Neutrino oscillations are well established in the three flavor paradigm and can be described by three mixing angles ($\theta_{12}$, $\theta_{23}$, $\theta_{13}$), a CP-violating phase $\delta$, and two mass-squared differences ($\Delta m_{21}^2$, $\Delta m_{32}^2$). Among the three mixing angles, $\theta_{13}$ is the smallest and has recently been revealed to be non-zero [1–7]. The value of $\theta_{13}$ is a critical input for plans to measure $\delta$ and the neutrino mass hierarchy. Furthermore, it may provide important clues for physics beyond the Standard Model. The current best measurements of $\theta_{13}$ come from the reactor $\nu_e$–disappearance experiments Double Chooz, Daya Bay, and RENO [6,7,5]. All three experiments rely on the detection of the inverse beta decay (IBD) interaction, $\nu_e + p \rightarrow e^- + n$, in Gd-doped liquid scintillator (LS). Typically these experiments search for a prompt positron signal followed by a delayed gamma energy deposition, $E_{\text{prompt}}$, and a delayed gamma energy deposition, $E_{\text{delay}}$, resulting from a neutron capture on hydrogen or Gd. The Double Chooz experiment has determined the value of the neutrino oscillation parameter $\theta_{13}$ from an analysis of inverse beta decay interactions with neutron capture on hydrogen. This analysis uses a three times larger fiducial volume than the standard Double Chooz assessment, which is restricted to a region doped with gadolinium (Gd), yielding an exposure of 113.1 GW·ton·years. The data sample used in this analysis is distinct from that of the Gd analysis, and the systematic uncertainties are also largely independent, with some exceptions, such as the reactor neutrino flux prediction. A combined rate- and energy-dependent fit finds $\sin^2 2\theta_{13} = 0.097 \pm 0.034$ (stat.) $\pm 0.034$ (syst.), excluding the no-oscillation hypothesis at 2.0$\sigma$. This result is consistent with previous measurements of $\sin^2 2\theta_{13}$. The article is available online and was accepted for publication in April 2013.
The separation in time and space, $\Delta t$ and $\Delta r$, of the coincident events are determined by neutron capture physics. Neutron capture times are 200 $\mu$s in the $\gamma$-catcher and 30 $\mu$s in the target, where the presence of Gd greatly increases the neutron capture probability. In this analysis, where we search for $E_{\text{delay}} \approx 2.2$ MeV without any fiducial volume cuts, we expect to detect candidates in both the target and $\gamma$-catcher. Given that only 13% of the IBD interactions in the target volume are followed by neutron capture on hydrogen [6], 95% of the signal events used in this analysis are located in the $\gamma$-catcher.

Vertex reconstruction is based on a likelihood maximization of the charge and timing of the pulses detected at each PMT [6]. It allows the spatial correlation of prompt and delayed events, effectively removing accidental backgrounds.

We reconstruct the energy of all events via two steps: (1) a total charge ($Q_{\text{tot}}$) to photoelectron (PE) conversion; and (2) a PE to visible energy ($E_{\text{vis}}$) conversion as done in the Gd analysis [6]. The first step takes into account a channel-by-channel, non-linear gain calibration. The second step uses a light yield of $\sim 230$ PE/MeV, defined by the neutron capture peak on hydrogen in $^{252}$Cf calibration source data. By applying correction factors derived from spallation neutron data, this step also corrects for the time variation and vertex dependence of the detector response. The same method is used to determine $E_{\text{vis}}$ for the MC sample.

This analysis uses data collected by the Double Chooz far detector between April 13, 2011 and March 15, 2012, which is the same time-period used in the latest Double Chooz Gd analysis [6]. The total live time is 240.1 days, which is different from 227.9 days used in the Gd analysis [6] because of different analysis cuts.

The IBD candidate selection is performed via the following procedure. To reduce muon-induced backgrounds, we reject all events that occur less than 1 ms after a cosmic muon crosses the IV or the ID. We use PMT charge isotropy and PMT pulse simultaneity cuts to reduce backgrounds caused by light emitted from PMT bases (“light noise”) [3]. We apply the following coincident selection cuts to the remaining events: 0.7 MeV $< E_{\text{prompt}} < 12.2$ MeV; 1.5 MeV $< E_{\text{delay}} < 3.0$ MeV; 10 $\mu$s $< \Delta t < 600$ $\mu$s; $\Delta r < 90$ cm. Furthermore, we reject prompt candidates that are coincident with a signal detected in the OV. This veto, along with the 10 $\mu$s lower bound of the $\Delta t$ cut, renders backgrounds due to stopped muons negligible. Finally, we apply a multiplicity cut to reduce fast neutron backgrounds. This cut demands that no trigger occur in the 600 $\mu$s preceding the prompt candidate and that no trigger other than the delayed candidate occur in the 1000 $\mu$s following the prompt candidate.

The selection cuts yield a total of 36,284 events. Among these IBD candidates are backgrounds due to uncorrelated accidental coincidences, fast neutrons produced by muons traversing the nearby rock, long-lived cosmogenic isotopes (mainly $^{9}$Li), and a small contribution from light noise. Accidental backgrounds are dominant background, comprising almost half the IBD candidate sample.

We measure the rate and energy spectrum of accidentals by analyzing a sample of off-time coincidences. We collect this sample by looking for a delayed trigger between 1 s $+ 10$ $\mu$s and 1 s $+ 600$ $\mu$s after a prompt candidate event and applying a multiplicity cut for a period of 1 s $+ 600$ $\mu$s to 1 s $+ 1000$ $\mu$s. To increase sample statistics, we open 124 consecutive windows after this first window, thus sampling accidentals between 1 s and 1.2 s after each prompt candidate. After correcting for inefficiencies associated with this selection method, we obtain an accidentals rate of 73,455 $\pm$ 0.16 events/day. The result is cross-checked among multiple independent methods, and the quoted value includes the largest systematic uncertainty among them.

The fast neutron background consists of a proton recoil, the prompt event, in coincidence with the capture of the neutron, the delayed event. A single muon passing close to the detector may generate one or more fast neutrons which traverse the IV and ID. We tag the number of IBD candidates in which fast neutrons are recorded simultaneously in the IV and ID by requiring $\geq 2$ IV PMT hits and an ID–IV pulse-timing correlation. We estimate the tagging efficiency from an event sample with $E_{\text{prompt}} > 12$ MeV, following the same method as used for the Gd analysis [6]. From this sample we obtain a spectrum shape and, using the tagging efficiency and sample purity, we calculate the fast neutron rate to be $2.50 \pm 0.47$ events/day.

Muon-induced radioactive isotopes which emit a neutron immediately following $\beta$-decay, such as $^{9}$Li, can be a background to IBD reactions. As the lifetime of $^{9}$Li is 257 ms, we use the correlation of the $^{8}$Li decay events to previously detected muons to estimate the $^{9}$Li background rate. To increase the purity of $^{9}$Li in our sample, we consider only the subset of IBD candidates for which the spatial separation between the prompt event and the reconstructed muon track is within a defined distance. While ID PMTs are used to reconstruct the muon tracks in the Gd analysis [6], IV PMTs are used in this analysis to account for muons going through non-scintillating buffer liquid. To estimate the $^{9}$Li rate in this subsample, we fit the time difference $\Delta t_{p}$ between the IBD candidate prompt events and preceding muons with an exponential function characterized by the $^{9}$Li lifetime, plus a flat function to accommodate remaining accidentals and IBD candidates. The estimated rate is found to be consistent with that in the Gd analysis [6], accounting for the different fiducial volumes and selection efficiencies, and the difference is included in the systematic uncertainty. We find a $^{9}$Li rate of 2.8 $\pm$ 1.2 events/day. Muon track reconstruction efficiency is evaluated by a MC study and added into the systematic uncertainty. We estimate the shape and associated systematic uncertainty from MC, as was done in the Gd analysis [6].

Finally, we found a small number of light noise events creating two consecutive triggers that are identified as IBD candidates. A volume cut on the reconstructed vertex is used to quantify the rate and $E_{\text{prompt}}$ spectrum shape for this type of background. We estimate this background rate as $0.32 \pm 0.07$ events/day.

Calibration data taken with a $^{252}$Cf source in both the neutrino target and the $\gamma$-catcher are used to evaluate the fraction of neutron captures on hydrogen within the selection cuts $\Delta t$, $\Delta E_{\text{delay}}$, $\Delta t_{p}$. From these data, biases in these neutron selection criteria are evaluated and their contribution to the systematic uncertainties is estimated. The neutron detection efficiency, $\epsilon_{n}$, which includes both the efficiency of the IBD selection and the fraction of neutron captures which occur on hydrogen, is found to be 78.53% in the $\gamma$-catcher, 1.66% lower than the fraction predicted by simulation. Therefore, the Monte Carlo simulation for the prediction of the number of captured neutrons was reduced by a factor of 0.984 in the $\gamma$-catcher. The remaining spread in the difference between the data and Monte Carlo across the $\gamma$-catcher amounts to 0.46%, resulting in $\epsilon_{n} = 0.7853 \pm 0.0036$. A similar procedure was implemented in the target giving $\epsilon_{n} = 0.8046 \pm 0.0018$.

Weighting by the fraction of predicted IBD candidates in each region, we estimate the uncertainty in the detection efficiency over the entire fiducial volume as 1.0%. Finally, we find that an uncertainty of 1.2% accounts for the MC modeling of neutron migration, called spill-in/out [6], between detector subvolumes. Adding these factors in quadrature, we obtain a total detection efficiency uncertainty of 1.6%. Energy scale uncertainty arises from three sources: time variation, non-linearity, and non-uniformity in the detector response. We treat the first two effects exactly as in Gd analysis [6]. The third effect has a larger impact on the hydrogen analysis because of its extended fiducial volume. We estimate it by comparing data...
and MC from calibration source deployments in the γ-catcher. In total, we find an energy scale uncertainty of 1.7%, as compared to 1.1% used in the Gd analysis [6].

The reference $E_{\text{prompt}}$ spectrum is selected from the same reactor power-based $\bar{\nu}_e$ MC sample generated for the Gd analysis [6]. Systematic uncertainties on the reference spectrum are the same as for the Gd analysis. We use the Bugey4 measurement to minimize the systematic uncertainty on the reactor neutrino flux prediction [12,6], which is the dominant uncertainty in this analysis. The no-oscillation expectation for the number of neutrino candidates is 36 680 ± 520, including background. The predicted number of events for both signal and backgrounds are summarized in Table 1, and uncertainties relative to the predicted signal statistics are shown in Table 2.

To extract $\sin^2 2\theta_{13}$ we compare both the rate and shape of the data to the reference $E_{\text{prompt}}$ spectrum in 31 variably sized energy bins from 0.7 to 12.2 MeV. The fit procedure is identical to that used in the Gd analysis [3,6], except that we use a single integration period and include the $\Delta r$ cut efficiency as an additional source of uncertainty. As in [3,6], the pull parameters in Table 3 are allowed to vary in the fit, subject to the constraints listed on their initial values. We use the MINOS value of $\Delta m^2 = (2.32 \pm 0.12) \times 10^{-3}$ eV$^2$ as input for the fit [13]. We find a best fit of $\sin^2 2\theta_{13} = 0.097 \pm 0.034$ (stat.) ± 0.034 (syst.) with $\chi^2$/DOF of 38.9/30. As in the Gd analysis [6], we define statistical error as the portion of the 1 σ error which can be improved by collecting more data. This includes uncertainty from our current statistics (see Table 2) and uncertainty on background shapes. We define systematic error as the uncertainty which cannot be reduced simply by collecting more data. Fig. 1 shows the complete spectrum of IBD candidates with the fitted background contributions, while Fig. 2 shows the background-subtracted $E_{\text{prompt}}$ spectrum along with the best fit. The pull parameters from the fit are summarized in Table 3 together with the input values. We have performed a frequentist study to determine the compatibility of the data and the no-oscillation hypothesis. Based on a Δχ$^2$ statistic, defined as the difference between the $\chi^2$ at the best fit and at $\sin^2 2\theta_{13} = 0$, the data exclude the no-oscillation hypothesis at 97.4% (2.0σ). A fit incorporating only the rate information yields $\sin^2 2\theta_{13} = 0.044 \pm 0.022$ (stat.) ± 0.056 (syst.). A simple ratio of observed to expected signal statistics yields $R = 0.978 \pm 0.011$ (stat.) ± 0.029 (syst.) at the far site.

The smaller best-fit value of $\sin^2 2\theta_{13}$ by the rate-only analysis can be explained by the $^9$Li background. The fit to the energy spectrum indicates a larger $^9$Li background contamination than the original estimate, although it is consistent within the systematic uncertainty. If the input $^9$Li rate is raised to the best-fit value, the rate-only best fit moves to 0.072 ± 0.055, in closer agreement with our rate + shape standard result.

In summary, due to the low level of backgrounds achieved in the Double Chooz detector, we have made the first measurement of $\sin^2 2\theta_{13}$ using the capture of IBD neutrons on hydrogen. This technique enabled us to use a different data set with partially different systematic uncertainties than that used in the standard Gd analysis [6]. An analysis based on rate and spectral shape information yields $\sin^2 2\theta_{13} = 0.097 \pm 0.034$ (stat.) ± 0.034 (syst.), which is in good agreement with the result of the Gd analysis $\sin^2 2\theta_{13} = 0.109 \pm 0.030$ (stat.) ± 0.025 (syst.) [6]. With increased statistics and a precise evaluation of the correlation of the system-
