta, \phi, \psi)$ and $F_\times (\theta, \phi, \psi)$ are the antenna functions for the source at $(\theta, \phi)$ (Thorne 1987). At the time of the storm, the polarization-independent rms antenna response $(F_+^2 + F_\times^2)^{1/2}$, which indicates the average sensitivity to a given sky location, was 0.39 for LIGO Hanford observatory and 0.46 for the LIGO Livingston observatory.

We can also set upper limits on the emitted isotropic GW emission energy $E_{\text{GW}}$ at a source distance $R$ associated with $h_+(t)$ and $h_\times(t)$ via (Shapiro & Teukolsky 1983)

$$E_{\text{GW}} = 4 \pi R^2 \frac{3}{16 \pi G} \int_{-\infty}^{\infty} (\langle h_+ \rangle^2 + \langle h_\times \rangle^2) \, dt.\quad (4)$$

The procedure for estimating loudest-event upper limits in the individual burst search is detailed in Kalmus (2008), Abbott et al. (2008a), and Acessnese et al. (2008). In brief, the upper limit is computed in a frequentist framework by injecting artificial signals into the background data and recovering them with the search pipeline (see for example Abbott et al. 2005a, 2005b). An analysis event is associated with each injection, and compared to the loudest on-source analysis event. The GW strain or isotropic energy at 90% detection efficiency is the strain or isotropic energy at which 90% of injections have associated events louder than the loudest on-source event.

We use the 12 waveform types described in Abbott et al. (2008a) to establish detector sensitivity and thereby set upper limits: linearly and circularly polarized RDs with $\tau = 200$ ms and frequencies in the range (1–3) kHz; and band- and time-limited white noise bursts (WNBs) with durations of 11 ms and 100 ms and frequency bands matched to the two lower frequency search bands.

These waveforms are used to construct compound injections determined by the emission model. In the flat model, 11 GW bursts comprise a compound injection, each is identical, and our stated $h_{\text{rss}}$ and $E_{\text{GW}}$ are for one such GW burst in the compound injection. In the fluence-weighted model, 18 GW bursts comprise a compound injection, they are weighted (in amplitude) with the square root of integrated counts, and our stated $h_{\text{rss}}$ and $E_{\text{GW}}$ are for the loudest GW burst in the compound injection. A single polarization angle is chosen randomly for every compound injection. In assuming that the bursts emitted are identical up to an amplitude scale factor, we implicitly assume that the star’s GW emission mechanism and symmetry axis are constant over bursts in the storm.
3. RESULTS

We find no statistically significant GW signal associated with the SGR 1900+14 storm. The significance of on-source analysis events is inferred by noting the rate at which background analysis events of equal or greater loudness occur. We examined 4 s stacked on-source regions in the flat and fluence-weighted emission models in the three search bands. The most significant on-source analysis event from these six searches was from the flat model in the (100–1000) Hz band and had a corresponding background rate of $5.0 \times 10^{-2}$ Hz (1 per 20 s) in that search.

Table 1 and Figure 3 give model-dependent loudest-event upper limits at 90% detection efficiency computed for the GW signal associated with the single loudest EM burst. We give strain upper limits ($h_{\text{uls}}^{10^6}$) and isotropic emission energy upper limits at a nominal SGR 1900+14 distance of 10 kpc ($E_{\text{GW}}^{10^6}$).

We also give upper limits $\gamma_{\text{UL}} = E_{\text{GW}}^{10^9}/E_{\text{EM}}$, a source-distance-independent measure of the extent to which an energy upper limit probes the GW emission efficiency, calculated using a conservative estimate of $1.0 \times 10^{-4}$ erg cm$^{-2}$ for the total fluence of the storm to estimate fluences for individual peaks. In the fluence-weighted model, $\gamma$ is the same for each individual burst. In the flat model, we report the mean value of $\gamma$ for the 11 bursts.

Superscripts in Table 1 give a systematic error and uncertainties at 90% confidence. (Similar estimates were made for the $E_{\text{GW}}^{10^9}$ but are not shown in the table.) The first and second superscripts account for the systematic error and statistical uncertainty, respectively, in the detector calibrations. The third is the statistical uncertainty from using a finite number of trials (200) in the Monte Carlos, estimated with the bootstrap method using 200 ensembles (Efron 1979). The systematic error and the quadrature sum of the statistical uncertainties are added to the final sensitivity estimates. One-sigma burst timing uncertainties from fits of burst rising edges are accounted for in the Monte Carlo simulations. Estimating uncertainties is further described in Kalmus et al. (2009).

4. DISCUSSION

The stacked search described here extends the recent LIGO search for GW associated with the 2004 SGR 1806–20 giant flare and 190 lesser events from SGR 1806–20 and SGR 1900+14 (Abbott et al. 2008a). That search was the first search sensitive to neutron star $f$-modes, and it set individual burst upper limits $E_{\text{GW}}^{10^9}$ ranging from $3 \times 10^{45}$ erg to $9 \times 10^{52}$ erg (depending on the waveform type and detector antenna factors and noise characteristics at the time of the burst), but did not detect any GWs. The best values of $\gamma_{\text{UL}}$ in Abbott et al. (2008a), for the giant flare, were in the range $5 \times 10^{11}$–$6 \times 10^{12}$ depending on the waveform type.

The upper limits obtained here are a factor of 12 more sensitive in energy than the SGR 1900+14 storm upper limits in Abbott et al. (2008a), which analyzed the storm in a single ±20 s on-source region. Those previous limits already overlapped the range of EM energies seen in the loudest flares as well as the range of GW energies predicted by the most extreme models (Ioka 2001). The flat model gives isotropic energy upper.
limits on average a factor of 4 lower than a reference $N = 1$ (nonstacked) scenario (with a $\pm 2$ s on-source region) and a factor of 2 lower than the fluence-weighted model. However, our storm $\gamma$ upper limits are still a few hundred times the SGR 1806–20 giant flare $\gamma$ upper limits, due to the tremendous EM energy released by the giant flare. There is very little discussion of $\gamma$ in the theory literature with which to compare.

The Advanced LIGO detectors promise an improvement in energy sensitivity of more than a factor of 100. Furthermore, on 2008 August 22, SGR 0501+4516 was discovered (Holland et al. 2008; Barthelmy et al. 2008; Palmer & Barthelmy 2008) and may be located only 1.5 kpc away (Gaensler & Chatterjee 2008; Leahy & Aschenbach 1995). SGR 0501+4516 searches will thus gain an additional 2 orders of magnitude in energy and $\gamma$ upper limits compared to SGRs at 10 kpc. A stacking analysis of SGR 0501+4516 bursts with Advanced LIGO (a gain of 4 orders of magnitude in energy sensitivity) could therefore reach $\gamma$ values below unity, even without another giant flare.

In the future, we plan to carry out stacking searches on both SGR storms, and also on isolated SGR bursts, as the sensitivity of detectors in the global network of GW interferometers continues to improve. For example, enhanced LIGO detectors will come online this year (2009), and data from the Virgo and GEO detectors in Europe can be used in future searches as well. Our stacked upper limits depend on theoretical guidance as to what weightings and time delays are possible, and the significance of our results depends on predictions of the range $E_{GW}$ and $\gamma$; yet all of these things are scarce. We hope that our continued efforts to search for GW associated with SGR and anomalous X-ray pulsar bursts encourage further modeling of GW emission from these intriguing objects.

The authors are grateful to the Swift team for the SGR 1900+14 storm data. The authors gratefully acknowledge the support of the United States National Science Foundation for the construction and operation of the LIGO Laboratory and the Science and Technology Facilities Council of the United Kingdom, the Max-Planck-Society, and the State of Niedersachsen/Germany for support of the construction and operation of the GEO600 detector. The authors also gratefully acknowledge the support of the research by these agencies and by the Australian Research Council, the Council of Scientific and Industrial Research of India, the Istituto Nazionale di Fisica Nucleare di Italy, the Spanish Ministerio de Educación y Ciencia, the Conselleria d’Economia Hisenda i Innovació of the Govern de les Illes Balears, the Royal Society, the Scottish Funding Council, the Scottish Universities Physics Alliance, The National Aeronautics and Space Administration, the Carnegie Trust, the Leverhulme Trust, the David and Lucile Packard Foundation, the Research Corporation, and the Alfred P. Sloan Foundation. This Letter is LIGO-P0900024.
