We can only estimate the distribution of stock returns but from option prices we observe the distribution of state prices. State prices are the product of risk aversion – the pricing kernel – and the natural probability distribution. The Recovery Theorem enables us to separate these so as to determine the market’s forecast of returns and the market’s risk aversion from state prices alone. Among other things, this allows us to recover the pricing kernel, the market risk premium, the probability of a catastrophe, and to construct model free tests of the efficient market hypothesis.

I want to thank the participants in the UCLA Finance workshop for their insightful comments as well as Richard Roll, Hanno Lustig, Rick Antle, Andrew Jeffrey, Peter Carr, Kevin Atteson, Jessica Wachter, Ian Martin, Leonid Kogan, Torben Andersen, John Cochrane, Dimitris Papanikolaou, William Mullins, Jon Ingersoll, Jerry Hausman, Andy Lo, Steve Leroy, George Skiadopoulos, Xavier Gabaix, Patrick Dennis, Phil Dybvig, Will Mullins, Nicolas Caramp, Rodrigo Adao, the referee and the associate editor and editor. All errors are my own.
Financial markets price securities with payoffs extending out in time, and the hope that they can be used to forecast the future has long fascinated both scholars and practitioners. Nowhere is this more apparent than in the fixed income markets with its enormous literature devoted to examining the predictive content of forward rates. But with the exception of foreign exchange and some futures markets, a similar line of research has not developed in other markets, and this absence is most notable in the equity markets.

While we have a rich market in equity options and a well developed theory of how to use their prices to extract the martingale or risk neutral probabilities (see Cox and Ross (1976a, 1976b)), there has been a theoretical hurdle to using these probabilities to forecast the probability distribution of future returns, i.e. real or natural probabilities. Risk neutral returns are natural returns that have been ‘risk adjusted’. In the risk neutral measure, the expected return on all assets is the risk free rate because the return under the risk neutral measure is the return under the natural measure with the risk premium subtracted out. The risk premium is a function both of risk and of the market’s risk aversion, and to use risk neutral prices to estimate natural probabilities we have to know the risk adjustment so we can add it back in. In models with a representative agent this is equivalent to knowing both the agent’s risk aversion and the agent’s subjective probability distribution and neither is directly observable. Instead, we infer them from fitting or ‘calibrating’ market models. Unfortunately, efforts to empirically measure the aversion to risk have led to more controversy than consensus. For example, measurements of the coefficient of aggregate risk aversion range from 2 or 3 to 500 depending on the model and the macro data used. Additionally, financial
data are less helpful than we would like because we have a lengthy history in which U.S. stock returns seemed to have consistently outperformed fixed income returns – the equity premium puzzle (Prescott and Mehra [1985]) – and that has even given rise to some worrisome practical investment advice based on the view that stocks are uniformly superior to bonds. These conundrums have led some to propose that finance has its equivalent to the dark matter cosmologists posit to explain the behavior of their models for the universe when observables seem insufficient. The dark matter of finance is the very low probability of a catastrophic event and the impact that changes in that perceived probability can have on asset prices (see, e.g., Barro [2006] and Weitzmann [2007]). Apparently, though, such events are not all that remote and ‘five sigma events’ seem to occur with a frequency that belies their supposed low probability.

When we extract the risk neutral probabilities of such events from the prices of options on the S&P 500, we find the risk neutral probability of, for example, a 25% drop in a month, to be higher than the probability calculated from historical stock returns. But since the risk neutral probabilities are the natural probabilities adjusted for the risk premium, either the market forecasts a higher probability of a stock decline than has occurred historically or the market requires a very high risk premium to insure against a decline. Without knowing which, it is impossible to separate the two out and infer the market’s forecast of the event probability.

Finding the market’s forecast for returns is important for other reasons as well. The natural expected return of a strategy depends on the risk premium for that strategy and, consequently, it has long been argued that any tests of efficient market hypotheses are simultaneously, tests of a particular asset pricing model
and of the efficient market hypothesis (Fama [1970]). But, if we knew the kernel, we could estimate how variable the risk premium is (see Ross [2005]), and a bound on the variability of the kernel would limit how predictable a model for returns could be and still not violate efficient markets. In other words, it would provide a model free test of the efficient markets hypothesis.

A related issue is the inability to find the current market forecast of the expected return on equities. Unable to obtain this directly from prices as we do with forward rates, we are left to using historical returns and resorting to opinion polls of economists and investors - asking them to reveal their estimated risk premiums. It certainly does not seem that we can derive the risk premium directly from option prices because by pricing one asset – the derivative – in terms of another, the underlying, the elusive risk premium does not appear in the resulting formula.

But, in fact, all is not quite so hopeless. While quite different, the results in this paper are in the spirit of Dybvig and Rogers [1997], who showed that if stock returns follow a recombining tree (or diffusion) then from observing an agent’s portfolio choice along a single path we can reconstruct the agent’s utility function. Borrowing their nomenclature, we will call these results recovery theorems as well. Section I presents the basic analytic framework tying the state price density to the kernel and the natural density. Section II derives the Recovery Theorem which allows us to estimate the natural probability of asset returns and the market’s risk aversion, the kernel, from the state price transition process alone.

\[\text{---------------------------}\]

\[1\text{ Although these too require a risk adjustment.}\]
To allow us to do so, two important non parametric assumptions are introduced here. Section III derives a second recovery theorem, the Multinomial Recovery Theorem, which offers an alternative route for recovering the natural distribution for binomial and multinomial processes. Section IV examines the application of these results to some examples and highlights some important limitations of the approach. Section V estimates the state price densities at different horizons from the S&P 500 option prices on a randomly chosen recent date, April 27, 2011, estimates the state price transition matrix, and applies the Recovery Theorem to derive the kernel and the natural probability distribution. We compare the model’s estimate of the natural probability with the histogram of historical stock returns. In particular, we shed some light on the dark matter of economics by highlighting the difference between the odds of a catastrophe as derived from observed state prices with that obtained from historical data. The analysis of Section V is meant to be illustrative and is far from the much needed empirical analysis, but it provides the first use of the Recovery Theorem to estimate the natural density of stock returns. Section VI outlines a model free test of efficient market hypotheses. Section VII concludes and summarizes the paper, and points to some future research directions.
I. The Basic Framework

Consider a discrete time world with asset payoffs $g(\theta)$ at time $T$, contingent on the realization of a state of nature, $\theta \in \Omega$. From the Fundamental Theorem of Asset Pricing (see Dybvig and Ross [1987, 2003]), no arbitrage (‘NA’) implies the existence of positive state space prices, i.e., Arrow Debreu contingent claims prices, $p(\theta)$ (or, in general spaces, a price distribution function, $P(\theta)$), paying $1$ in state $\theta$ and nothing in any other states. If the market is complete, then these state prices are unique. The current value, $p_g$, of an asset paying $g(\theta)$ in one period is given by

$$p_g = \int g(\theta) dP(\theta).$$  \hspace{1cm} (1)

Since the sum of the contingent claims prices is the current value of a dollar for sure in the future, letting $r(\theta^0)$ denote the riskless rate as a function of the current state, $\theta^0$, we can rewrite this in the familiar forms

$$p_g = \int g(\theta) dP(\theta)$$  \hspace{1cm} (2)

$$= \left( \int dP(\theta) \right) \int g(\theta) \frac{dP(\theta)}{dP(\theta)} \equiv e^{-r(\theta^0)\tau} \int g(\theta) d\pi^*(\theta)$$

$$\equiv e^{-r(\theta^0)\tau} E^*[g(\theta)] = E[g(\theta) \varphi(\theta)]$$

where an asterisk denotes the expectation in the martingale measure and where the pricing kernel, i.e., the state price/probability, $\varphi(\theta)$, is the Radon Nikodym derivative of $P(\theta)$ with respect to the natural measure which we will denote as $F(\theta)$. With continuous distributions, $\varphi(\theta) = p(\theta)/f(\theta)$ where $f(\theta)$ is the natural
probability, i.e., the actual or relevant subjective probability distribution, and the risk neutral probabilities, are given by \( \pi^*(\theta) = \frac{p(\theta)}{\int p(\theta) d\theta} = e^{r(\theta)T} p(\theta) \).

Let \( \theta_i \) denote the current state and \( \theta_j \) a state one period forward. We assume that this is a full description of the state of nature including the stock price itself and other information that is pertinent to the future evolution of the stock market index, thus the stock price can be written as \( S(\theta_i) \). From the forward equation for the martingale probabilities

\[
Q(\theta_i, \theta_j, T) = \int_{\theta} Q(\theta_i, \theta, t) Q(d\theta, \theta_j, T - t),
\]

where \( Q(\theta_i, \theta_j, T) \) is the forward martingale probability transition function for going from state \( \theta_i \) to state \( \theta_j \) in \( T \) periods and where the integration is over the intermediate state \( \theta \) at time \( t \). Notice that the transition function depends on the time interval and is independent of calendar time.

This is a very general framework and allows for many interpretations. For example, the state could be composed of parameters that describe the motion of the process, e.g., the volatility of returns, \( \sigma \), as well as the current stock price, \( S \), i.e., \( \theta = (S, \sigma) \). If the distribution of martingale returns is determined only by the volatility, then a transition could be written as a move from \( \theta_i = (S, \sigma) \) to \( \theta_j = (S(1 + R), \sigma') \) where \( R \) is the rate of return and

\[
Q(\theta_i, \theta_j, t) = Q((S, \sigma), (S(1 + R), \sigma'), t).
\]
To simplify notation we will use state prices rather than the martingale probabilities so that we do not have to be continually correcting for the interest factor. Defining the state prices as

\[
P(\theta_i, \theta_j, t, T) \equiv e^{-r(\theta_i)(T-t)} Q(\theta_i, \theta_j, T - t),
\]

and, assuming a time homogeneous process where calendar time is irrelevant, for the transition from any time \( t \) to \( t+1 \), we have

\[
P(\theta_i, \theta_j) = e^{-r(\theta_i)} Q(\theta_i, \theta_j).
\]

Letting \( f \) denote the natural (time homogeneous) transition density, the kernel in this framework is defined as the price per unit of probability in continuous state spaces,

\[
\varphi(\theta_i, \theta_j) = \frac{p(\theta_i, \theta_j)}{f(\theta_i, \theta_j)},
\]

and an equivalent statement of no arbitrage is that a positive kernel exists.

A canonical example of this framework is an intertemporal model with a representative agent with additively time separable preferences and a constant discount factor, \( \delta \). We will use this example to motivate our results but it is not necessary for the analysis that follows. Letting \( c(\theta) \) denote consumption at time \( t \) as a function of the state, over any two periods the agent seeks

\[
\max_{(c(\theta_i), c(\theta_j)) \in \Theta} \{ U(c(\theta_i)) + \delta \int U(c(\theta)) f(\theta_i, \theta) d\theta \}
\]

s.t.
The first order condition for the optimum allows us to interpret the kernel as

\[ \varphi(\theta_i, \theta_j) = \frac{p(\theta_i, \theta_j)}{f(\theta_i, \theta_j)} = \frac{\delta U'(c(\theta_j))}{U'(c(\theta_i))} \quad (9) \]

Equation (9) for the kernel is the equilibrium solution for an economy with complete markets in which, for example, consumption is exogenous and prices are defined by the first order condition for the optimum. In a multiperiod model with complete markets and state independent, intertemporally additive separable utility, there is a unique representative agent utility function that satisfies the above optimum condition. The kernel is the agent’s marginal rate of substitution as a function of aggregate consumption (see Dybvig and Ross [1987, 2003]).

Notice, too, that in this example the pricing kernel depends only on the marginal rate of substitution between future and current consumption. This path independence is a key element of the analysis in this paper, and the kernel is assumed to have the form of (9), i.e., it is a function of the ending state and depends on the beginning state only through dividing to normalize it.

Definition 1

A kernel is transition independent if there is a positive function of the states, \( h \), and a positive constant \( \delta \) such that for any transition from \( \theta_i \) to \( \theta_j \), the kernel has the form,
The intertemporally additive utility function is a common example that generates a transition independent kernel but there are many others.²

Using transition independence we can rewrite (7) as

\[
p(\theta_i, \theta_j) = \varphi(\theta_i, \theta_j)f(\theta_i, \theta_j) = \delta \frac{h(\theta_j)}{h(\theta_i)} f(\theta_i, \theta_j)
\]  

where \( h(\theta) = U'(c(\theta)) \) in the representative agent model. Assuming that we observe the state price transition function, \( p(\theta_i, \theta_j) \), our objective will be to solve this system to recover the three unknowns, the natural probability transition function, \( f(\theta_i, \theta_j) \), the kernel, \( \varphi(\theta_i, \theta_j) = \delta h(\theta_j)/h(\theta_i) \), and the discount rate, \( \delta \).

Transition independence or some variant, is necessary to allow us to separately determine the kernel and the natural probability distribution from equation 7. With no restrictions on the kernel, \( \varphi(\theta_i, \theta_j) \), or the natural distribution, \( f(\theta_i, \theta_j) \), it would not be possible to identify them separately from knowledge of the product alone, \( p(\theta_i, \theta_j) \). Roughly speaking, there are more unknowns on the right hand side of (7) than equations.

There is an extensive literature on a variety of approaches to this problem. For example, Jackwerth and Rubinstein [1996] and Jackwerth [2000] use implied binomial trees to represent the stochastic process. Ait Sahalia and Lo [2000]

² For example, it is easy to show that Epstein-Zin recursive preferences (Epstein and Zin [1989]) also produce a transition independent kernel.
combine state prices derived from option prices with estimates of the natural
distribution to determine the kernel. Bliss and Panigirtzoglou [2004] assume
constant relative or absolute risk aversion preferences and estimate the elasticity
parameter by comparing the predictions of this form with historical data.
Bollerslev and Tederov [2008] use high frequency data to estimate the premium
for jump risk in a jump diffusion model and, implicitly, the kernel. These
approaches have a common element; they use the historical distribution of returns
to estimate the unknown kernel and thereby link the historical estimate of the
natural distribution to the risk neutral distribution and, or, they make parametric
assumptions on the utility function of a representative agent (and often assume the
distribution follows a diffusion).

In the next section we will take a different tack and show that the equilibrium
system of equations, (11), can be solved without the need to use either historical
data or any further assumptions than a transition independent kernel.
II. The Recovery Theorem

To gain some insight into equation (11) and to position the apparatus for empirical work from now on we will specialize it to a discrete state space model, and, while it is not necessary, we will illustrate the analysis with the representative agent formulation,

\[ U'_i p_{ij} = \delta U'_j f_{ij} \quad , \tag{12} \]

where we can interpret

\[ U'_i \equiv U'(c(\theta_i)) \quad , \tag{13} \]

But, more generally, \( U' \) is any positive function of the state. Writing this in terms of the kernel and denoting the current state \( \theta_i \) as state \( i = 1 \),

\[ \varphi_j \equiv \varphi(\theta_1, \theta_j) = \delta(U'_j / U'_1) \quad . \tag{14} \]

We will define the states from the filtration of the stock value, so that the kernel is the projection of the kernel across the broader state space onto the more limited space defined by the filtration of the asset price. Notice that while marginal utility is monotone declining in consumption it need not be monotone declining in the asset value, \( S(\theta_i) \).

Rewriting the state equations (11) in matrix form we have

\[ DP = \delta FD \quad , \tag{15} \]

where \( P \) is the \( mxm \) matrix of state contingent Arrow Debreu prices, \( p_{ij} \), \( F \) is the \( mxm \) matrix of the natural probabilities, \( f_{ij} \), and \( D \) is the diagonal matrix with the
undiscounted kernel, i.e., the marginal rates of substitution, \( \varphi_i / \delta \), on the diagonal,

\[
D = \left( \frac{1}{U_i} \right) \begin{bmatrix}
U_i' & 0 & 0 \\
0 & U_i' & 0 \\
0 & 0 & U_m'
\end{bmatrix} = \begin{bmatrix}
\varphi_1 & 0 & 0 \\
0 & \varphi_i & 0 \\
0 & 0 & \varphi_m
\end{bmatrix} \left( \frac{1}{\delta} \right).
\] (16)

With a discrete or compact state space for prices we will have to make sure that the model does not permit arbitrage. In a model with exogenous consumption the absence of arbitrage is a simple consequence of an equilibrium with positive state prices which assures that the carrying cost net of the dividend compensates for any position that attempts to profit from the rise out of the lowest asset value or the decline from the highest value.

Continuing with the analysis, keep in mind that we observe the state prices, \( P \), and our objective is to see what, if anything, we can infer about the natural measure, \( F \), and the pricing kernel, i.e., the marginal rates of substitution. Solving (15) for \( F \) as a function of \( P \),

\[
F = \left( \frac{1}{\delta} \right) DPD^{-1},
\] (17)

Clearly if we knew \( D \), we would know \( F \). It appears that we only have \( m^2 \) equations in the \( m^2 \) unknown probabilities, the \( m \) marginal utilities, and the discount rate, \( \delta \), and this appears to be the current state of thought on this matter. We know the risk neutral measure but without the marginal rates of substitution across the states, i.e., the risk adjustment, there appears to be no way to close the system and solve for the natural measure, \( F \). Fortunately, though, since \( F \) is a matrix whose rows are transition probabilities, it is a stochastic matrix, i.e., a
positive matrix whose rows sum to one, and there is an additional set of m constraints,

\[ Fe = e, \tag{18} \]

where \( e \) is the vector with 1 in all the entries.

Using this condition we have

\[ Fe = \left( \frac{1}{\delta} \right) DPD^{-1}e = e, \tag{19} \]

or

\[ Pz = \delta z, \tag{20} \]

where

\[ z \equiv D^{-1}e. \tag{21} \]

This is a characteristic root problem and offers some hope that the solution set will be discrete and not an arbitrary cone. With one further condition, the theorem below verifies that this is so and provides us with a powerful result.

From NA, \( P \) is nonnegative and we will also assume that it is irreducible, i.e., all states are attainable from all other states in \( n \) steps. For example, if \( P \) is positive then it is irreducible. More generally, though, even if there is a zero in the \( ij \) entry then it could be possible to get to \( j \) in, say, two steps by going from \( i \) to \( k \) and then
from $k$ to $j$ or along a path with $n$ steps. A matrix $P$ is irreducible if there is always some path such that any state $j$ can be reached from any state $i$.\footnote{Notice that since the martingale measure is absolutely continuous with respect to the natural measure, $P$ is irreducible if $F$ is irreducible.}

Theorem 1 – The Recovery Theorem

If there is no arbitrage, if the pricing matrix is irreducible and if it is generated by a transition independent kernel, then there exists a unique (positive) solution to the problem of finding the natural probability transition matrix, $F$, the discount rate, $\delta$, and the pricing kernel, $\varphi$. In other words, for any given set of state prices there is a unique compatible natural measure and a unique pricing kernel.

Proof:

Existence can also be proven directly, but it follows immediately from the fact that $P$ is assumed to be generated from $F$ and $D$ as shown above. The problem of solving for $F$ is equivalent to finding the characteristic roots (eigenvalues) and characteristic vectors (eigenvectors) of $P$ since, if we know $\delta$ and $z$ such that

$$Pz = \delta z,$$

then the kernel can be found from $z = D^{-1}e$.

From the Perron Frobenius Theorem (see Meyer [2000]) all nonnegative irreducible matrices have a unique positive characteristic vector, $z$, and an associated positive characteristic root, $\lambda$. The characteristic root $\lambda = \delta$ is the
subjective rate of time discount. Letting \( z \) denote the unique positive characteristic vector with root \( \lambda \), we can solve for the kernel as

\[
\frac{U'(c(\theta_i))}{U'(c(\theta_j))} = \left( \frac{1}{\delta} \right) \varphi_i = d_{ii} = \frac{1}{z_i} .
\] (23)

To obtain the natural probability distribution, from our previous analysis,

\[
F = \left( \frac{1}{\delta} \right) D P D^{-1} \quad \text{(24)}
\]

and

\[
f_{ij} = \left( \frac{1}{\delta} \right) \frac{\varphi_i}{\varphi_j} = \left( \frac{1}{\delta} \right) \frac{U'_i}{U'_j} p_{ij} = \left( \frac{1}{\lambda} \right) \frac{z_j}{z_i} p_{ij} .
\] (25)

\[\square\]

Notice that if the kernel is not transition independent then we have no assurance that the probability transition matrix can be separated from the kernel as in the proof. Notice, too, that there is no assurance that the kernel will be monotone in the ordering of the states by, for example, stock market values.

Corollary 1

The subjective discount rate, \( \delta \), is bounded above by the largest interest factor.

Proof:

From The Recovery Theorem the subjective rate of discount, \( \delta \), is the maximum characteristic root of the price transition matrix, \( P \). From the Perron Frobenius Theorem (see Meyer [2000]) this root is bounded above by the
maximum row sum of \( P \). Since the elements of \( P \) are the pure contingent claim state prices, the row sums of \( P \) are the interest factors and the maximum row sum is the maximum interest factor.

\[ \square \]

Now let’s turn to the case where the riskless rate is the same in all states.

**Theorem 2**

If the riskless rate is state independent then the unique natural density associated with a given set of risk neutral prices is the martingale density itself, i.e., pricing is risk neutral.

**Proof:**

In this case we have

\[ Pe = \gamma e \quad , \quad (26) \]

where \( \gamma \) is the interest factor. It follows that \( Q = (1/\gamma)P \) is the risk neutral probability matrix and, as such, \( e \) is its unique positive characteristic vector and \( 1 \) is its characteristic root. From Theorem 1

\[ F = \left( \frac{1}{\gamma} \right) P \quad . \quad (27) \]

\[ \square \]

Given the apparent ease of creating intertemporal models satisfying the usual assumptions without risk neutrality this result may seem strange, but it is a consequence of having a finite irreducible process for state transition. When we
extend the recovery result to multinomial processes that are unbounded this is no longer the case.

Before going on to implement these results, there is a simple extension of this approach that appears not to be well known, and is of interest in its own right.

Theorem 3

The risk neutral density for consumption and the natural density for consumption have the single crossing property and the natural density stochastically dominates the risk neutral density. Equivalently, in a one period world, the market natural density stochastically dominates the risk neutral density.

Proof:

From

\[ \varphi(\theta_i, \theta_j) = \frac{p(\theta_i, \theta_j)}{f(\theta_i, \theta_j)} = \frac{\delta U'(c(\theta_j))}{U'(c(\theta_i))}, \]

we know that \( \varphi \) is declining in \( c(\theta_j) \). Fixing \( \theta_i \), since both densities integrate to one and since \( \varphi \) exceeds \( \delta \) for \( c(\theta_j) < c(\theta_i) \), defining \( v \) by \( \delta U'(v) = U'(c(\theta_i)) \), it follows that \( p > f \) for \( c < v \) and \( p < f \) for \( c > v \). This is the single crossing property and verifies that \( f \) stochastically dominates \( p \). In a single period model, terminal wealth and consumption are the same.

\[ \square \]
Corollary 2

In a one period world the market displays a risk premium, i.e., the expected return on the asset is greater than the riskless rate.

Proof:

In a one period world consumption coincides with the value of the market. From stochastic dominance at any future date, T, the return in the risk neutral measure

\[ R^* \sim R - Z + \varepsilon \]

where \( R \) is the natural return, \( Z \) is strictly nonnegative and \( \varepsilon \) is mean zero conditional on \( R - Z \). Taking expectations we have

\[ E[R] = r + E[Z] > r \]

\( \square \)

The Recovery Theorem embodies the central intuitions of recovery and is sufficiently powerful for the subsequent empirical analysis. But, before leaving this section we should note that, while there are extensions to continuous state spaces, the Recovery Theorem as developed here relied heavily on the finiteness of the state space. In the next section we will take a different tack and derive a recovery theorem when the state space is infinite and generated by a binomial or multinomial process and in Section IV we will examine a continuous state space example.
III. A Binomial and Multinomial Recovery Theorem

While the Recovery Theorem can be applied to a binomial or multinomial process, doing so requires a truncation of the state space. To avoid this step and since such processes are so ubiquitous in finance (see Cox, Ross, and Rubinstein [1979]), it is useful to look at them separately. Throughout this analysis the underlying metaphorical model is a tree of height $H$ that grows exogenously and bears exogenous fruit, ‘dividends’, that are wholly consumed. Tree growth is governed by a multinomial process and the state of the economy is $<H, \theta_i>$, $i = 1, \ldots, m$. The multinomial process is state dependent and the tree grows to $a_j H$ with probability $f_{ij}$. In every period the tree pays a consumption dividend $kH$ where $k$ is a constant. Notice that the state only determines the growth rate and the current dividend depends only on the height of the tree, $H$, and not on the complete state, $<H, \theta_i>$. The value of the tree – the market value of the economy’s assets – is given by $S = S(H, \theta_i)$. Since tree height and, therefore, consumption follow a multinomial process, $S$ also follows a multinomial, but, in general, jump sizes will change with the state.

The marginal utility of consumption depends only on the dividend, and without loss of generality we set initial $U'(kH) = 1$. The equilibrium equations are

$$p_{ij}(H) = \delta U'(k a_j H) f_{ij} \quad , \quad (31)$$

or, in terms of the undiscounted kernel $\varphi_j = U'_j$

$$p_{ij}(H) = \delta \varphi_j f_{ij} \quad . \quad (32)$$
In matrix notation,

\[ P = \delta F D \quad , \quad (33) \]

\[ F = \left( \frac{1}{\delta} \right) P D^{-1} \quad , \quad (34) \]

and, since \( F \) is a stochastic matrix,

\[ F e = \left( \frac{1}{\delta} \right) P D^{-1} e = e \quad (35) \]

or

\[ P D^{-1} e = \delta e \quad . \quad (36) \]

Assuming \( P \) is of full rank, this solves for the \textit{undiscounted kernel}, \( D \), as

\[ \left( \frac{1}{\delta} \right) D^{-1} e = P^{-1} e \quad , \quad (37) \]

and \( F \) is recovered as

\[ F = \left( \frac{1}{\delta} \right) P D^{-1} \quad . \quad (38) \]

We can now proceed node by node and recover \( F \) and \( \delta D \), but the analysis does not recover \( \delta \) and \( \phi \) separately. By taking advantage of the recombining feature of the process, though, we can recover \( \delta \) and \( \phi \) separately. For simplicity, consider a binomial process that jumps to \( a \) or \( b \). The binomial is recurrent, i.e., it eventually returns arbitrarily close to any starting position, which is equivalent to irreducibility in this setting. For a binomial, the infinite matrix has only two nonzero elements in any row, and at a particular node we only see the marginal
price densities at that node. To observe the transition matrix we want to return to 
that node from a different path. For example, if the current stock price is $S$ and 
there is no exact path that returns to $S$, then we can get arbitrarily close to $S$ along 
a path where the number of up $(a)$ steps, $i$, and the number of down $(b)$ steps, 
$n - i$, satisfy

$$\frac{i}{n - i} \rightarrow -\frac{\log b}{\log a}$$

(39)

for large $n$.

Sparing the obvious continuity analysis, we will simply assume that the 
binomial recurs in two steps, i.e., $ab = 1$. At the return step from $aH$ to $H$, then, 
since the current state is $<aH, \theta_a>$, the price of receiving 1 in one period is

$$p_{ab}(aH) = \delta \left( \frac{U'(kH)}{U'(kaH)} \right) f_{ab} = \delta \left( \frac{1}{\varphi_a} \right) f_{ab}$$

(40)

Since we have recovered $\delta \varphi_a$ from equation 37, we can now solve separately 
for $\delta$ and $\varphi_a$ and, more generally, for $\delta$ and $\varphi$. The analysis is similar for the 
general multinomial case.

To implement recovery, if the current state is $a$, say, we need to know $p_{ba}(H)$ 
and $p_{bb}(H)$, and if there are no contingent forward markets that allow them to be 
observed directly, we can compute them from current prices. The prices of going 
from the current state to $a$ or $b$ in three steps along the paths $(a,b,a)$ and $(a,b,b)$ 
when divided by the price of returning to the current state in two steps by the 
path $(a,b)$ are $p_{ba}(H)$ and $p_{bb}(H)$, respectively. Alternatively, if we know the 
current price of returning to the current state in two steps, $p_{a1}$, then
\[ p_{a1} = p_{aa}(H)p_{ab}(aH) + p_{ab}(H)p_{ba}(bH) \]  

\[ = \delta^2[\varphi_a f_{aa} \left( \frac{1}{\varphi_a} \right) (1 - f_{aa}) + \varphi_b (1 - f_{aa}) \left( \frac{1}{\varphi_b} \right) (1 - f_{bb})] \]

\[ = \delta^2(1 - f_{aa})(1 + f_{aa} - f_{bb}) \]

is an independent equation which completes the system and allows it to be solved for \( \delta, F, \) and \( \varphi. \)

If the riskless rate is state independent, then \( P \) has identical row sums and if it is of full rank, then, as with the first Recovery Theorem, we must have risk neutrality. To see this, let

\[ Pe = \gamma e \]  

\[ \left( \frac{1}{\delta} \right) D^{-1} e = P^{-1} e = \left( \frac{1}{\gamma} \right) e \],

all the marginal utilities are identical and the natural probabilities equal the martingale probabilities.

If \( P \) is not of full rank, while there is a solution to

\[ Fe = \left( \frac{1}{\delta} \right) PD^{-1} e = e \]

in general, there is a (nonlinear) subspace of potential solutions with dimension equal to the rank of \( P, \) and we cannot uniquely recover the kernel and the probability matrix. As an example, consider a simple binomial process that jumps
to a with probability $f$. In this case $P$ has two identical rows and recombining gives us a total of three equations in the four unknowns, $\delta$, $f$, $\varphi_a$ and $\varphi_b$:

\begin{align}
p_a &= \delta \varphi_a f, \quad (45) \\
p_b &= \delta \varphi_b (1 - f), \quad (46) \\
\end{align}

and

\begin{align}
p_{a,1} &= 2\delta^2 f (1 - f), \quad (47) \\
\end{align}

which, with positivity, has a one dimensional set of solutions.

In the special case where the interest rate is state independent, though, even if the matrix is of less than full rank risk neutrality is one of the potential solutions.

We summarize these results in the following theorem.

**Theorem 4  The Multinomial Recovery Theorem**

Under the assumed conditions on the process and the kernel, the transition probability matrix and the subjective rate of discount of a binomial (multinomial) process can be recovered at each node from a full rank state price transition matrix alone. If the transition matrix is of less than full rank, then we can restrict the potential solutions, but recovery is not unique. If the state prices are independent of the state, then risk neutrality is always one possible solution.

**Proof:**

See the analysis above preceding the statement of the theorem.

□
In Section V we will use the Recovery Theorem but we could also have used the Multinomial Recovery Theorem. Which approach is preferable will depend on the availability of contingent state prices and, ultimately, it is an empirical question. Now we look at some special cases.

A. Relative Risk Aversion

An alternative approach to recovery is to assume a functional form for the kernel. Suppose, for example, that the kernel is generated by a constant relative risk aversion utility function and that we specialize the model to a binomial with tree growth of a or b, \( a > b \). State prices are given by

\[
p_{xy}(H) = \varphi(kH, kyH) f_{xy}.
\]

(48)

Hence, after the current dividend, the value of stock (the tree) is

\[
S(a_a, H) = p_{aa}(H)[S(a_a, aH) + kaH] + p_{ab}(H)[S(b, bH) + kbH]
\]

(49)

and

\[
S(b, H) = p_{ba}(H)[S(a, aH) + kaH] + p_{bb}(H)[S(b, bH) + kbH].
\]

(50)

Assuming constant relative risk aversion,

\[
\varphi(x, y) = \delta \left( \frac{y}{x} \right)^{-\gamma}
\]

(51)

this system is linear with the solution

\[
S(x, H) = \gamma_x H
\]

(52)
where
\[
\begin{pmatrix}
\gamma_a \\
\gamma_b
\end{pmatrix}
= 
\begin{bmatrix}
1 - \delta f_a a^{1 - \gamma} & -\delta (1 - f_a) b^{1 - \gamma} \\
-\delta (1 - f_b) a^{1 - \gamma} & 1 - \delta f_b b^{1 - \gamma}
\end{bmatrix}^{-1}
\begin{pmatrix}
\delta f_a k a^{1 - \gamma} + \delta (1 - f_a) k b^{1 - \gamma} \\
\delta f_b k b^{1 - \gamma} + \delta (1 - f_b) k a^{1 - \gamma}
\end{pmatrix} .
\] (53)

Thus the stock value $S$ follows a binomial process and at the next step takes on the values $S(a,aH)$ or $S(b,bH)$ depending on the current state and the transition,

\[
S(a, H) = \gamma_a H \to \gamma_a aH = S(a, aH) , \quad \text{or} \quad \gamma_b bH = S(b, bH)
\] (54)

and

\[
S(b, H) = \gamma_b H \to \gamma_a aH = S(a, aH) , \quad \text{or} \quad \gamma_b bH = S(b, bH)
\] . (55)

Notice, that even if $ab = 1$, the binomial for $S$ is not recombining. If it starts at $S(a,aH)$ and first goes up and then down it returns to $S(b,abH) = S(b,H) \neq S(a,H)$, but, if it goes down and then up, it does return to $S(a,baH) = S(a,H)$.

Without making use of recombination, the state price equations for this system are given by:

\[
p_{aa} = \delta f_a a^{-\gamma} ,
\] (56)

\[
p_{ab} = \delta (1 - f_a) b^{-\gamma} ,
\] (57)

\[
p_{ba} = \delta (1 - f_b) a^{-\gamma} ,
\] (58)

and

\[
p_{bb} = \delta f_b b^{-\gamma} .
\] (59)
Assuming state independence, \( f_b \neq 1 - f_a \), these are four independent equations in the four unknowns, \( \delta, \gamma, f_a, f_b \), and the solution is given by

\[
\begin{align*}
(f_a & f_b) = \left( \frac{p_{ab} p_{ba}}{p_{aa} p_{bb}} - 1 \right)^{-1} \left( \frac{p_{ab}}{p_{bb}} - 1 \right) \\
\gamma &= \frac{-\ln \left( \frac{f_a}{1 - f_a} \right) + \ln(p_{aa})}{\ln \left( \frac{b}{a} \right)} \\
\delta &= \frac{p_{aa} a^\gamma}{f_a} 
\end{align*}
\]  

(60)

(61)

and

This example also further clarifies the importance of state dependence. With state independence there are only two equilibrium state equations in the three unknowns, \( \gamma, f, \) and \( \delta \),

\[ p_a(H) = \delta f a^{-\gamma} \]  

(63)

and

\[ p_a(H) = \delta (1 - f) b^{-\gamma} \]  

(64)

Nor can this be augmented by recombining since, assuming \( ab = 1 \),

\[ p_a(bH) = \delta f \left( \frac{1}{b^{-\gamma}} \right) = \delta f b^\gamma = \delta f a^{-\gamma} \]  

(65)

which is identical to the first equation. In other words, while the parametric assumption has reduced finding the two element kernel to recovering a single
parameter, \( \gamma \), it has also eliminated one of the equations. As we have shown, though, assuming meaningful state dependency once again allows full recovery.

This approach also allows for recovery if the rate of consumption is state dependent. Suppose, for example, that consumption is \( k_a \) or \( k_b \) in the respective states, \( a \) and \( b \). The equilibrium state equations are now

\[
p_{aa} = \delta f_a a^{-\gamma}, \tag{66}
\]

\[
p_{ab} = \delta (1 - f_a) \left( \frac{k_a}{k_b} \right)^\gamma b^{-\gamma}, \tag{67}
\]

\[
p_{ba} = \delta (1 - f_b) \left( \frac{k_b}{k_a} \right)^\gamma a^{-\gamma}, \tag{68}
\]

and

\[
p_{bb} = \delta f_b b^{-\gamma}. \tag{69}
\]

These are four independent equations which can be solved for the four unknowns, \( \delta, \gamma, f_a, \text{and } f_b \).  

Consider a model with a lognormally distributed payoff at time T and a representative agent with a constant relative risk aversion utility function,

\[ U(S_T) = \frac{S_T^{1-\gamma}}{1-\gamma} \]  

(70)

The future stock payoff, the consumed ‘fruit’ dividend, is lognormal,

\[ S_T = e^{(\mu - \frac{1}{2}\sigma^2)T + \sigma\sqrt{T}z} \]  

(71)

where the parameters are as usual and z is a unit standard normal variable.

The pricing kernel is given by

\[ \varphi_T = \frac{e^{-\delta T} U'(S_T)}{U'(S)} = e^{-\delta T} \left[ \frac{S_T}{S} \right]^{-\gamma} \]  

(72)

where S is the current stock dividend that must be consumed at time 0.

Given the natural measure and the kernel, state prices are given by

\[ P_T(S, S_T) = \varphi_T \left( \frac{S_T}{S} \right) n_T(\ln S_T) = e^{-\delta T} \left[ \frac{S_T}{S} \right]^{-\gamma} n \left( \frac{\ln S_T - (\mu - \frac{1}{2}\sigma^2)T}{\sigma\sqrt{T}} \right), \]  

(73)

where \( n(\cdot) \) is the normal density function, or, in terms of the logs of consumption, \( s \equiv \ln(S) \) and \( s_T \equiv \ln(S_T) \),

\[ P_T(s, s_T) = e^{-\delta T} e^{-\gamma(s_T-s)} n \left( \frac{s_T - (\mu - \frac{1}{2}\sigma^2)T}{\sigma\sqrt{T}} \right). \]  

(74)
In this model we know both the natural measure and the state price density and our objective is to see how accurately we can recover the natural measure and, thus, the kernel from the state prices alone using the Recovery Theorem. Setting $T = 1$, Table I displays natural transition probability matrix, $F$, the pricing kernel and the matrix $P$ of transition prices. The units of relative stock movement, $S_T/S$, are the grid of units of sigma from -5 to +5. Sigma can be chosen as the standard deviation of the derived martingale measure from $P$, but alternatively we chose the current at the money implied volatility from option prices on the S&P 500 index as of March 15, 2011. [Insert Table I]

With an assumed market return of 8%, a standard deviation of 20% we calculate the characteristic vector of $P$. As anticipated, there is one positive vector and it exactly equals the pricing kernel shown in Table I and the characteristic root is $e^{-0.02} = .9802$, as was assumed. Solving for the natural transition matrix, $F$, we have exactly recovered the posited lognormal density.

This static example fits the assumptions of the Recovery Theorem closely except for having a continuous distribution rather than a discrete one. The closeness of the results with the actual distribution and kernel suggests that applying the theorem by truncating the tail outcomes is an appropriate approach in this case. Notice that since we can take the truncated portions as the cumulative prices of being in those regions, there is no loss of accuracy in estimating cumulative tail probabilities.

Finding this result in a continuous space example is important since the Recovery Theorem was proven on a discrete and, therefore, a bounded state
space. To explore the impact of significantly loosening this assumption, we can extend the example to allow for consumption growth.

Assuming that consumption follows a lognormal growth process,

\[ S_T = S_0 e^{(\mu - \frac{1}{2} \sigma^2) T + \sigma \sqrt{T} z} , \]  

(75)

state prices are given by

\[ P_T(s, s_T) = e^{-\delta T} e^{-\gamma(s_T - s)} n \left( \frac{s_T - s - (\mu - \frac{1}{2} \sigma^2) T}{\sigma \sqrt{T}} \right) . \]  

(76)

Taking logs,

\[ \log P_T(x, y) \]

\[ = -\delta T - \gamma (s_T - s) - \left( \frac{1}{2 \sigma^2 T} \right) (s_T - s - (\mu - \frac{1}{2} \sigma^2) T)^2 \]

\[ - \log \sqrt{2\pi T \sigma} , \]

(77)

and, as \((s_T - s)\) varies, state prices depend on the quadratic form

\[ - \left( \frac{1}{2 \sigma^2 T} \right) (s_T - s)^2 - \left( \gamma - \left( \frac{1}{\sigma^2} \right) \left( \mu - \frac{1}{2} \sigma^2 \right) \right) (s_T - s) \]

\[ - \left( \delta T + \left( \frac{T}{2 \sigma^2} \right) \left( \mu - \frac{1}{2} \sigma^2 \right)^2 + \log \sqrt{2\pi T \sigma} \right) , \]

(78)

Since the prices follow a diffusion, even if we assume that we know \(\sigma\) it is not possible to extract the three parameters, \(\mu, \gamma, \) and \(\delta\) from the two relevant parameters of the quadratic,
This indeterminacy first arose with the Black Scholes Merton option pricing formula and similar diffusion equations for derivative pricing in which, with risk neutral pricing, the risk free interest rate is substituted for the drift, $\mu$, in the valuation formulas.

What happens, then, if we attempt a continuous space analogue to the Recovery Theorem? The analogous space characteristic equation to be solved is:

$$\int_0^{\infty} p(s, s_T)\nu(s_T)dy = \lambda \nu(s) \quad .$$

(80)

By construction $1/U'(x)$ and $\delta$ satisfy this equation, but they are not the unique solutions, and a little mathematics verifies that any exponential, $e^{\alpha x}$, also satisfies the characteristic equation with characteristic value

$$\lambda(\alpha) = e^{-\delta T} e^{(\alpha - \gamma)(\mu - \frac{1}{2} \sigma^2)T + \frac{1}{2} \sigma^2 T(\alpha - \gamma)^2} \quad ,$$

(81)

Since $\alpha$ is arbitrary, this agrees with the earlier finding and the well established intuition that given risk neutral prices and even assuming that $\sigma$ is observable – as it would be for a diffusion, we cannot determine the mean return, $\mu$, of the underlying process.

Why, then, did we have success in finding a solution in the original static version?\(^4\) One important difference between the two models arises when we

\(^4\) From (74) it is easy to see that $e^{-\gamma x}$ is the unique characteristic solution.
discretize by truncation. By truncating the process we are implicitly making the marginal utility the same in all the states beyond a threshold and that is a substitute for bounding the process and the state space. A natural conjecture would be that if the generating kernel has a finite upper bound on marginal utility (and, perhaps, too, a nonzero lower bound as well), then the recovered solution will be unique.\footnote{The multiplicity of solutions in the continuous case was pointed out to me by Xavier Gabaix. In an unpublished manuscript Peter Carr and Jiming Yu [2012] have established recovery with a bounded diffusion.} Whether or not the kernel is generated by a representative agent with bounded marginal utility cannot be resolved by theory alone, but in practice one natural approach would be to examine the stability of the solution with different extreme truncations

A more directly relevant comparison between the two models is that in the growth model the current state has no impact on the growth rate. When combined with a constant relative risk aversion kernel, the result is that state prices depend only on the difference between the future state and the current state. This makes the growth model a close relative of the state independent binomial process examined in the previous section. As was shown there, an alternative approach to aid recovery is to introduce some explicit state dependence. For example, we could model the dependence of the distribution on a volatility process by taking advantage of the observed strong empirical inverse relation between changes in volatility and current returns. This could once again allow us to apply the Recovery Theorem as we have done above.\footnote{An explicit example is available from the author upon request.}
V. Applying the Recovery Theorem

With the rich market for derivatives on the S&P 500 index and on futures on the index, we will assume that the market is effectively complete along dimensions related to the index, i.e., both value and the states of the return process. The Recovery Theorem relies on knowledge of the martingale transition matrix and given the widespread interest in using the martingale measure for pricing derivative securities it is not surprising that there is an extensive literature on estimating the martingale measure (see, e.g., Rubinstein [1994], Rubinstein and Jackwerth [1996] and Jackwerth [1999], Derman and Kani [1994] and [1998], Dupire [1994], Ait-Sahalia and Lo [1998], Figlewski [2008]). We will draw on only the most basic findings of this work.

Figure 1 displays the surface of implied volatilities on S&P puts and calls, the 'volatility surface', on March 20, 2011 drawn as a function of time to maturity, 'tenor', and the strike. Option prices are typically quoted in terms of implied volatilities from the Black Scholes Merton formula, i.e., the volatilities that when put into the model give the market premium for the option. Note that doing so is not a statement of the validity of the Black-Scholes Merton model, rather it is simply a transformation of the market determined premiums into a convenient way to quote them. The source of the data used in this paper is a bank over the counter bid/offer sheet. While the data is in broad agreement with exchange traded options, we chose this source since the volume on the over the counter
market is multiples of that on the exchange even for at the money contracts.\textsuperscript{7}

[Insert Figure I]

The surface displays a number of familiar features. There is a ‘smile’ with out of the money and in the money options having the highest implied volatilities. The shape is actually a ‘smirk’ with more of a rise in implied volatility for out of the money puts (in the money calls). One explanation for this is that there is an excess demand for out of the money puts to protect long equity positions relative to the expectations the market has about future volatilities. Notice, too, that the surface has the most pronounced curvature for short dated options and that it rises and flattens out as the tenor increases. A story supporting this is the demand for long dated calls by insurance companies that have sold variable annuities. Whatever the merit of these explanations, these are persistent features of the vol surface at least since the crash in 1987.

Implied volatilities are a function of the risk neutral probabilities, the product of the natural probabilities and the pricing kernel (i.e., risk aversion and time discounting), and, as such, they embody all of the information needed to determine state prices. Since all contracts can be formed as portfolios of options (Ross [1976]) it is well known that from the volatility surface and the formula for

\textsuperscript{7} Bank for International Settlements Quarterly Review, June 2012 Statistical Annex, pages A135 and A136. While there is some lack of clarity as to the exact option terms, the notional on listed equity index options is given as $197.6 billion of notional, and that for OTC equity options is given as $4.244 billion.
the value of a call option we can derive the state price distribution, \( p(S, T) \) at any tenor \( T \):

\[
C(K, T) = \int_0^\infty [S - K]^+ p(S, T) dS = \int_K^\infty [S - K] p(S, T) dS ,
\]

(82)

Where \( C(K, T) \) is the current price of a call option with a strike of \( K \) and a tenor of \( T \). Differentiating twice with respect to the strike we obtain the Breeden and Litzenberger [1978]) result that

\[
p(S, T) = C''(K, T) .
\]

(83)

Numerically approximating this second derivative as a second difference along the surface at each tenor yields the distribution of state prices looking forward from the current state, with state defined by the return from holding the index until \( T \). Setting the grid size of index movements at 0.5%, the S&P 500 call options on April 27, 2011 produced the state prices reported in the top table of Table II. The results are broadly sensible with the exception of the relatively high implied interest rates at longer maturities which we will address below.

[Insert Table II]

To apply the Recovery Theorem, though, we need the \( m \times m \) state price transition matrix,

\[
P = [p(i, j)], \text{where } p(i, j) \text{ is the state } i \text{ price of an Arrow - Debreu security paying off in state } j .
\]

(84)
Unfortunately, since a rich forward market for options does not exist, and we do not directly observe \( P \), we will estimate it from the state price distributions at different tenors.

Currently the system is in some particular state, \( c \), and we observe the current prices of options across strikes and tenors. As shown above in equation (83), from these option prices we can extract the state prices at each future date \( T \),

\[
p^T(c) = < p(1, T), ..., p(m, T) > . \tag{85}
\]

Let the stock price at time \( T \), \( S_T \), index the states and denote the current stock price, \( S_0 \). The row of the state price transition matrix, \( P \), corresponding to the current state, \( c \), is simply \( p_c \), i.e., the vector of one period ahead state prices with \( T = 1 \) in equation (85). Since our intention is illustrative we have ignored the potential state dependence on past returns and on other variables such as implied volatility itself, and identified the states only by the price level. For relatively short periods this may not be much different than if we also used returns, since the final price over, for example, a quarter, is a good surrogate for the price path – this is clearly a matter for further study.

To solve for the remaining elements of \( P \) we apply the forward equation recursively to create the sequence of \( m-1 \) equations:

\[
p^{t+1} = p^t P, \quad t = 1, ..., m \quad , \tag{86}
\]

where \( m \) is the number of states. Each of the equations in (86) expresses that the current state price for a security paying off in state \( j \) at time \( T+1 \) is the state price for a payment at time \( T \) in some intermediate state \( k \) multiplied by the transition
price of going from state k to state j, \( p(k,j) \), and then added up over all the possible intermediate states, \( k \). Thus, by looking at only \( m \) time periods we have the \( m^2 \) equations necessary to solve for the \( m^2 \) unknown \( p(i,j) \) transition prices.

This is a system of \( m^2 \) individual equations in the \( m^2 \) variables \( P_{ij} \) and since we know the current prices, \( p^t \) it can be solved by recursion. In an effort to minimize the errors in the estimation of \( P \), it was required that the resulting state prices, the rows of \( P \), be unimodal.

The grid is chosen to be from -5 to + 5 standard deviations with a standard deviation of 9%/quarter. This seemed a reasonable compromise between fineness and coverage in the tails. The analysis above was then implemented numerically to derive the transition pricing matrix, \( P \) by varying the choice of \( P \) so as to minimize the sum of squared deviations between the resulting prices and the state price vectors of Table II. The resulting forward transition price matrix, \( P \), is shown in Table II under the table of the state prices, \( p^t \).

The state prices in Table II should sum to the riskless interest factor. The rates are relatively accurate out to about 1 but then rise from 1.85% at 1 year to 7.93% at 3 years. This is significantly higher than 3 year (swap) rates at the time and indicative of a bias in the computation of the state prices which impacts some subsequent results, as will be pointed out below. This has nothing to do with the recovery theory per se, but, rather, is a consequence of the crudeness in the computation of state prices from option prices and speaks to the critical need to do a better job at this step.
The final step applies the Recovery Theorem to the transition pricing matrix, $P$, to recover the pricing kernel and the resulting natural probability (quarterly) transition matrix shown in Table III. The kernel declines monotonically as the stock value rises, but this need not be the case. The recovered characteristic root, $\delta$, the social rate of discount in a representative agent model, is 1.0018. Alternatively, if we were to use monthly data instead of quarterly observations, the characteristic root is 0.9977, which is less than one – as it should be. This serves as a warning about the delicate nature of the estimation procedure.

[Insert Table III]

Table IV shows the recovered natural marginal distributions at the future dates, summary statistics for the recovered distributions and comparable summary statistics for the historical distribution estimated by a bootstrap of S&P 500 returns from 60 years of data (1960 – 2010). Table IV also displays the implied volatilities from the option prices on April 27, 2011. The summary statistics display some significant differences between the recovered and the historical distributions. For the recovered, which is a forward looking measure, the annual expected return at all horizons is approximately 6%/year as compared with 10%/year for the historical measure. The recovered standard deviation, on the other hand, is comparable at about 15%/ year – an unsurprising result given the greater accuracy inherent in implied volatilities and the fact that with diffusions they coincide – albeit with bias – more closely with realized volatilities than do expected and realized returns. The upward biased estimates of the risk free interest rate beyond two years, are the source of the risk premium (and thus the Sharpe ratio) in Table IV declining and turning negative at 2.5 years.
Notice that the at the money implied volatilities are significantly higher than those derived from the recovered distribution. This is a phenomena closely related to the observation that implied volatilities are generally significantly greater than realized volatility and it is not surprising that the volatilities from the recovered distribution have a similar relation to realized volatility. This difference is consistent with the existence of a risk premium for bearing volatility risk, but of and by itself it is not dispositive.

Table V compares the recovered natural density and distributions with those obtained from a bootstrap of historical data, and Figure 2 plots these densities. Of particular interest is what they say about the long standing concern with tail events. Rietz [1988] argued that a large but unobserved probability of a catastrophe – ‘tail risk’ - could explain the equity risk premium puzzle, i.e., the apparent dominance of stocks over bonds and related questions. Barro [2006] lent support to this view by expanding the data set to include a wide collection of catastrophic market drops beyond what one would see with a single market and Weitzmann [2007] provided a deep theoretical argument in support of fat tails. More pithily, Merton Miller observed after the 1987 crash that 10 standard deviation events seemed to be happening every few years.

As was suggested in the introduction, tail risk is the economists’ version of the cosmologists’ dark matter. It is unseen and not directly observable but it exerts a force that can change over time and that can profoundly influence
markets. By separating the kernel from the forward looking probabilities embedded in option prices we can shed some light on the dark matter and estimate the market’s probability of a catastrophe. As Figure 2 shows, the recovered density has a fatter left tail than the historical distribution. Table V puts the probability of a six month drop in excess of 32% at 0.0008 or 4 in 5,000 bootstraps. By contrast, the recovered density puts this probability at 1.2%. Similarly, the historical probability of a drop in excess of 26% in a six month period is 0.002 (10 times in 5,000 bootstraps) while the recovered market probability of 0.0223 is 10 times greater, at over 2%.

[Insert Figure 2]

This is only a first pass at applying the Recovery Theorem, and it is intended to be indicative rather than conclusive. There is an enormous amount of work to be done starting with doing a more careful job of estimating the state price density from option prices and then estimating the state price transition matrix from the state price density at different horizons and strikes. There are also many improvements required to accurately recover the kernel and the natural measure implicit in the state prices.
VI. Testing the Efficient Market Hypothesis

It has long been thought that tests of efficient market hypotheses are necessarily joint tests of both market efficiency and a particular asset pricing model (see Fama [1970]). Under the hypothesized conditions of the Recovery Theorem we can separate efficiency from a pricing model and to that extent we can derive model free tests of the efficient market hypothesis. In Ross [2005] an approach to testing efficient market hypotheses was proposed that depended on finding an upper bound to the volatility of the pricing kernel; such a bound is a simple byproduct of recovery.

Assume that $\mu$ is stochastic and depends on some unspecified or unobserved conditioning information set, $I$. From the Hansen – Jagannathan bound [1991] we have a lower bound on the volatility of the pricing kernel

$$
\sigma(\varphi) \geq (e^{-rT}) \frac{\mu}{\sigma},
$$

where $\mu$ is the absolute value of the excess return and $\sigma$ is the standard deviation on any asset, which implies that $\sigma(\varphi)$ is bounded from below by the largest observed discounted Sharpe ratio.

Equivalently, this is also an upper bound on the Sharpe ratio for any investment. From the recovered marginal density function reported in Table V we can compute the variance of the kernel at, for example, one year out. The computation is straightforward and the resulting variance is

$$
\sigma^2(\varphi) = 0.1065,
$$
or an annual standard deviation of

\[ \sigma(\varphi) = 0.3264 \].

(89)

Which, ignoring the small interest factor, is the upper limit for the Sharpe ratio for any strategy to be consistent with efficient markets. It is also a bound used in the literature on when a deal is ‘too good’ (see Cochrane [1999] and Bernardo and Ledoit [1999] for a discussion of good deals, and Ross [1976] for an early use of the bound for asset pricing).

Alternatively (see Ross [2005]), we can decompose excess returns, \( x_t \), on an asset or portfolio strategy as

\[ x_t = \mu(I_t) + \epsilon_t , \]

(90)

where the mean depends on the particular information set, \( I \), and where the residual term is uncorrelated with \( I \), and

\[ \sigma^2(x_t) = \sigma^2(\mu(I_t)) + \sigma^2(\epsilon_t) \leq E[\mu^2(I_t)] + \sigma^2(\epsilon_t) . \]

(91)

Rearranging yields an upper bound to the \( R^2 \) of the regression,

\[ R^2 = \frac{\sigma^2(\mu(I_t))}{\sigma^2(x_t)} \leq \frac{E[\mu^2(I_t)]}{\sigma^2(x_t)} \leq e^{2r^T \sigma^2(\varphi)} , \]

(92)

i.e., the \( R^2 \) is bounded above by the volatility of the pricing kernel (see Ross [2005]). Notice that the kernel can have arbitrarily high volatility by simply adding orthogonal noise to it, so the proper maximum to be used is the volatility of the projection of the kernel on the stock market, and, hence, these are tests on strategies that are based on stock returns and the filtration they generate. A
potential advantage of the tests such as these is that they depend on the second moments, much like the volatility tests of efficiency, and, as such might be more robust than standard t-statistic tests on coefficient.

Using our estimate of the variance of the pricing kernel we find that the maximum it can contribute to the $R^2$ of an explanatory regression is about 10%. In other words, 10% of the annual variability of an asset return is the maximum amount that can be attributed to movements in the pricing kernel and 90% should be idiosyncratic in an efficient market. Hence any test of an investment strategy that uses publicly available data, and has the ability to predict future returns with an $R^2 > 10\%$ would be a violation of efficient markets independent of the specific asset pricing model being used, subject to the maintained assumptions of the Recovery Theorem. Of course, any such strategy must also overcome transactions costs to be an implementable violation, and a strategy that could not overcome those costs would be purely of academic interest.
VII. Summary and Conclusions

No arbitrage implies the existence of positive Arrow Debreu state prices, a risk neutral measure under which the expected return on any asset is the risk free rate, and, equivalently, the existence of a strictly positive pricing kernel that can be used to price all assets by taking the expectation of their payoffs weighted by the kernel. To this framework we have added some additional nonparametric conditions. First, we made the common assumption that the underlying process is Markov in the state variables, and for implementation we discretized the state space. Second, we assumed that the kernel was transition independent, i.e., it was a function of the final state and depended only on the current state as a normalization, as is the case for the marginal rate of substitution across time for an agent with an intertemporally additively separable utility function.

In this setting we were able to prove the Recovery Theorem that allowed us to uniquely determine the kernel, the discount rate, future values of the kernel, and the underlying natural probability distribution of returns from the transition state prices alone. There was no need to use either the historical distribution of returns or independent parametric assumptions on preferences to find the market’s subjective distribution of future returns. Put another way, we have a setting in which even though risk neutral probabilities are the product of an unknown kernel (i.e., risk aversion) and natural probabilities, the two can be disentangled from each other.

A novel element of the approach is that it focuses on the state transition matrix whose elements give the price of one dollar in a future state, conditional on any
other state. This is a challenge for implementation when we do not observe the price of a dollar in a future state conditional on being in a different state from the current one, due to the absence of appropriate contingent forward markets. An example illustrated how to find these transition prices from the state prices for different maturities derived from the market prices of simple options by using a version of the forward equation for Markov processes. The accuracy with which this can be done and the accuracy with which state prices can be estimated from option prices will eventually determine how useful the Recovery Theorem will be both empirically and practically. In an example it was assumed that the state could be summarized by the current level of the index. This is clearly not the case: for example, implied volatility is also a relevant state variable. Extending the empirical analysis to include such variables will be important, along with gauging the extent to which this has significant impact. Particularly for short horizons, this remains to be explored.

Finding the limitations and appropriate extensions of the Recovery Theorem is a rich research agenda. Several conjectured extensions to allow recovery in such cases include bounding the assumed kernel, bounding the underlying process, and incorporating various forms of state dependence in the process. In general, we want to know what is necessary to apply the theorem or extensions to continuous or unbounded processes, and what sort of bounds on the underlying process and, or, bounds on the assumed kernel will allow recovery. We also need to further explore the Multinomial Recovery Theorem and, perhaps, introduce some weak parametric assumptions into both recovery theorems. While we have focused on the equity markets, bounds on the process are natural for interest rates and fixed
income markets, and this will be an important area to explore (see Carr and Yu (2012)).

Once we have recovered the kernel (i.e., the market’s risk aversion) and the market’s subjective assessment of the distribution of returns, there are a host of applications. We can use the market’s future distribution of returns much as we use forward rates as forecasts of future spot rates, albeit without a theoretical bias. Institutional asset holders, such as pension funds, use historical estimates of the risk premium on the market as an input into asset allocation models. The market’s current subjective forecast should be superior, and at the least will be of interest. Project valuation also uses historical estimates of the risk premium. Risk control models such as VAR typically use historical estimates to determine the risk of various books of business and this, too, would be enhanced by using the recovered distribution. Moreover, with time series data we will be able to test these predictions against the realizations.

These results can also be applied to a wide variety of markets such as fixed income, currency, and futures. Indeed, beyond using forward rates, we make little use of interest rate options to estimate the future probability distribution of rates and applying recovery techniques to this market is a promising line of research. For the stock market, the kernel and the recovered distribution can be used to recover the distribution of returns for individual stocks, and to examine the host of market anomalies and potential violations of market efficiency. The ability to better assess the market’s perspective of the likelihood of a catastrophic drop will have both practical and theoretical implications. The kernel is important on its own since it measures the degree of risk aversion in the market, and just as the
market portfolio is a benchmark for performance measurement and portfolio selection, the pricing kernel serves as a benchmark for preferences. Knowledge of both the kernel and the natural distribution would also shed light on the controversy of whether the market is too volatile to be consistent with rational pricing models (see, e.g., Leroy and Porter [1981], Shiller [1981]).

In conclusion, contrary to finance folklore, under the appropriate assumptions it is possible to separate risk aversion from the natural distribution, and estimate each of them from market prices. With a pun intended, we have only scratched the surface of discovering the forecasts imbedded in market prices both for the market itself and, more generally, for the economy as a whole.
The above matrices are derived from the one period model elaborated in Section IV. The rows and columns in the matrices refer to ranges for the stock price state variable, e.g., 3 standard deviations from the current level is 1.82. The shaded row highlights the current state.
Figure 1

The Implied Volatility Surface on March 20, 2011

Figure 1 displays the surface of implied volatilities on puts and calls on the S&P500 index on March 20, 2011, drawn as a function of both time to maturity in years (‘tenor’) and the strike price divided by current price (‘moneyness’). Option prices are typically quoted in terms of implied volatilities from the Black-Scholes formula, and are displayed here on the vertical axis. The source of the data used in this paper is a bank over-the-counter bid/offer sheet.
The first matrix above displays the Arrow-Debreu state prices for the current values of $1 in the relevant stock price return range given in the left hand column at the tenors given in the top row. These are derived by taking the numerical second derivative with respect to the strikes of traded call option prices from a bank offer sheet. The row labeled discount factor sums each column of the first state price matrix to obtain the risk free discount factors. The second matrix is the estimated table of contingent state prices that are consistent with the given Arrow-Debreu state prices. These were derived by applying the forward equation to find the transition matrix that best fit the Arrow-Debreu state prices subject to the constraint that the resulting transition matrix have unimodal rows. The two top rows and two leftmost columns express the state variable in terms of both standard deviations from the current level, and the stock price.
