ABSTRACT

Mechanical Turk provides an on-demand source of human computation. This provides a tremendous opportunity to explore algorithms which incorporate human computation as a function call. However, various systems challenges make this difficult in practice, and most uses of Mechanical Turk post large numbers of independent tasks. TurKit is a toolkit for prototyping and exploring truly algorithmic human computation, while maintaining a straight-forward imperative programming style. We present the crash-and-rerun programming model that makes TurKit possible, along with a variety of applications for human computation algorithms. We also present a couple case studies of TurKit used for real experiments outside our lab.

ACM Classification: H5.2 [Information interfaces and presentation]: User Interfaces. - Prototyping.

General terms: Algorithms, Design, Experimentation

Keywords: Human computation, Mechanical Turk, toolkit

INTRODUCTION

Amazon’s Mechanical Turk (MTurk) is a popular web service for paying people to do simple human computation tasks. Workers on the system (turkers) are typically paid a few cents for Human Intelligence Tasks (HITs) that can be done in under a minute. MTurk has already been used by industry and academia for labeling images, categorizing products, and tagging documents.

Currently, MTurk is largely used for independent tasks. Task requesters post a group of HITs that can be done in parallel, such as labeling 1000 images. We want to explore tasks that build on each other. Figure 1 shows a simple example of an algorithm that generates a list of suggestions for what to see in New York, and then sorts them. A more sophisticated example might have turkers iteratively improve a passage of text, and vote on each other’s work. In general, this paper considers human computation algorithms, where an algorithm coordinates the contributions of humans toward some goal.

Human computation and Mechanical Turk are already being explored and studied in the HCI community [7] [8] [9]. We want to extend this study to explore algorithms involving humans, which is an HCI issue in itself. It requires knowing the right interface to present to each turker, as well as the right information for the algorithm to pass from one turker to the next.

Unfortunately, implementing algorithms on MTurk is not easy. HITs cost money to create, and may take hours to complete. Algorithms involving many HITs may run for days. These factors present a significant systems building challenge to programmers. Programmers must worry about issues like: what if the machine running the program crashes? What if the program throws an exception after a bunch of HITs have already been completed? These challenges are prohibitive enough to prevent easy prototyping and exploration of human computation algorithms.

This paper introduces the crash-and-rerun programming model to overcome these systems challenges. In this model, a program can be executed many times, without repeating costly work.
TurKit is a toolkit for writing human computation algorithms using the crash-and-rerun model. TurKit allows the programmer to think about algorithmic tasks as simple straight-line imperative programs, where calls to MTurk appear as ordinary function calls.

This paper makes the following contributions:

- **Crash-and-Rerun Programming**: A novel programming model suited to long running processes where local computation is cheap, and remote work is costly.
- **TurKit Script**: An API for writing algorithmic MTurk tasks using crash-and-rerun programming.
- **TurKit Online**: A public web GUI for running and managing TurKit scripts.
- **Example Applications**: Examples of algorithmic tasks explored by people outside our lab using TurKit.
- **Performance Evaluation**: An evaluation of TurKit's performance drawn from a corpus of 20 scripts posting almost 30,000 tasks over the past year.

**CRASH-AND-RERUN PROGRAMMING**

Consider a standard quicksort algorithm which outsources comparisons to Mechanical Turk (see Figure 2). This is a scenario where a local algorithm is making calls to an external system. Local computation is cheap, but the external calls cost money, and must wait for humans to complete work. The algorithm may need to run for a long time waiting on these results.

The challenge in this scenario is managing state over a long running process. This state can be kept in the heap, but this is dangerous in case the machine reboots or the program running process. This state can be kept in the heap, but this complicates logic of the program itself, rather than storing it explicitly in the database. Hence, *once* is important in the following conditions:

- **Non-determinism**. Since all calls to *once* need to happen in the same order every time the program is executed, it is important that execution be deterministic. Wrapping non-deterministic calls in *once* ensures that their outcomes are the same in all subsequent runs of the program.
- **High cost**. The whole point of crash-and-rerun programming is to avoid incurring more cost than necessary. If a function is expensive (in terms of time or money), then it is important to wrap it in *once* so that the program only pays that cost the first time the program encounters the function call. Typical tasks posted to Mechanical Turk cost 1 to 10 cents, and take between 30 seconds and an hour to complete.
- **Side-effects**. If functions have side-effects, then it may be important to wrap them in *once* if invoking the

```plaintext
quicksort(A)
if A.length > 0
    pivot ← A.remove(A.randomIndex())
    left ← new array
    right ← new array
    for x in A
        if compare(x, pivot)
            left.add(x)
        else
            right.add(x)
quicksort(left)
quicksort(right)
A.set(left + pivot + right)
```

```plaintext
compare(a, b)
hitId ← createHIT(....a....b....)
result ← getHITResult(hitId)
return (result says a < b)
```

![Figure 2: Standard quicksort algorithm that outsources comparisons to Mechanical Turk.](image)

```plaintext
quicksort(A)
if A.length > 0
    pivot ← A.remove(once A.randomIndex())
    left ← new array
    right ← new array
    for x in A
        if compare(x, pivot)
            left.add(x)
        else
            right.add(x)
quicksort(left)
quicksort(right)
A.set(left + pivot + right)
```

```plaintext
compare(a, b)
hitId ← once createHIT(....a....b....)
result ← once getHITResult(hitId)
return (result says a < b)
```

![Figure 3: Standard quicksort augmented with the *once* primitive, to remember costly and non-deterministic operations for subsequent runs.](image)
side-effect multiple times will cause problems. For instance, accepting results from a HIT multiple times causes an error from Mechanical Turk.

We can add \texttt{once} to our quicksort algorithm by surrounding the non-deterministic random pivot selection, as well as the expensive MTurk calls (see Figure 3). These modifications maintain the imperative style of the algorithm.

If the program crashes at any point, then subsequent runs will encounter all calls to \texttt{once} in the same order as before. Any calls which succeeded on a previous run of the program will have a result stored in the database, which will be returned immediately, rather than re-performing the costly or non-deterministic operation inside \texttt{once}.

Since crashing is so inexpensive in this model, we can crash instead of blocking. For instance, we implement \texttt{get-HITResult} by crashing the program if the results are not ready, rather than blocking until the results are ready. This works because \texttt{once} only stores results if the operation succeeds.

If the user needs to change an algorithm so that it is incompatible with a recorded sequence of \texttt{once} calls, then they can clear this record in the database, and start afresh. \texttt{Once} also detects when the database is out of sync with the program by recording information about each operation, and ensuring that the same operation is performed on subsequent runs. In such cases, the program crashes, and the user is notified that the database and program no longer agree.

The benefits of the crash-and-rerun model include:

- **Incremental Programming**: When a crash-and-rerun program crashes, it is unloaded from the runtime system. This provides a convenient opportunity to modify the program before it is executed again, as long as the modifications do not change the order of important operations that have already been executed. TurKit programmers can take advantage of this fact to write the first part of an algorithm, run it, view the results, and then decide what the rest of the program should do with these results.

- **Easy to Implement**: Crash-and-rerun programming is easy to implement, and does not require any special runtime system, language support, threads or synchronization. All that is required is a database to store a sequence of results from calls to \texttt{once}.

- **Retroactive Print-Line-Debugging**: In addition to adding code to the end of a program, it is also possible to add code to parts of a program which have already executed. This is true because only expensive or non-deterministic operations are recorded. Innocuous operations, like printing debugging information, are not recorded, since it is easy enough to simply re-perform these operations on subsequent runs of the program. This provides a cheap and convenient means of debugging in which the programmer adds print-line statements to a program which has already executed, in order to understand where it went wrong. This technique can also be used to retroactively extract data from an experiment, and print it to a file for analysis in an external program, like Excel.

### TURKIT SCRIPT

TurKit Script is built on top of JavaScript. Users have full access to JavaScript, in addition to a set of APIs designed around crash-and-rerun programming and Mechanical Turk. JavaScript was chosen because it is a common scripting language, popularized primarily within webpages, but general purpose enough for many prototyping applications.

#### Crash-and-Rerun

TurKit supports crash-and-rerun programming in JavaScript by providing the \texttt{once} function described in the previous section. \texttt{Once} accepts another function as an argument. It calls this function, and if it succeeds (i.e. it returns without crashing), then it records the return value in the database, and returns the result back to the caller. When \texttt{once} is called on a subsequent run of the script, it checks the database to see whether a return value has already been stored. If so, it skips calling the argument function, but rather simply returns the stored value. For example:

\begin{verbatim}
var r = once(function () {
return Math.random()
});
\end{verbatim}

The first time the script runs, the function is evaluated, generating a new random number. This number is stored as the result for this call to \texttt{once}. The next time the script runs, \texttt{Math.random} is not called, and the random number generated on the previous call is returned instead.

TurKit also provides a convenient way to crash a script. The \texttt{crash} function throws a "crash" exception. Crash is most commonly called when external data is not ready, e.g., tasks on MTurk are not complete.

TurKit automatically reruns the script after an adjustable time interval. Rerunning the script effectively polls Mechanical Turk every so often to see if any tasks have completed. In addition, the online version of TurKit receives notifications from MTurk when tasks complete, and reruns any scripts waiting on these tasks.

#### Parallelism

Although TurKit is single-threaded, and the programmer does not need to worry about real concurrency in the sense of multiple paths of execution running at the same time, it does provide a mechanism for simulating simple parallelism. This is done using \texttt{fork}, which creates a new branch in the recorded execution trace. If \texttt{crash} is called inside this branch, the script resumes execution of the former branch. Note that \texttt{fork} can be called within a \texttt{fork} to create a tree of branches that the script will follow.

\texttt{Fork} is useful in cases where a user wants to run several processes in parallel. They may want to run them in parallel for efficiency reasons, so they can post multiple HITs on Mechanical Turk at the same time, and the script can make
results are ready. It is called a turker, and returns their response:

TurKit also provides a from Amazon into suitable JavaScript objects. TurKit also handle the job of converting XML responses into a gramm. These wrappers use the same naming conventions as calls safe, e.g., the wrappers build on the crash-and-rerun library to make these wrappers around Amazon's MTurk REST API. These

In addition to these high level functions, TurKit provides a

The simplest way to use Mechanical Turk in TurKit is with the

TurKit also provides a function, which ensures that a series of forks have all finished. The function ensures that all the previous forks along the current path did not terminate prematurely. If any of them crashed, then join itself crashes the current path. In our example above, we would use join if we had an additional HIT E that required results from both HIT B and D:

The first time around, TurKit would get to the first fork, create HIT A, and try to wait for it. It would not be done, so it would crash that forked branch (rather than actually waiting), and then the next fork would create HIT C. So the first time the script runs, HITs A and B will be created, and each subsequent time it runs, it will check on both HITs to see if they are done.

TurKit also provides a function, which shows a string of text to the user:

function (function () {
    a = createHITAndWait() // HIT A
    b = createHITAndWait(...) // HIT B

    c = createHITAndWait() // HIT C
    d = createHITAndWait(...) // HIT D
})

Currently, HITs A and B must complete before HIT C is created, even though HIT C does not depend on the results from HITs A or B. We can instead create HIT A and C on the first run of the script using fork as follows:

fork(function () {
    a = createHITAndWait() // HIT A
    b = createHITAndWait(...) // HIT B
});

c = createHITAndWait() // HIT C
d = createHITAndWait(...) // HIT D
}

The first time around, TurKit would get to the first fork, create HIT A, and try to wait for it. It would not be done, so it would crash that forked branch (rather than actually waiting), and then the next fork would create HIT C. So the first time the script runs, HITs A and C will be created, and each subsequent time it runs, it will check on both HITs to see if they are done.

TurKit's version of this function takes an optional third parameter to indicate the number of votes required for a single option. One could also imagine extending this function to support different voting schemes.

Sorting

Another building block is sorting. A first attempt at sorting is simple using the crash-and-rerun model. We just take JavaScript's sort function and pass in our own comparator. Recall from Figure 1:

```javascript
ideas.sort(function (a, b) {
    return a < b ? -1 : 1
});
```

One problem with this approach is that all of the comparisons are performed serially, and there is no good way to get around this using JavaScript’s sort function because it requires knowing the results of each comparison before making additional comparisons. However, in TurKit we can implement a parallel quicksort, as shown in Figure 4. This implementation is fairly straightforward, and shows where TurKit's parallel programming model succeeds. Limits of this approach are discussed more in the discussion section.

Creating Interfaces for Turkers

The high level functions described so far use Mechanical Turk's custom language for creating interfaces for turkers. However, more complicated UIs involving JavaScript or
The crash-and-rerun module makes use of E4X 2 to handle XML results from MTurk. The basic idea is to record results between runs of the script. The basic idea is to record a trace of once calls in an array. As the script runs, we maintain a pointer to the next location in this array.

When once is called, it checks the information stored at the next location in the trace. If there is a return value there, it returns this immediately. Otherwise, it calls the function passed as a parameter to once. If the function succeeds, then it writes information about this call into the trace. After the call to once completes, the pointer moves to the next location in the trace.

Implementing fork requires managing a stack of instruction pointers. Fork also consumes an element in the array of once calls, except instead of storing a return value there, it stores another array of once calls.

The crash function is implemented by throwing a “crash” exception. This exception is caught internally by the fork function, so that it can pop the forked branch off the stack of instruction pointers, and return. If crash is ever called, even if it is caught by a fork, then TurKit will schedule a rerun of the script after some time interval.

**ONLINE WEB INTERFACE**

Figure 5 shows the TurKit web-based user interface, an online IDE for writing TurKit scripts, running them, and automatically rerunning them. The interface also has facilities for managing projects, editing files, viewing output, and managing the execution trace.

The run controls allow the user to run the project, and start and stop automatic rerunning of the script. This is necessary in the crash-and-rerun programming model since the script is likely to crash the first time it runs, after creating a HIT and seeing that the results for the HIT are not ready yet. Starting automatic rerunning of the script will periodically run the script, effectively polling Mechanical Turk until the results are ready.

There are also controls for switching between sandbox and normal mode on Mechanical Turk, as well as clearing the database. Together, these tools allow users to debug their scripts before letting them run unattended. Sandbox mode does not cost money, and is used for testing HITs. Users typically run a script in sandbox mode and complete the HITs themselves in the MTurk sandbox.

After the script appears to be working in the sandbox, the programmer may reset the database. Resetting the database clears the execution trace, as well as deletes any outstanding HITs or webpages created by the script. The user may now run the script in normal mode, and it will create HITs again on the real MTurk without any memory of having done so in the sandbox. Resetting the database is also useful after correcting major errors in the script that invalidate the recorded execution trace.

The execution trace panel shows a tree view representing the recorded actions in previous runs of the script. Note that calling fork creates a new branch in this tree. Some items are links, allowing the user to see the results for certain actions. In particular, createHIT has a link to the Mechani-
ical Turk webpage for the HIT, and the `webpage.create` function has a link to the public webpage that was created.

New users can get started by cloning a project from the panel in the lower-right. These projects demonstrate many common programming idioms in TurKit. Users may modify their cloned version of these projects to suit their own needs. There is also a link to the TurKit API for reference.

**Implementation**

The web-based GUI runs on Google App Engine (GAE). This choice was made because it is a free scalable server, and because it provides an easy way for users to log in using their existing Google account.

The web-app is built on top of TurKit, with extra security enhancements. In particular, Rhino generally allows JavaScript code to access Java directly. In order to protect users from damaging the server, or accessing each other’s data, we only allow access to a secure set of Java classes.

**EXAMPLE APPLICATIONS**

This section describes applications we have explored using TurKit, as well as use cases outside our group.

---

Iterative Writing

TurKit has been used to run many experiments which involve asking one turker to write a paragraph with some goal. The process then shows the paragraph to another person, and asks them to improve it. The process also has people vote between iterations, so that we eliminate contributions which don’t actually improve the paragraph. This process is run for some number of iterations. Figure 6 shows template code for a simple version of this algorithm.

From our iterative paragraph writing experiments, we have observed that most improvements involve making the paragraph longer (note that we limit the size to 500 characters). Also, people tend to keep the style and formatting introduced by earlier turkers in an iterative sequence.

Blurry Text Recognition

As another example of an iterative task using a similar structure, but achieving a different goal, consider the task of doing hard OCR. This is similar to reCAPTCHA, except it may work when the text is so unreadable that context and seeing other people’s guesses may be necessary to decipher the passage. Figure 8 shows an example transcription of an artificially blurred passage.

---

We can see the guesses evolve over several iterations, and the final result is almost perfect. We have had good success getting turkers to translate difficult passages, though there is room for improvement. For instance, if one turker early in the process makes poor guesses, these guesses can lead subsequent turkers astray.

Decision Theory Experimentation
TurKit has been used to coordinate a user study in a Master’s thesis outside our lab by Manal Dia: “On Decision Making in Tandem Networks” [4]. The thesis presents a decision problem where each person in a sequence must make a decision given information about the decision made by the previous person in the sequence. Dia wanted to test how well humans matched the theoretical optimal strategies for a particular decision problem:

Consider a sequence of N numbers, each chosen randomly between -10 and 10. The goal of the participants is to guess whether the sum of the N numbers is positive or negative. Each person is provided two options, “negative” or “positive”, and sometimes a third option “I don’t know”. Person x in the sequence is given three pieces of information:
- the fact that they are person x in the sequence
- the xth number of the N numbers
- the decision of the (x – 1)th person, if x > 1

TurKit was used to simulate this setup using real humans on Mechanical Turk, and run 50 trials of this problem for two conditions: with and without the option “I don’t know”. The first condition replicated the findings of prior results which used classroom studies, and the second condition found some interesting deviations in human behavior from the theoretical optimal strategy.

Dia found TurKit helpful for coordinating the iterative nature of these experiments. However, she used an early version of TurKit, and had difficulty discovering the parallelization features in that version.

Psychophysics Experimentation
Phillip Isola, a PhD student in Brain and Cognitive Science, is using TurKit to explore psychophysics. He is interested in having turkers collaboratively sort, compare, and classify various stimuli, in order to uncover salient dimensions in
those stimuli. For instance, if turkers naturally sort a set of images from lightest to darkest, then we might guess that brightness is a salient dimension for classifying images. This work is related to the staircase-method in psychophysics, where experimenters may iteratively adjust stimuli until it is on the threshold of what a subject can perceive [3].

His current experiments involve using TurKit to run genetic algorithms where humans perform both the mutation and selection steps. For instance, he has evolved pleasant color palettes by having some turkers change various colors in randomly generated palettes, and other turkers select the best from a small set of color palettes.

He has also applied genetic algorithms to sorting. In one experiment, he shows users a list of animals, and asks them to reposition one of the animals in the list. Other users select the best ordering from several candidates. Users are not told how they should sort the animals. In one instance, the result is an alphabetical sorting.

Isola found TurKit to be the right tool for these tasks, since he needed to embed calls to MTurk in a larger algorithm. However, he also used an early version of TurKit, and had difficulty discovering the parallelization features. This issue is discussed more in the Discussion section below.

**PERFORMANCE EVALUATION**

This paper claims that the programming model is good for prototyping algorithmic tasks on MTurk, and that it sacrifices efficiency for programming usability. One question to ask is whether the overhead is really as inconsequential as we claim, and where it breaks down.

We consider a corpus of 20 TurKit experiments run over the past year, including: iterative writing, blurry text recognition, website clustering, brainstorming, and photo sorting. These experiments paid turkers a total of $364.85 for 29,731 assignments across 3,829 HITs.

Figure 9 and Figure 10 give a sense for how long tasks take to complete once they are posted on MTurk. Figure 9 shows the round-trip time for the first assignment to complete after posting HITs with various payoffs. Part of this time is spent waiting for turkers to accept each task, and the rest is spent waiting for turkers to perform the work. Our higher paying tasks are typically more difficult, so we expect them to take longer to perform. However, if we subtract this time, the chart still increases, meaning it takes longer for turkers to start the higher paying tasks. One explanation is that turkers sort by reward, and 10-cent tasks are not on the first page of results. Another explanation is that turkers are looking for quick and easy tasks.

Figure 10 gives a better picture of the round-trip time-to-completion for the 1-cent tasks. The average is 4 minutes, where 82% take between 30 seconds and 5 minutes. About 0.1% complete within 10 seconds. The fastest is 7 seconds.

Figure 11 gives a sense for how long TurKit scripts take to rerun given a fully recorded execution trace, in addition to how much memory they consume. Both of these charts are in terms of the number of HITs created by a script, since this measure is more correlated to space and time requirements than “calls to once” or “assignments created”. Note that for every HIT created, there is an average of 6 calls to once, and 7.8 assignments created.

The largest script in our corpus creates 956 HITs. It takes 10.6 seconds to rerun a full trace, and the database file is 7.1MBs. It takes Rhino 0.91 seconds to parse and load the database into memory, where the database expands to 25.8MBs.

This means that waiting for a single human takes an order of magnitude longer than running most of our scripts, which suggests that crash-and-rerun programming is suitable for many applications. The slowest script is faster than 99% of our hit-completion times. Note that making the script 10x slower would only be faster than 70% of hit-completion times. For such a slow script, it may be worth investigating options beyond the crash-and-rerun model.

**DISCUSSION**

We have iterated on TurKit for over a year, and received feedback from a number of users (four in our group, and
two outside our group, noted above). This section discusses what we’ve learned, including some limitations of TurKit, and areas for future work.

Usability
The TurKit crash-and-rerun programming model makes it easy to write simple scripts, but users have uncovered a number of usability issues. First, even when users know that a script will be rerun many times, it is not obvious that it needs to be deterministic. In particular, it is not clear that `Math.random` is dangerous, and must be wrapped in `once`. This led us to override `Math.random` with a wrapper that uses a random seed the first time the script executes, and uses the same seed on subsequent runs (until the database is reset).

Users were also often unclear about which aspects of a TurKit script were stored in the execution trace, and which parts could be modified or re-ordered. This was due primarily to the fact that many functions in TurKit call `once` internally (such as `createHIT` and `waitForHIT`). We mitigated this problem by adding a view of the execution trace to the GUI, making clear which aspects of the script were recorded. This also allows users to delete records from the execution trace for fine-grained control of their script. Doing this before required advanced knowledge of how the trace was stored in the database.

Finally, many early TurKit users did not know about the parallel features of TurKit. Multiple users asked to be able to create multiple HITs in a single run, and were surprised to learn that they already could. The relevant function used to be called `attempt`, a poor naming choice based on implementation details, rather than the user’s mental model. We renamed this function to `fork`. We also added `join`, since most uses of the original `attempt` function would employ code to check that all of the attempts had been successful before moving on.

Scalability
The crash-and-rerun model favors usability over efficiency, but does so at an inherent cost in scalability. Whereas a conventional program could create HITs and wait for them in an infinite loop, a crash-and-rerun program cannot. The crash-and-rerun program will need to rerun all previous iterations of the loop every time it re-executes, and eventually the space required to store this list of actions in the database will be too large. Alternatively, the time it takes to replay all of these actions will grow longer than the time it takes to wait for a HIT to complete, in which case it may be better to poll inside the script, rather than rerun it.

One way to overcome this barrier is to use continuations and coroutines. Rhino supports first-class continuations, which provide the ability to save and serialize the state of a running script, even along multiple paths of execution. Continuations could be saved after all important calls (like `createHIT`), and a try-catch block around the entire script would catch any exceptions and store all the continuations in a database. The main drawback of this approach is that a serialized continuation includes the code of the script, so it cannot be reused if the script changes. This means that users could not incrementally modify their code between runs of a program, or use retroactive print-line debugging.

Parallel Programming Model
Parallel programming in the crash-and-rerun model is not completely general. For instance, we proposed a parallel version of quicksort that performs the partition in parallel, and then sorts each sublist in parallel. However, it joins between partitioning the elements, and sorting the sublists. In theory, this is not necessary. Once we have a few elements for a given sublist, we should be able to start sorting it right away (provided that we chose a pivot from among the elements that we have so far). Doing so is possible in TurKit by storing extra state information in the database, but is infeasible using `once`, `fork` and `join` alone.

Experimental Replication
The crash-and-rerun programming model offers a couple of interesting benefits for experimental replication using Mechanical Turk. First, it is possible to give someone the source code for a completed experiment, along with the database file. This allows them to rerun the experiment without actually making calls to Mechanical Turk. In this way, people can investigate the methodology of an experiment in great detail, and even introduce print-line statements retroactively to reveal more information.

Second, users can use the source code alone to rerun the experiment. This provides an exciting potential for experimental replication where human subjects are involved, since the experimental design is encoded as a program. We post most of our experiments on the Deneme blog, along with the TurKit code and database needed to rerun them.

RELATED WORK

Programming Model
Crash-and-rerun programming is related to early work on reversible execution [11], as well as more recent work on the Java Whyline which can answer causality questions about a program after it has already executed [10]. Our implementation is more light weight, and does not require instrumenting a virtual machine. Crash-and-rerun programming is also similar to web application programming. Web servers typically generate HTML for the user and then “crash” (forget their state) until the next request. The server preserves state between requests in a database. The difference is that crash-and-rerun programming uses an imperative programming model, whereas web applications must be written using an event-driven state-machine model.

Some innovative web application frameworks allow for an imperative model, including Struts Flow and stateful django. These and similar systems serialize continuations between requests in order to preserve state, which means they do not share many of the important benefits of crash-and-rerun programming, including incremental programming.

http://code.google.com/p/django-stateful/
and retroactive debugging. This is less of an issue for web services since the preserved state generally deals with a single user over a small time-span, whereas TurKit scripts may involve hundreds of people over several days.

**Human Computation**

Human computation systems generally involve many workers making small contributions toward a goal. Quinn and Bederson give a good overview of distributed human computation systems [16]. Individual systems have also been studied and explored in academic literature, including Games with a Purpose [1], Wikipedia [9] [15], and Mechanical Turk [7] [8] [12] [13] [14].

**Human Computation Algorithms**

Many human computation systems are embarrassingly parallel, where tasks to not depend on each other. Human computation algorithms involve more complicated orchestration of human effort, where workers build on each other’s work. Kosorukoff uses humans in genetic algorithms [11]. Wikipedia itself may be viewed as a human computation algorithm. Each article involves many humans adding, improving and moderating content.

TurKit is a toolkit for exploring human computation algorithms. Human genetic algorithms, and processes within Wikipedia can be encoded as TurKit scripts and tested on Mechanical Turk. The applications and algorithms presented in this paper are merely first attempts at exploring this space. Already Dai, Mausam and Weld propose decision-theoretic improvements to algorithms proposed in this paper [5], which we could encode and test empirically using TurKit.

**CONCLUSION**

TurKit is a toolkit for exploring human computation algorithms on Mechanical Turk. We introduce the crash-and-rerun programming model for writing fault-tolerant scripts. Using this model, TurKit allows users to write algorithms in a straight-forward imperative programming style, abstracting Mechanical Turk as a function call. We present a variety of applications for TurKit, including real-world use cases from outside our lab.

The online version of TurKit is available now, as well as the source code: turkit-online.appspot.com. In addition to enhancing the TurKit UI and API, we are actively using TurKit to continue exploring the field of human computation algorithms as future work.

**ACKNOWLEDGMENTS**

We would like to thank everyone who contributed to this work, including Mark Ackerman, Michael Bernstein, Jeffrey P. Bigham, Thomas W. Malone, Robert Laubacher, Manal Dia, Phillip Isola, everyone who has tried TurKit, and members of the UID group. This work was supported in part by Xerox, by the National Science Foundation under award number IIS-0447800, by Quanta Computer as part of the TParty project, and by the MIT Center for Collective Intelligence. Any opinions, findings, conclusions or recommendations expressed in this publication are those of the authors and do not necessarily reflect the views of the sponsors.
